# A RANDOM WORD GENERATOR FOR PRONOUNCEABLE PASSWORDS

The random word generator is a PL/I program designed to run on Honeywell's Multics system that generates random pronounceable words suitable for use as passwords for Multics users.
ACKNOWLEDGEMENT

Special acknowledgement is extended to Lt. Col. Robert Park and 1Lt. Brian Woodruff for their expert guidance in the preparation of Section IV of this report on the statistical analysis of the random word generator.

SECTION I

BACKGROUND

The random word generator is a PL/I program designed to run on Honeywell’s Multiplexed Information and Computer System (Multics), a large timesharing system. The purpose of the program is to generate passwords that serve to authenticate the identities of users of Multics.

Users of the standard Multics system authenticate themselves at each login (start of a terminal session) by typing in a password known only to the user and the system. Usually the user selects a password for himself at initial login and can change this password at any subsequent login. The ability to change a password is useful when a user suspects that someone else may have guessed his password.

A password is the key to user identification and protection. From previous experience, however, it has become apparent that user-selected passwords are frequently fairly easy to guess. For example, passwords are often the user’s own first name, a name of a family member, or his telephone number. [1] Some Multics installations, such as the Air Force Data Services Center (AFDSC), are used to process classified information, and installations like the AFDSC cannot take a chance that one of their user's passwords will be guessed. The solution to the problem at the AFDSC was a decision to assign passwords to users, rather than to allow users to pick their own. [2]

The administrative overhead of assigning a random password manually whenever a user changes his password is generally too much of a burden -- especially when one considers that only a select few individuals may have access to other users' passwords. Instead, the possibility of providing computer generated passwords that are printed out at the user's console on each password change was investigated. A user’s request to change his password would then become a call to a system password generator program. This password generator has been given the more general and descriptive name of "random word generator" in this report.

Section II of this paper discusses the goals and methods used by the random word generator. Section III contains implementation details and discusses the word generating algorithm. Section IV contains an analysis of the algorithm and presents certain statistics. A sample of random words generated can be found in Appendix IV.
Most of this report describes the random word generator that is being made available for users on Multics. In order to satisfy a more stringent criterion of "randomness" a modified version of the random word generator has also been prepared that generates random words that are all equally probable. This modified version is discussed at the end of Section IV.
SECTION II
METHODOLOGY

requirements and goals

The need for the Multics random word generator program can be satisfied by fulfilling the following two requirements:

- generate easily remembered words, and
- make the words difficult to guess.

The first requirement is very important because users might be inclined to write down passwords that are difficult to remember, thereby increasing the chances of a password compromise. Also, if too many users forget their passwords, the administrative overhead of getting the users logged in again could be greater than that of distributing easier-to-remember passwords manually. The need for the second requirement is apparent.

Both of these requirements are of course far too subjective for direct implementation as a computer program. It is necessary to restate these requirements in a much more concrete manner so that meaningful algorithms can be designed.

The requirement of "making the words difficult to guess" is most easily satisfied by giving the program the ability to generate a very large set of possible words, and the ability to generate these words in a random manner. Both these capabilities can easily be achieved, and thus we will be more concerned at this point with the first requirement.

Consider that the random word generator either needs a large database of words to choose from -- an impractical approach that has been discarded -- or has to form words out of sequences of letters it creates through some algorithm. The requirement of rememberability can then be fulfilled if these sequences of letters are of one or more of the following types:

1. Sequences of letters that can be easily visualized, such as "aabbaa" or "xyxyxy".
2. Sequences of letters that form real English words.
3. Sequences of letters that form pronounceable "words", but are not necessarily real words.

Of these three choices, methods 1 and 2 suffer from the difficulty of specifying a practical algorithm for such sequences. Alternatively, method 1 could be implemented using rules that yield an arbitrarily defined subset of all possible easy-to-visualize sequences, but this subset is likely to be small for a reasonable number of rules. There is no alternative for method 2 other than storing a vast data base of real words.

The third method — that of using pronounceable sequences — is the selected approach. The data base required for this method is relatively small, the rules can be fairly well-defined, and the set of words that can be generated is quite large. Realizing that the more "English" a word looks the easier it usually is to remember, an attempt was made to restrict the set of words generated to those which obeyed some kinds of rules of English pronunciation. This attempt was restructured as an attempt to make it theoretically possible for the word generator to form most English words.

Because of this goal of making the generated words look like English, the word "pronounceable" in this paper refers not just to structures that can be phonetically vocalized, but to a set of more restrictive and English-looking structures. For example, "tsip" is easily pronounceable, but is "un-English" because of the "ts" at the beginning of the word. A different type of example is the "gh" combination. The word "cough" is pronounceable because "gh" in this context can be pronounced like "f", but "ghrom" is not pronounceable as "from" because "gh" never sounds like "f" at the beginning of a word.

PRONOUNCEABLE?

One may wonder how a goal of "pronounceability" can be attained with well-defined rules, considering how undefined and exception-laden the rules of English pronunciation are. The answer is simple: the program does not care how a given word is to be pronounced -- it only needs to make sure that the word can be pronounced. For example, "tophat" could be pronounced "top-hat" or "to-fat", depending on the reader's preference. On the other hand, "tophsat" is only pronounceable as "tof-sat", not "top-hsat". Also, the vowel "o" in this word might be pronounced in one of several ways.

Everyone knows that a given letter or sequence of letters could be pronounced differently in different contexts, but the program is usually not required to distinguish between the different contexts or pronunciations. Unlike the "rules of pronunciation", the "rules of
pronounceability" can be made fairly precise.¹

However precise, the rules and method used to generate pronounceable words have been arrived at in a "refined" ad hoc manner and based on the author's intuition. The method is not described in any published source. Hence, the words generated may be considered pronounceable only by the author. Others may find some of these words very difficult to pronounce, as when trying to pronounce a foreign word with a strange combination of letters. Because of this possible bias, the program was designed to incorporate as few global rules as possible within its text. An external database, a table, is used to contain most of the subjectively determined rules. These external rules consist of "yes" or "no" answers to various questions asked by the program. The answers to the questions can easily be modified to suit the user's preference. "New" rules -- those asking new kinds of questions -- cannot be added without modifying the program.

THE POOR APPROACH

Letters are poor sources on which to base rules of pronounceability. Not only do individual letters sound different in different words, but pairs or triplets of letters often form single sounds that may be unlike any of the component letters. Determining whether a letter is pronounceable or "legal" in a given word often involves knowing how the letter is to be pronounced, which is in turn dependent on such things as its position in the word or syllable and adjacent letters. The large number of details that have to be checked for each letter makes determination of pronounceability very complex.

THE IDEAL APPROACH

The ideal approach that will always generate good pronounceable words would be to relieve the program of any notion of letters and use

¹Phonological theory is a well developed science that in part attempts to describe the phonetic structure of English (and other languages) in a complete and consistent manner. The totality of rules and theorems used in such a description form far too complex a system for the scope of the application discussed in this report. Creation of a smaller subset of this system -- one that might be small enough to implement and would still give reasonable results -- appeared to be too vast an undertaking. Thus, standard phonological theory was not considered in this work.
"phonemes"\(^2\) instead. A phoneme is an "element" of pronunciation -- a unit of sound that cannot be usefully broken down into smaller sounds. For example, the pair "sh" as pronounced in English can always be represented as a single phoneme; the vowel "a" can be represented as one of several phonemes depending on its context. If the rules could be defined, it should be possible to put together random phonemes to form a pronounceable phoneme-word.

Unfortunately, though this method yields good pronounceable sequences, the translation from phonemes to letters is very difficult and very un-algorithmic. An example of this difficulty is the phoneme representing the sound of "k". This phoneme can be translated into "c", "k", or "ck". Which one should be used? At the end of a word, usually any one of these will work, and another randomization factor has to be included to make the choice. At the beginning of a word, "k" is always legal, "ck" is never legal, and "c" is legal only if the following letter is not "e", "i", or "y" (in which case "c" would have been pronounced like "s"). Then, to determine whether "c" is a candidate the following phoneme must first be translated into letters, which may in turn depend on other adjacent phonemes. One can fix the translation so that the "k" sound is always translated to the letter "k", but then the goal of being able to generate most English words would be far from satisfied (not to mention that the letter "e" would never be used).

THE COMPROMISE APPROACH

One may notice that with the phoneme method the program "knows" how the generated word is pronounced -- specifically not a requirement as mentioned earlier. A compromise approach was chosen that uses simple "units", instead of phonemes, that consist of a single letter or a two-letter pair. A given unit is considered by the program as having only one "sound" in all its usages, although in reality that unit may be pronounced in many different ways.

Rules can be determined for each unit, without regard to how that unit is pronounced in context, by merely stating a rule that includes all usages of that unit. This composite rule is usually simpler than all of the individual rules for the different pronunciations of that unit. For example, the letter "g" can be treated as a unit, and the rule for this unit at the beginning of a word says "this unit may only be followed by a, e, i, l, o, r, u or y." In some of these cases "g" is pronounced soft and in others hard -- in fact there is no simple rule for how "g" is pronounced (e.g., "gigantic" and "giggle"),

\(^2\)also called "phonetic segments" in phonology.

12
but the program doesn't need to make any distinctions.

The 34 units presently used are listed below. These units are stored in a table and are input to the random word generator. A larger or smaller set can be defined if experience indicates these to be unsatisfactory.

```
a f k p v ch th
b g l r w gh wh
c h m s x ph qu
d i n t y rh ck
e j o u z sh
```

Note that the letter "q" is the only letter not appearing as a one-letter unit because English usage makes it more convenient to treat "qu" as a unit. Many two-letter vowel combinations, such as "ea", "ie", "ai", etc., that should be considered separate units are not included because little loss of generality occurs (i.e., the set of words that can be generated is nearly the same whether these vowels are separate units or not). Also, double letter pairs like "ll", "rr" and "tt" need not be included for similar reasons. On the other hand, the pair "sh" is needed because words such as "shrink" and "wash" are not pronounceable when "s" and "h" are treated as separate units.

**SYLLABLES**

Besides the rules used by the program, there is a primary assumption that governs the formation of words: if pronounceable syllables are concatenated (subject to some minor restrictions), they will form a pronounceable word. Thus, the task of the random word generator is to form pronounceable syllables.

This task requires precise definition of "syllable"; thus the following definition is made at this point: a syllable is an arbitrary series of units that contains exactly one or two consecutive vowel units. Vowel units are "a", "e", "i", "o", "u", and "y". For example, the following are legal syllables (where "v" represents a vowel unit and "c" represents a non-vowel unit, or consonant unit):

```
ccv cvvcvc cv v vv vc
```

and the following are illegal syllables:

```
cc (no vowels)
vvv (more than 2 consecutive vowels)
vccvc (all vowels not consecutive)
vcv (all vowels not consecutive)
```
Note that each of the last two examples can possibly be split into two syllables, such as "vo-cvo" and "v-cv".

The above definition of "syllable" seems to work in English except for one common case: the silent "e" at the end of words or sometimes syllables often forms a syllable containing two non-contiguous vowels. Of course, that is because English usually only requires a vowel sound in a syllable, and in the case of silent "e" the "e" should not be considered a vowel. The program, however, has no way of telling whether the "e" is silent. To make matters worse, there are words, such as "subtle", "bugle", "little" that do have a final syllable whose only vowel is the final (silent) "e". These are common enough cases in English to warrant special consideration in the word generator.

JUXTAPOSITION

The random word generator forms syllables from left to right, by combining random units one at a time. For each new unit the program determines whether that unit can legally be appended to the units already in the syllable. If it cannot, the unit is discarded and another random unit is tried.

In English the legality of a unit is usually determined by checking immediately adjacent units. Units separated from each other frequently affect each other’s pronunciation but only occasionally determine whether the construction is legal or not. The random word generator uses rules of juxtaposition as the bases for creating pronounceable syllables.

Each time the program gets a new random unit, it forms a pair consisting of that unit and the previous unit. This unit-pair is looked up in a table and bits of information are extracted that specify what can be done with that pair. For example, the unit-pair "rt" will have bits specifying that the pair may not begin a syllable and that a vowel must precede this pair if it is entirely contained within a syllable. The table may sometimes specify that a unit-pair must always be split between two syllables (for example, the pair "kp"), which is one way in which a new syllable can be started. Some pairs, such as "hh", can never appear together, even if split between syllables. The different types of rules that can be specified in the table are discussed in the next section.

3 The vowel pair "ue" in "baroque" and "catalogue" is another exception, though much less common.
MISCELLANEOUS ASSUMPTIONS

Several more assumptions have to be made before syllables can be generated properly. Again, these assumptions were arrived at intuitively and no claim is made for their completeness. The assumptions discussed below are those that have been incorporated into the program structure, as opposed to those that are specified in external tables. They are presented in order of importance.

Consecutive Vowels

A rule, in part already stated, involving consecutive vowels, says that a maximum of two consecutive vowel units is permitted. This rule pertains to all consecutive vowel units even across syllables. The reason for this extension across syllables is that sequences such as "aiea" look "funny" and are sometimes difficult to pronounce, even though there can be a syllable split in the middle. The English language itself "admits" of this difficulty between consecutive words by trying to correct it in two common cases: the use of "an" instead of "a", and the alternate pronunciation of "the", when the following word begins with a vowel sound. There are few English examples of more than two consecutive vowels (the "eau" combination is one of them). Note that the word "queen" is legal according to random word generator rules because "qu" is considered to be a consonant unit.

A difficulty with this assumption involves the unit "y". For purposes of syllabification, "y" must be treated as a vowel (i.e., a syllable can contain the single vowel "y"), but for the above assumption "y" should not be treated as a vowel. Three-vowel sequences involving "y" are very common: "eye" and "you" being two examples. Thus the requirement of at most two consecutive vowel units must be waived if one of the vowels is "y".

The Vowel "y"

In order to solve the consecutive vowel problem above it sufficed to treat "y" always as a consonant. However, it should also be legal for "y" to be the only vowel in a syllable. Therefore, for the purposes of syllabification only, the random word generator treats "y" as a vowel only if the "y" is not immediately preceded by a vowel within that syllable. The sequence "vowel-y-vowel" would thus have to be split between two syllables, but "y-vowel-vowel" would not. The additional rule about silent "e" below allows a "vowel-y-e" sequence to end a word.
The Silent "e"

The special case of final "e" has previously been mentioned. The final "e" in a word in English is almost never pronounced and therefore cannot be used as the only vowel in the last syllable. There is no problem taking care of such exceptions in a uniform way. However, there is a very large set of exceptions to this final "e" rule: words such as "meddle", "nestle", "double" — all ending in "le" -- are legal words in English, yet no vowel is pronounced in the last syllable. The rules used by the word generator do not allow final syllables of "ble" and "tle" and therefore such words cannot be generated. This class of words appears to be the largest that cannot be handled by the word generator. In order to solve this deficiency it would be necessary to first include "le" as a unit in the table, and then make special kinds of tests to determine whether this unit is legal in a given context. It is not possible, without creating new rules specific to this "le" unit, to specify the necessary restrictions. Creating new rules for this case was considered feasible, but appeared to be too awkward and so was left out.

The Initial "y"

The unit "y" may not be the only vowel in the first syllable of a word if the word begins with "y". Only strange words like "yclept" violate this rule. This is a minor point but must be taken care of explicitly. Otherwise, many strange words are generated.

Three Identical Units

There is nothing in the rules so far stated that prohibits three or more identical consecutive consonants. This condition may possibly be legal, provided that no more than two consecutive consonants occur in the same syllable. Instead of trying to force a syllable split between such groups, the decision was made to merely limit the number of consecutive identical units to two. Note that this restriction is not a pronounceability problem, but a case of an un-English-looking construction.

SUMMARY

The goal of the random word generator is to generate easily remembered words that are difficult enough to guess to be suitable for passwords. This goal has been translated into requirements of pronounceability and randomness. An attempt was made to include almost all English words in the set of words that can be generated, and to exclude constructions that are never found in English words.
The random word generator works by forming pronounceable syllables and concatenating them to form a word. Rules of pronounceability are stored in a table for every unit and every pair of units. The rules are used to determine whether a given unit is illegal or legal, based on its position within the syllable and adjacent units. Most rules and checks are syllable oriented and do not depend on anything outside the current syllable. In a few cases checks do extend outside the current syllable. These cases are:

1. Three identical consecutive units
2. Three consecutive vowel units
3. Silent "e" at the end of a word
4. "y" beginning a word
5. Certain illegal pairs of units
SECTION III
IMPLEMENTATION DETAILS

The random word generator is organized as a main procedure that references two tables and an external procedure. The user supplies the two tables: a "unit" table that defines the units (such as those listed on page 7) and specifies rules about each unit, and a "digram" table that specifies rules about all possible pairs of such units. The random_unit subroutine, which returns a random unit when called by random_word_, must also be provided by the user. The method used by this subroutine to generate the random units may be any method desired and based on any distribution. Such a distribution might, for example, be based on the frequency of use of the individual units in English.

SPECIFICATION OF RULES

As mentioned in Section II, the random word generator uses two types of rules: those that are fixed and embodied in the program structure and those that are variable and embodied in external tables. The fixed rules are general in that they are not specific to any one letter or unit. The tables specify rules pertaining to individual units or the juxtaposition of units. The tables will be discussed first, followed by specification of the internal rules.

The Digram Table

This table contains one entry for every possible pair of units (digram), whether that pair is allowed or not. Thus, with 34 different units, there would be 1156 entries. The entry for each pair consists of eight bits of information that together form the "rules" for that particular digram. Each bit is a yes or no answer to a specific question asked by the program. The name of each of these bits and the questions answered are as follows:

1. must_begin Must this pair begin a syllable?
2. not_begin Is this pair prohibited from beginning a syllable?
3. break Is this pair illegal within a syllable (i.e. must it be split between two syllables)?
4. prefix  Must this pair be preceded by a vowel unit if it does not begin a syllable?
5. suffix  Must this pair be followed by a vowel unit if it does not end a syllable?
6. end    Must this pair end a syllable?
7. not_end Is this pair prohibited from ending a syllable?
8. illegal_pair  Is this pair illegal (even if split between syllables)?

Obviously all eight bits are inherently non-independent. There are actually far fewer combinations of these eight bits that can be specified. Out of these, less than sixteen combinations are ever used in practice due to the structure of the English language. Thus, four bits yielding 16 combinations would be enough. The actual internal representation of these bits only affects speed and storage space, however, and is not of importance in this discussion. In addition, some other application of the random word generator (perhaps with a different language) may use more combinations. Appendix I contains the digram table currently in use for the 34 units defined on page 7.

An example will best illustrate the usage of these bits. Consider the digram table entry for the pair of units "f" and "l" as shown in Appendix I. The bits that are set for "fl" are:

\begin{verbatim}
must_begin
suffix
not_end
\end{verbatim}

The must_begin bit says that if an "fl" is encountered in a syllable, it must begin that syllable. The suffix bit says that the unit following "fl" must be a vowel if "fl" is not the last pair in a syllable. The not_end bit says that "fl" may not be the last pair in a syllable. The specification of the digram "fl", thus, restricts its use within a syllable as the first pair in one of the following six contexts:

\begin{verbatim}
fla..., fle..., fli..., flo..., flu..., fly...
\end{verbatim}

where "..." signifies additional units within the syllable. Of course, if there are any further restrictions on the use of the pairs "la", "le", etc. that prevent them from appearing after the "f", these restrictions must be taken into account. Note that none of the eight digram bits except illegal_pair apply when the pair is split between two syllables. If "fl" is split, the "l" becomes the first unit of
the next syllable, and rules for pairs beginning with "l" must be examined. A quick glance at the digram table shows that all pairs beginning with "l" have the not_begin bit set, except the six pairs:

la, le, li, lo, lu, and ly,

and processing can continue with this information.

The random word generator makes sure that at all times the rules specified in the digram table are satisfied for every two consecutive units in the word being formed.

The Unit Table

In addition to rules for unit pairs, there is a table containing four bits of information pertaining to the individual units. For each unit, the four bits are as follows.

1. not_begin_syllable

   This bit indicates that this unit may not begin a syllable. This bit is redundant in that the digram table can specify that all possible pairs beginning with this unit may not begin a syllable. The purpose for using this bit is for efficiency -- when generating the first unit of a new syllable, the program would otherwise have to search through all possible digrams beginning with this unit in order to determine whether this unit is legal. This bit is currently set for the units "x" and "ck". A small number of words in English do begin with "x", but they are mostly technical or scientific terms.

2. no_final_split

   This bit indicates that this unit, when appearing at the end of a word, must not be the only vowel in the final syllable. This bit is only set when the "vowel" bit is set, and is currently set only for the unit "e".

3. vowel

   This bit is set for vowel units. It is currently set for the units: a, e, i, o, u, but may also be set for any units consisting of vowel pairs or that are to be treated as vowels that one might add to the table at some future time.
4. alternate_vowel

This bit indicates that this unit is to be treated as either a vowel or a consonant, depending on context as discussed in Section II of this report on page 9. This bit is set only for the unit "y".

Admittedly these four bits are highly specialized and at least bits 2 and 4 could just as easily be incorporated into the program logic as tests for specific units. However, the program actually works with numbers representing units, rather than the units themselves, and the assignment of a particular number to a particular unit is arbitrary. By using a bit in the unit table for all special cases, all references to specific letters or units are removed from the program. Refer to Appendix I for the unit table currently in use.

Random Units

As stated earlier, the random word generator requires the user to supply the subroutine random_unit. This routine is called by the word generator each time a random unit is needed. The random units are generated based on some predetermined distribution. Of course, not all units thus generated will be acceptable to the word generator in every position of the word: random_unit will be repeatedly called until an acceptable unit is returned. The actual distribution of legal units is different for every position in a particular word, which, for any unit, depends on the units that precede it and the digram and unit tables. The random_unit subroutine itself makes no tests for legal units, but merely uses its fixed distribution each time it is called.

The distribution of units that is currently in use along with the digram and unit tables discussed earlier is shown in Appendix VI in the description of the random_unit subroutine. There is another entry point in random_unit called random_vowel, which is called by the word generator for efficiency in cases when it is known that only a vowel unit will be acceptable. The distribution of vowels returned by this second entry is also shown.

The Algorithm

The digram table, the unit table, and the random_unit subroutine are considered user-supplied in that they may be modified without affecting the word generator program logic. The external rules were specified in the two tables. The algorithm used to generate random words based on these external rules defines the fixed internal rules. The internal rules cannot be modified without changing the logic of the algorithm. The complete algorithm is shown in Appendix II, writ-
ten in a PL/I-like language, and a high level flowchart is shown in figure 1. Appendix III contains the source program listing of random_word which implements this algorithm.

The function of the main body of the algorithm is to determine whether a given unit, generated by random_unit, can be appended to the end of the partial word formed so far. If illegal, the unit is discarded and random_unit is called again. Once a unit is accepted, various state variables are updated and a unit for the next position in the word is tried. A unit previously generated and accepted can never be discarded.

The flowchart in figure 1 shows generally how a word is built up. The names in all capitals (INDEX, SYLLABLE_LENGTH, etc.) are references to variables initialized within the flowchart. Names in quotes (e.g., "syllable_length") refer to the bits in the digram table or unit table for the last pair of units or the current unit. The array UNIT holds the units of the word as they are generated, where UNIT(INDEX) is the current unit.

Beginning at the top of the flowchart, the first unit of the word is selected at random by random_unit and inserted into UNIT(1). If this unit is legal, according to rules in the unit table, the second unit of the word is selected and loaded into UNIT(2). This time the rules must be satisfied for both the unit table entry for UNIT(2) and the digram table entry for the pair [UNIT(1),UNIT(2)]. If a given unit is not acceptable, another is tried in its place. When the end of the word is reached (as determined by the number of letters desired by the caller of random_word_), additional checks are made before the algorithm can terminate.

If the digram table is consistent, there should always be some unit that will be legal for any legal state of the algorithm. However, self-consistency checks on the digram table are extremely difficult to make. Therefore, an arbitrary limit of 100 tries is placed on generating any particular unit. If 100 calls to random_unit fail to yield a legal unit, the whole word is discarded and the program starts over. This 100 tries limit is not explicitly shown in the flowchart but is contained in the program text (see Appendix III).

Another observation concerning the 100 limit is that, because the program is dealing with random events, it is theoretically possible for 100 tries to fail to yield a legal unit even though there is a

---

4) A "state" here is defined by the values of the state variables used in the algorithm as given in Appendix II, and includes the units already accepted as part of the word being formed.
Figure 1. Random Word Flowchart
unit that is legal. Thus, in order to prevent excessively long loops, it is useful to place a limit on the number of tries, even though the digram table may be consistent.

RESULTS

Appendix IV contains a printout of 2000 random words of five to eight letters. The length of five to eight letters was chosen for this run because such words are more pronounceable than longer words, and fewer than five letters causes too many duplicates to be generated, thus making the words unsuitable for use as passwords. Actually the random word generator has a capability of generating words of any length. The words in the printout have been sorted alphabetically merely as an aid to checking certain constructs. The possible relationships between successively generated words depend on the random number generator in use, which is outside the scope of this discussion.

Notice in the printout that alongside each word is the same word divided into syllables (hyphenated). An interesting by-product of the algorithm is the ability to determine syllable divisions in the word generated. In certain cases the syllable split can not be precisely defined. For example, the word "without" can be split as "with-out" or "wi-thout" according to the rules. In such cases the random word generator makes an arbitrary (but predetermined) choice of where to split the syllables.

It may also be that certain hyphenations are not the most logical as an aid to pronunciation. An example can again be found in "without", which would be hyphenated as "wit-hout" if the "t" and "h" were generated as individual units instead of as a "th" unit. The decisions about hyphenation made by the program are built into the algorithm and are based on what the author considers the most likely to be acceptable in the general case.
SECTION IV
ANALYSIS

Of the two requirements of the random word generator stated on page 3, the requirement of making the words "difficult to guess" was stated as being easy to achieve by giving the word generator the capability of generating a very large set of words. The more difficult requirement of pronounceability guided the design, and it was intuitively assumed that a large enough set of words to satisfy some criterion of randomness would automatically result.

In this section an attempt is made to present some quantitative measurements and statistics that may allow one to determine whether the word generator is actually "random enough" in some sense. With a tool as crucial to the security of the system as a password generator, it must be assured that the passwords really are "difficult to guess".

There is no one quantity to be calculated that will provide a meaningful description of the random word generator's effectiveness in all its possible applications. For example, in an application where the random words are used to create identifiers of individuals, the total number of possible words and the probability of duplication are of interest. In the application as a Multics password generator, duplicates are not as important as the probability that a given user's password will be guessed by another user. For other applications the probability distribution of the words might be required.

It is hoped that enough statistical data is provided in this section so that, with sufficient further analysis, most quantities of interest can be calculated. A complete statistical analysis is beyond the scope of this discussion. However, attention will be focused on areas of interest to users of the random word generator as a password generator for Multics.

---

5In Multics, it is of little value to know a password without knowing the name of the user to whom it belongs; i.e., one cannot login to the system merely by typing a password and thereby impersonating whoever that password happened to belong to. Other systems may actually use the password to identify rather than verify.
The following four topics have been chosen for consideration:

- total number of different pronounceable words,
- probability of a given word being generated,
- most probable word, and
- distribution of word probabilities.

Some quantitative measure of each of the above has been obtained, but through empirical analysis of the random word generator's output rather than through an analysis of the algorithm. Analysis of the algorithm would of course yield the most precise statistics, but the complexity of the algorithm and its states, and the large amount of data in the supporting tables (which might be subject to change by anyone), make such an analysis extremely difficult and somewhat limited in applicability. Instead, minor modifications to the random word generator and some additional programs were incorporated to supply the data necessary for this analysis. If a change is made in one of the supporting tables, new data can be obtained merely by re-running these additional programs.

It should be noted that all of the statistics and numerical figures presented in this section apply only when the tables are set up as in Appendix I. The methods used to obtain the results, however, apply to any tables the user may supply.

NUMBER OF WORDS

The number of possible random words, though extremely difficult to determine by analyzing the algorithm, can be established to any degree of accuracy in a fairly simple manner.

Consider all possible words of a given length $L$ that can be formed from the 26 letters of the alphabet, without regard to pronounceability. If $N$ is the number of such words, then

$$N = 26^L. \quad (1)$$

Out of these, a certain fraction $f$ are "pronounceable" according to random word generator rules. The value of $f$ may, of course, depend on $L$. If we can determine $f$, we can calculate the number of pronounceable words $n$ of a given length simply by

$$n = fN. \quad (2)$$

An estimate for the value of $f$ can be obtained by picking a random subset of size $m$ out of the $N$ words, and finding out what fraction of this subset is pronounceable. The larger the value of $m$, the
smaller the probable error we will have in our estimated value of $f$. Actually the accuracy of our estimate can be expressed in terms of a probability that its absolute error is less than a certain amount.

Generating a random subset of $N$ words of length $L$ is easy with a uniform random number generator. With a small modification the random word generator can be given a particular word, and will "run through its rules" to determine whether the word is legal (i.e., pronounceable). A sample run of 100,000 words of eight letters was made. The length of eight letters was chosen for this run because that is the maximum length of a user’s password acceptable to Multics. There were 2653 acceptable words out of this run of 100,000, yielding an estimate for $f$ of .02653. For eight letters, 

$$N = 26^8 = 208,827,064,576$$

and the estimated value for $n$ is 

$$n = 0.02653N = 5.540 \times 10^9.$$ 

The accuracy of the estimate for $f$ as determined above can be calculated as a confidence interval for $f$. This confidence interval is written approximately, for large $m$, in the form 

$$k/m \pm z \sqrt{\frac{k/m(1-k/m)}{m}}$$

where $k$ is the number of acceptable words out of the sample of $m$, and $z$ is an appropriate percentage point of the standard normal distribution. For example, we might be interested in a 95% confidence interval, which corresponds to a value of $z = 1.96$. In the sample of 100,000 above, this yields 

$$[0.02653 \pm 0.00099]$$

For other confidence regions, and for sample runs of words of different lengths, see figure 2.

---

6The only change is to use a special version of the random_unit subroutine (which is user-supplied) that supplies units of a known word rather than random units.
Figure 2. Number of Words of 6, 8 and 10 Letters

PROBABILITY OF A WORD

The words produced by the random word generator are not all equally probable for two reasons. First, different units have different probabilities of being generated by random_unit. Second, not all units thus generated are always acceptable. The probability of a given word must be calculated by examining the conditional probabilities of the individual units in that word.

Since random words are created left to right, at a given point during the creation of a word the units accepted so far determine which units may follow. Thus the probability of a particular unit appearing in a particular position of a word is the ratio of that unit's probability (of being returned by random_unit) to the total probability of all the units that are legal in that position. This calculation can be made for each unit based only on the units that precede it. In order to calculate the probability of a particular word, the probabilities of the individual units in that word are determined in this manner and then multiplied together.7

---

7The 100-try limit discussed on page 15 may cause entire words to be rejected even though some units were accepted. However, test runs have shown that the 100-try limit is almost never reached.
The method described above works because, for each position of the word, the random word generator keeps trying random units until a legal unit is found. The unacceptable units play no part in the probability that a particular legal unit will appear. For example, suppose in a given position of a particular word the only legal units are "e" and "a". If it is known that the probability of "e" appearing at random is .057, and the probability of "a" is .047, then the probability that the unit will be an "e" is .057/(.057+.047).

Since the random word generator does not throw out a unit once it has been accepted, it is merely necessary to multiply the individual conditional unit probabilities together to arrive at the probability of the word. Note that this probability only applies to words of a given length (i.e., the length of the word whose probability is calculated). The random word generator does not pick a length, but is asked to generate a word of a specified length. If random lengths are supplied to the random word generator, the distribution of these random lengths must be figured into the probability of the word calculated.

The special program described in the previous subsection that "gives" the random word generator known words was modified to calculate the probability of the known word in the manner described. The answer is exact in most cases, and the method will work regardless of the definition of the units, the tables, or the nature of the algorithm. The only restriction is that the word generator not discard units that have already been accepted in a given position of a word, and that the distribution of the units returned by random_unit remain constant during the formation of the word.

MOST PROBABLE WORD

The "most probable" word (or words) and its probability as determined in the above manner is meaningful to those interested in the difficulty of guessing random words. In the password application, for

Some words can be divided into units in one of two ways. For example, "w-i-t-h-o-u-t" and "w-i-th-o-u-t" are two ways of specifying the units of "without", both of which are legal. An exact calculation of the probability of this word would require adding the probabilities of both forms. In general, however, the probability of the version that contains more units (i.e., "w-i-t-h-o-u-t") is much lower because of the extra unit, and thus makes little difference in the total probability of the word. In calculating probabilities of words containing two-letter units that may possibly be split into two one-letter units the calculation is based on the word with the two-letter units.

---

8 Some words can be divided into units in one of two ways. For example, "w-i-t-h-o-u-t" and "w-i-th-o-u-t" are two ways of specifying the units of "without", both of which are legal. An exact calculation of the probability of this word would require adding the probabilities of both forms. In general, however, the probability of the version that contains more units (i.e., "w-i-t-h-o-u-t") is much lower because of the extra unit, and thus makes little difference in the total probability of the word. In calculating probabilities of words containing two-letter units that may possibly be split into two one-letter units the calculation is based on the word with the two-letter units.
example, it does not matter if there are one billion random words if
the most probable word has a probability as high as 50\% (even though
the probability of all other words may be small). A systematic method
for guessing a particular user's password would be to first try the
most probable word and work down from there. If the first word tried
has a high probability, a large set of legal words is of little value.

As important as this statistic is, it appears that only an ex-
tremely complex analysis will yield the most probable word. The obvi-
ous method of selecting only the most probable units to form a proba-
ble word does not work. For example, two of the most probable units
are "e" and "t". One might expect that the most probable six letter
word is something like "teetee". Actually, a word like "hehehe" is
almost twice as probable. A simple calculation can show that the
first two units of a word are much more likely to be "he" than "te".
Even though "t" has twice the probability of being first, the set of
legal units following "t" is greater than the set of units following
"h". It turns out that with the tables in use there are only six
units that may follow "h", whereas there are eight that may follow
"t". The probability that one of those six will be "e" is fairly
high. The low probability of "h" multiplied by the high probability of
"e" yields a value greater than the probability of the pair "te".9

An empirical approach to arriving at the most probable word might
be to generate a large number of random words and to calculate their
probabilities. Unfortunately, even the most probable word may have a
probability sufficiently low so that millions of words might be gener-
ated before the most probable word appears. Moreover, one would have
no assurance that any particular word really is the most probable.

Once more, intuition and a "feeling" of the rules and restric-
tions of the algorithm were relied upon. The utility programs previ-
ously described made it easy to try many expected high-probability
words manually. In this way, a guess of the highest probability words
of 6, 7, 8 and 10 letters has been made. The words are listed below,
along with their probabilities. There may actually be several words
of each length with the same probability. The results below only ap-
ply if the specific digram and unit tables listed in Appendix I are
used, and if the distribution of the units is as listed in that appen-
dix.

9One should also consider that the use of two-letter units increases
the probability of certain words. The six-letter word "quequo" is an
order of magnitude more probable that "teetee", because it actually
only contains four units (qu-e-qu-o), even though the probability of
"qu" coming from the random unit is very low.
The probabilities above only apply to words of the specific length shown. For example, if the word generator is asked to generate words of a random length of 6, 7 or 8 letters, and each length is equally likely, then the probabilities above are multiplied by 1/3. Of course, the probability of the six letter word is so high that the other two words are of little interest if six letter words are allowed.

**DISTRIBUTION OF PROBABILITIES**

The ability to calculate the probability of a given word, and the total number of words allows us to arrive at an approximate distribution of the probabilities of the pronounceable words, from most probable to least probable. This distribution yields a kind of profile of the word generator that may be the best overall measure of the word generator’s effectiveness. One method of arriving at such a distribution is outlined below. As with the number of words, the accuracy of the distribution curve depends on the size of the sample of random words used.

Assume that all n pronounceable words of length L are listed in order of probability, and that a "word number" x, running from 1 to n, is assigned to each word, where x = 1 for the most probable word. Let p(x) be the probability of word x. If we had all n words, we could plot x against p(x) as in figure 3 to obtain a series of points. The distribution p(x) will be loosely referred to as a "curve" although strictly it is not a continuous function. Of course, p(x) is monotonically non-increasing by definition. The area under

---

10 The letter "x" has been chosen for the word number instead of the more obvious choice of "i" to represent an integer in order to be more consistent with the notation generally used for some of the calculations in the following pages that treat x as a continuous variable.
the curve is unity, or more precisely

\[
\sum_{x=1}^{n} p(x) = 1. \tag{7}
\]

Once the curve is obtained, quantities like the total probability of the m most probable words, the probability of duplicates within a certain number of tries, etc., can be calculated or measured from a graph of the curve.

Figure 3. Distribution of Probabilities of Random Words

**Determination of Distribution**

If all n pronounceable words (and probabilities) were available, producing \( p(x) \) exactly would be no problem. In reality, we can only obtain a certain fraction of the n words. If we could in some way select every millionth word in the ordered list of n words, we could
still estimate a curve of \( p(x) \) by merely plotting every millionth point in figure 3 and interpolating to get the values in between. The accuracy of such a plot will depend on the "smoothness" of \( p(x) \) in some sense (and of course on the method used to make the interpolation).

There is no direct way to arrive at every millionth word in the list. We can generate \( k \) random words but we have no way of knowing what their positions are in the list (i.e., their values of \( x \)). In fact, if we generate \( k \) random words, their values of \( x \) will not be evenly distributed in the interval \([1, n]\), but will be weighted towards the lower end since the words of higher probability are more likely to appear at random. It is possible, however, to pick a random subset of the \( n \) words that is evenly distributed in the interval.

The uniform random word generator discussed near the top of page 21 can be used to provide a large enough set of equally likely random words so that the desired number \( k \) of these will be pronounceable. The \( k \) words thus obtained can be assumed to be equally spaced in the interval \([1, n]\) because they were arrived at in a manner totally independent of their probabilities. That is to say, the least probable of the \( k \) words has just as high a probability of appearing (using the uniform generator) as does the most probable word.

An approximate graph of \( p(x) \) was obtained by taking the 2653 pronounceable words used to estimate the value of \( n \) in (4) and ordering them according to probability. Each word was assigned an index \( i \),

\[
i = 1, 2, \ldots, k,
\]

where \( i = 1 \) for the most probable of these words. For each word, the position on the \( x \)-axis was determined by

\[
x(i) = \frac{i}{k+1}.
\]

A plot of the probabilities of the 2653 words is shown in figure 4.

**Application of the Distribution**

Figure 4 is a complete profile of the word generator and it can be used to measure various quantities. For example, the total probability of the \( m \) most probable words is simply the area under the curve from \( x = 0 \) to \( x = m \). The number of words that make up any given fraction of the population can also easily be measured.

Remember that in figure 4 the value of \( x \) is actually the "word
Figure 4. Distribution of Probabilities of 2653 Eight Letter Words
number$^u$ where $x = 1$ for the most probable word and $x = n$ for the least probable. The value of $x(i)$ for $i = 1$ in our sample of 2653 pronounceable words has a value of approximately 2,000,000 as calculated by (9). The most probable eight letter word out of the entire population is of course at $x = 1$. If we can believe for a moment that figure 4 is an exact representation, we can enlarge the extreme leftmost end of the curve where $x$ is small as in figure 5, and extrapolate to the left of the point at $x = 2,000,000$ to double check the determination of the most probable word on page 25. Of course this extrapolation is not mathematically valid since there is no sound basis for assuming that the curve continues in any specific pattern. However, it does appear that extrapolation yields a value of the most probable word very close to that obtained by trial and error.

Another check on the distribution curve can be made by measuring the area under the curve. In order to approximately calculate this area, Simpson's rule was used where the first point (at $x = 1$) was assumed to be the most probable word as previously determined, and successive points are at intervals of $n/2654$. The area thus calculated came out to 1.006, only 0.6% off the expected value of 1.000.

Figures 4 and 5 apply only to a specific sample run for eight letter words. Appendix V presents similar data for six and ten letter words as a comparison. Of course, a different digram table or unit table would greatly change these distributions.

AN ALTERNATIVE METHOD

The main difficulty in the analysis of the random word generator lies in the complexity of the algorithm. The nature of the algorithm is such that a highly asymmetric distribution of probabilities of words results, with some words being many orders of magnitude more probable than others. The goal of the preceding analysis was to provide information as to the shape of the probability distribution curve so that the word generator's suitability for any particular application could be examined.

In its application as a Multics password generator, the results of figure 4 may indicate that the word generator is not suitable for passwords due to the high probability of the words at the leftmost end of the curve. Some installations may need passwords that have a probability less than $2.19 \times 10^{-6}$. It is possible to improve this probability by changing the digram and unit tables and the distribution of the units returned by the random_unit_ subroutine, but it is very difficult to anticipate the effect of any particular change on the probability distribution. Once the change is made in the tables, there is no easy way to determine what the most probable word actually is.
Figure 5. Enlarged Left Edge of Distribution
There is an alternative method, however, that can be employed without changing any of the tables, that yields a distribution that is much easier to determine.

In order to illustrate this alternative method, assume that we wish to improve the word generator's distribution so that no word is more probable than a word composed of six random letters. This example was chosen because the six random letter criterion for passwords is applied to several systems in use today. This criterion translates to a maximum probability of

\[
\frac{1}{26^6} = 3.24 \times 10^{-9}
\]  

for any word. The most probable eight letter word shown on page 25 has a probability of $2.19 \times 10^{-8}$ -- too high by a factor of seven, and Multics does not allow (nor would it be desirable considering the rememberability requirement) passwords longer than eight characters. Note, however, that the total number of pronounceable eight letter words from equation (4) is much greater than the total number of random six letter words. Thus, if there were some way to force the word generator to generate all $n$ pronounceable words with equal probability, then the probability of any particular word would be $1/n$ and the analysis would be trivial.

By utilizing the random word generator in a slightly different way, at an additional cost in overhead, it is possible to force the probabilities of all words to be equal without changing the total number of words. Consider the method used to obtain the estimated value of $n$ in equation (4). This value was obtained by generating words at random such that all eight letter words are equally likely, and computing the fraction of those that were pronounceable. A method for generating equally probable pronounceable words, then, is to generate equally likely random words and test them for pronounceability until an acceptable word turns up. All acceptable words thus generated are equally probable, and the randomness criterion is satisfied. Appendix VII contains the source code and the documentation for the two program modules that have been altered in order to optionally produce uniformly distributed random words. In addition, for those interested, a listing of the Multics encipher subroutine is included. This is the subroutine used to generate random numbers.

The question that arises is whether this "sampling" method is feasible considering the possible additional computer time required for testing and rejecting words. The answer depends on the fraction of words that are accepted, and whether it is more or less expensive.
to test a word for pronounceability rather than to generate it.

The fraction of pronounceable words was determined on page 21 for eight letter words using specific digram and unit tables. The value .02653 is an acceptance ratio of approximately 1 in 37. Thus we would expect, on the average, to make 37 tries before getting an acceptable word.

The time required to generate pronounceable eight letter words with the word generator is somewhat greater than the time required to generate a word at random and to test its pronounceability. This is because the word generator does not accept every unit supplied to it by random_unit in the word being formed, whereas all units of a pronounceable word to be tested are immediately accepted. The time required to test an unpronounceable word is usually less than the time required to test a pronounceable word because the whole word is rejected as soon as an illegal unit is encountered. If we expect, on the average, to make 37 tries to find a pronounceable word, we would expect the time required to do this to be no more 37 times that required to generate one pronounceable word. This is born out by empirical evidence indicating that the average time required to find a pronounceable eight letter word by trial and error is about 10 times that required to generate one pronounceable word. In Multics computer time, the figures are about .10 second and .01 second per word \(^{11}\) respectively.

Since the number of pronounceable words is much greater (by a factor of 18) than that required to fulfill the six random letter criterion, it may be possible to significantly increase the pronounceability of words generated by modifying the tables to yield a smaller set of possible words. Consider the possible results if, for example, one could delete 17 out of every 18 words in the list in Appendix IV and save only the most pronounceable ones. Of course, by restricting the rules further, the "acceptance ratio" of 1 in 37 is decreased, thereby resulting in additional time spent finding a pronounceable word. A decrease by a factor of 18 will increase the average time of .10 seconds for finding a pronounceable eight letter word to several seconds. This may not be tolerable for some installations.

Thus, particularly when employing the alternative sampling method for generating pronounceable words, one must weigh the advantages of

---

\(^{11}\) The time of .10 second for the sampling method was obtained by using a modified version of the random word generator that discards a partial word and starts over any time a unit is rejected. In this way extra (possibly unused) units are not generated as in the case when a whole random word is first created before testing.
pronounceability against overhead in computer time in determining what modifications to make to the tables. The advantage of using the sampling method is that the only statistical quantity to be determined, the total number of words, is fairly easily estimated. The effect of a change in the digram table on this estimate can be quickly examined.
SECTION V

CONCLUSION

EVALUATION

The random word generator described in this report has been successfully implemented and demonstrated on the Multics system. The list of 2000 random words contained in Appendix IV was shown to various people, and it became apparent that the degree to which words are considered pronounceable varies a great deal among individuals. Some people had many more complaints than others about particular words. In most cases, complaints were about words containing certain combinations of units that the individual did not consider to be "legal".

For the most part, combinations considered illegal could be directly eliminated using the rules of the digram table. In other much less frequent cases, eliminating the offending construct was either impossible or would result in eliminating many more constructs that should be legal. As mentioned earlier, there were many fewer complaints about the shorter words of four to six letters than about the longer ones.

The statistics discussed in Section IV and Appendix V, if presenting an unsatisfactory performance for a particular application, can be improved by modifying the digram table and unit table or by altering the manner in which the random word generator is utilized as discussed near the end of Section IV. For example, by eliminating all double-letter units, the most probable word will have a much lower probability than that indicated on page 25. This is done, however, at the cost of a reduction in the total number of different words. Or, at an increase in overhead, the alternative method for generating words discussed on page 29 can be employed. By modifying the rules in the digram table, particular statistical properties can be adjusted, but one must be aware of the interrelationships between the various properties and performance features before changing the tables to achieve a given result.

In conclusion it appears that the tables that are input to the word generator and the manner in which it is used could be tailored for almost any application, whether the main interest is in pronounceability or performance.
OTHER APPLICATIONS

Pronounceability and randomness were the primary goals of the word generator in its use for generating random words. However, the support program discussed in Section IV that gives the word generator a word to be tried, combined with the word generator's ability to divide a word into syllables, partially supports the facility of a general purpose word hyphenator for text processing. The random word generator can be given any word for hyphenation. If the word is accepted, the word will be returned hyphenated into syllables just as if it had been randomly generated. If rejected, the word is illegal according to random word generator rules and the tables. Of course, the hyphenation will not always be the "right" one according to the dictionary, but exceptions are apt to be few. Perhaps some pre- or post-processing, combined with a list or dictionary of exceptional constructs, can yield a word hyphenator of general utility.

12 An example of a common exception is found in words containing "tion", which is hyphenated "ti-on" as two syllables. This and many other problems could be avoided by defining new kinds of double letter units and changing the tables. Such modifications may make the word generator unsuitable for generating random words because many unpronounceable words may be considered legal. However, when used as a hyphenator the legality of a word is of no concern.
APPENDIX I

TABLES

The following pages list the unit table and digram table as described in Section III. The unit table appears first. Each entry in the unit table has the following format:

n cc wxyz

where:

n is a unit number (1 to 34).
cc is the unit (1 or 2 letters).
w is 0 or 1, representing the value of "not_begin_syllable".
x is the value of "no_final_split".
y is "vowel".
z is "alternate_vowel".

The digram table follows, with each entry of the following format:

abd-cc+ef

where:

a is 0 or 1, which is the value of "begin".
b is "not_begin".
d is "break".
- appears if "prefix" is set, otherwise blank.
cc is a pair of units (2, 3, or 4 letters).
+ appears if "illegal_pair" is set. If it is "-", that means "suffix" is set. Otherwise it is blank.
e is "end".
f is "not_end".

APPENDIX II

RANDOM WORD ALGORITHM

This appendix lists the algorithm described on page 15. Below is a description of the notation and the variables used to describe a state.

State Variables

Each loop through the algorithm produces new values of several state variables and possibly adds a unit to the random word being formed. The variables used to describe the state are defined as follows. "Binary" variables may have the value "true" or "false"; "decimal" variables have a number as their value.

vowel_found
Set when a vowel is found in a syllable (binary).

last_vowel_found
Value of vowel_found for previous unit in the random word (binary).

syllable_length
Number of units in syllable so far (decimal, initially 1).

index
Number of units in word so far (decimal, initially 1).

cons_count
Number of consecutive consonants (decimal).

nchars
Number of letters in word to be generated. Initially this is set to the length of the word (in letters) desired. This value is decremented each time a two-letter unit is generated so that the number of units (index) can be compared to nchars to determine if the end of the word has been reached.

unit(1), unit(2), ... unit(index)
Unit(i) represents the i'th unit in the word. Unit(index) is the current unit.

In addition to the state variables, two variables are defined for use only internal to the algorithm. They are used to simplify the notation.
v A binary variable which is set when the unit just generated is a vowel (or an alternate_vowel to be treated as a vowel).

b A binary variable which gets set when a "break" pair (as defined on page 12) is encountered, or when the previous pair was a "suffix" pair and the current unit is not a vowel.

Notation

The following names are used in the algorithm for the eight flags in the digram table:

- begin,
- not_begin,
- end,
- not_end,
- break,
- prefix,
- suffix,
- and illegal_pair.

If one of these names appears with a value in parentheses immediately following it, as "break(i)", the reference is to the "break" flag for the pair of units [unit(i-1), unit(i)]. If no value appears, the reference is to the pair [unit(index-1), unit(index)] -- that is, the reference is to the last two units.

The following names are used for the flags in the unit table:

- no_final_split,
- not_begin_syllable,
- vowel,
- alternate_vowel,
- and double_letter.

The "double_letter" flag was not explicitly mentioned in the discussion earlier. It is set for units consisting of more than one letter. A value in parentheses following the name, as in vowel(i), refers to the vowel flag for unit(i). If no value appears the reference is to the flag for unit(index), or the current unit.

Three procedures are referred to: "random_unit" is a user-supplied procedure to generate a random unit; "random_vowel" is a user supplied procedure to generate a random vowel unit; and "done" is an internal procedure appearing near the end of the algorithm.
Algorithm

The algorithm is shown in the following pages. The text of the algorithm is essentially the same as the main body of the random_word subroutine appearing in Appendix III. The algorithm is shown here only for completeness -- it can stand alone and does not depend on any support subroutines. Since the random_word subroutine as shown in Appendix III is well documented and commented, no comments are supplied below. A correspondence between this algorithm and the random_word subroutine can easily be made.

The RANDOM_WORD procedure has an internal procedure DONE listed near the end. The extents of the if-then-else clauses are indicated by indentation.

APPENDIX III

SOURCE CODE

The following pages contain source program listings of every command and subroutine applicable to the random word generator. The listings are in alphabetical order by program name. Below is a list of the programs with a brief description of the function of each. Complete documentation of the usage of each of these may be found in Appendix VI.

In Multics there is a distinction between commands and subroutines. Commands are callable by the user from his terminal, while subroutines can only be called by other subroutines or commands. The naming convention for programs specifies that subroutine names end with a trailing underscore, while command names should not. Generally the commands described below are user interfaces to specific subroutines.

columns

Prints lists of random words in columns.

convert_word_

Subroutine that converts an array of unit numbers to characters. Used by generate_word_.

convert_word_char_

Subroutine that inserts hyphens into a given word and formats the word for printing. Used by hyphen_test.

digram_table_compiler

Compiler for digram table.

generate_word_

Standard interface for user-written programs to generate a random word. Used by generate_words.

generate_words

Command to generate a list of random words.

get_line_length

Command and subroutine to return the line length of the output medium for the purposes of formatting output. Used by columns and digram_table_compiler. Also called get_line_length_.

hyphen_test

Command to hyphenate a supplied word using the rules of the random word generator. Also used to calculate the probability of a given word.
hyphenate_  Subroutine interface to perform same function as hyphen_test. Used by hyphen_test.

random_unit_  Standard subroutine for generating a random unit. Referenced by generate_word_ and hyphenate_ and called by random_word_.

random_unit_stat_  Assembly language program containing definitions of external static variables used by random_unit_.

random_word_  Subroutine implementing the word generator. Called by generate_word_ and hyphenate_.

read_table_  Subroutine that compiles the digram table. This is an internal interface only called by digram_table_compiler.
COMPILATION LISTING OF SEGMENT columns
Compiled by: Experimental FL/I Compiler of Tuesday, March 25, 1975 at 14:19
Compiled on: 04/01/75 17:20.7 ext Tue
Options: check source

1 /* This program takes a segment consisting of ASCII lines
2 and rearranges them so that they may be printed out in
3 columns on a page, reading top to bottom in each column.
4 To call, enter command:
5 columns seg -option-
6 1) seg is the pathname of the segment to reformat.
10 2) option is one or more of the following
12 -no, -segment specifies that output will be put in the segment
13 Default sends output to terminal.
15 -line_length nn is a number from 1 to 132 that specifies the length of
16 -ll nn the output line. If missing, the defaults are:
18 output to terminal -- length of terminal line
20 output to segment -- 132
22 output via file_output -- 132
24 -no_pagination, -npn specifies that the page length is assumed
25 to be infinite, and no page skips occur.
26 In this case each columns reads all the way
down to the bottom of the printout.
28 -page_length nn page length to use, rather than the default of 60.
30 -pl nn

236
237 /* if probabilities are being calculated, we proceed as follows:
238 In every position of the word, we send off to random_word all possible units except the one
239 that is actually in the word. We send these as negative numbers so that random_word will not actually use
240 them, but will tell us whether they are legal. Since we know the probabilities of all units, the
241 total of the probabilities of the acceptable units can be calculated and normalized to 1 in order
242 to determine the probability of the unit we are actually trying. For example, if "a" is the only legal
243 unit in a given position of the word, then its probability of appearing in that position is 1, since
244 random_word will not accept anything else.
245 when all units but the actual unit have been tried, we send off the actual unit with a positive sign.
246 It should be accepted by random_word if the word is legal, and the ratio of its probability
247 to the total probability of the legal units is the probability of the unit being in this word position.
248 This multiplied by the product of these probabilities of the previous units gives us a "running product"
249 that will eventually yield the probability of the whole word.

/* This is the standard random unit generating routine for random_word_. */
1
2 It is specified in the call to random_word_ by generate_word_.
3 It does not reference the digram table, but assumes that it contains
4 24 units in a certain order. This routine attempts to return
5 unit indexes with a distribution approaching that of the distribution
6 of the 24 units in English. In order to do this, a random number
7 (supposedly uniformly distributed as returned from encipher_.)
8 is used to do a table lookup into an array containing unit indexes.
9 There are 211 entries in the array for the random_unit_entry point.
10 The probability of a particular unit being generated is equal to the
11 fraction of those 211 entries that contain that unit index. For example,
12 the letter "a" is unit number 1. Since unit index 1 appears 10 times
13 in the array, the probability of selecting an "a" is 10/211.
14 Changes may be made to the digram table without affect to this procedure
15 providing the letter-to-number correspondence of the units does
16 not change. Likewise, the distribution of the 24 units may be altered
17 (and the array size may be changed) in this procedure without affecting
18 the digram table or any other programs using the random_word_ subroutine.

117
I-

1. Each syllable must contain exactly 1 or 2 consecutive vowels, where y is considered a vowel.
2. Syllable end is determined as follows:
   a. Vowel is generated and previous unit is a consonant and syllable already has a vowel. In this case new syllable is started and already contains a vowel.
   b. A pair determined to be a "break" pair is encountered.
   c. End of password is encountered.
   d. "begin" pair is encountered legally. New syllable is started with this pair.
   e. "end" pair is legally encountered. New syllable has nothing yet.
3. Try generating another unit if:
   a. third consecutive vowel and not y.
   b. "break" pair generated but no vowel yet in current syllable or previous 2 units are "not_end".
   c. "begin" pair generated but no vowel in syllable preceding begin pair, or both previous 2 pairs are designated "not_end".
   d. "end" pair generated but no vowel in current syllable or in "end" pair.
   e. "not_begin" pair generated but new syllable must begin (because previous syllable ended as defined in 2 above).
   f. vowel is generated and 2a is satisfied, but no syllable break is possible in previous 3 pairs.
4. Second & third units of syllable must begin, and first unit is "alternate_vowel".

The done routine checks for required prefix vowels & end of word conditions.

APPENDIX IV

2000 RANDOM WORDS

The 2000 random words listed on the following pages were generated in one particular sample run using the tables described in Appendix I. See page 18 for a description of this listing.

APPENDIX V

STATISTICS

In Section IV complete data was presented for an analysis of random words of eight letters. The two figures in this appendix are the probability distribution curves for words of six and ten letters, similar to that shown in figure 4 for eight letter words.
Figure 6. Distribution of Probabilities of 5893 Six Letter Words
Figure 7. Distribution of Probabilities of 1039 Ten Letter Words
APPENDIX VI

DOCUMENTATION

The documentation on the programs contained in this appendix is in the form of Multics Programmers' Manual command and subroutine descriptions. [3] The individual write-ups are in alphabetical order.
Name: columns, col

The columns command will reformat a segment consisting of short lines into columns that read vertically down the page. The number of columns that will appear depends on the length of the longest line in the segment and the length of the output line. The reformatted segment is printed on the terminal with blank lines between pages, or can be stored for dprinting.

Usage

    columns pathname -control_args-

1) pathname    Name of the segment to be reformatted. Lines in the segment may be of any length up to 132 characters, and all lines need not be the same length.

2) control_args are one or more of the following:

   -segment, -sm If present, this argument specifies that the reformatted segment will be stored in a segment called pathname.columns, in a format suitable for dprint. If this argument does not appear, output will be printed on the terminal.

   -line_length nn, -ll nn
   If present, nn is the length of line to be used for output. This must be a number in the range 1 to 132. If this argument is missing, the length of line used will be 132 for the -segment option, or the length of the terminal output line if -segment is not specified. If the user is absentee or file_output is being used, a length of 132 will be used.

   -page_length nn, -pl nn
   This argument sets the length of the page produced by columns. If output is to the terminal, nn lines will be printed on each page, and blank lines will be used to pad the end of each page up to a total of 66 lines per page. If output is to a segment, a page will be
columns

MULTICS PROGRAMMERS' MANUAL

Page 2

ejected every nn lines. The default page length is 60 lines. This control argument is incompatible with the -no_pagination control argument.

-adjust, -ad  specifies that the blank space between the columns is to be adjusted so that the maximum amount of white space appears between the columns. If this control argument does not appear, there will always be one blank space between the columns. Note that the number of columns to be printed is not affected by the use of this control argument. The only effect is to possibly add some blanks between the columns that would otherwise appear at the end of each line of output.

-no_pagination, -npgn

This argument specifies that the output is not to be paged, i.e., the page length is assumed to be infinite. This argument is useful for terminal output when page breaks are not desired, and avoids extra blank lines at the end of the last page.

Notes

The command first determines how many columns can fit on a line by scanning the segment for the longest line, and using that length as the width of each column. If -adjust is not specified, there will be one blank space between columns, otherwise any extra space will be inserted between the columns. Lines from the input segment that are shorter than the longest line will be left justified in the columns.

When the -segment option is not specified (and -no_pagination is not specified), columns will put 60 lines per page, with 3 blank lines at the top and bottom of each page. When -segment is specified without -no_pagination, there will be 60 lines per page with no blank lines between pages (NEWPAGE characters are inserted into the output segment to eject a page when dprinting).

When dprinting the output segment, the -no_endpage option should be specified for the dprint command. This is necessary to avoid extra blank pages because columns formats its own pages.
Warning

This command expands tabs into spaces properly, but treats backspaces and all other control characters as single characters. Generally, if the segment contains any control characters (other than tabs and newlines) the columns on the output will not line up properly.
**Name:** convert_word_

This subroutine is used to convert the random word array returned by random_word_ to ASCII.

**Usage**

```plaintext
dcl convert_word_ entry ((0:* ) fixed bin, (0:* ) bit(1) aligned, fixed bin, char(*), char(*))

call convert_word_ (word, hyphenated_word, word_length, ascii_word, ascii_hyphenated_word);
```

1) **word**
   Array of random units returned from a previous call to random_word_. (Input)

2) **hyphenated_word**
   Array of bits indicating where hyphens are to be placed, returned from random_word_. (Input)

3) **word_length**
   Number of units in word, returned from random_word_. (Input)

4) **ascii_word**
   This string will contain the word, left justified, with trailing blanks. This string should be long enough to hold the longest word that may be returned. This is normally the value of "maximum" supplied to random_word_. (Output)

5) **ascii_hyphenated_word**
   This string will contain the word, with hyphens between the syllables, left justified within the string. The length of this string should be at least 3*maximum/2+1 to guarantee that the hyphenated word will fit. (Output)

**Entry:** convert_word_$no_hyphens

This entry can be used to obtain the ASCII form of a random word without the hyphenated form.
Usage

dcl convert_word_$no_hyphens ((0:*)) fixed bin, fixed bin, char(*));

call convert_word_$no_hyphens (word, word_length, ascii_word);

Arguments are the same as above.
**Name:** convert_word_<br><br>This subroutine facilitates printing of the hyphenated word returned from a call to hyphenate_.

**Usage**

dcl convert_word_char_ entry (char(*), (*) bit(1) aligned, fixed bin, char(*) varying);

call convert_word_char_ (word, hyphens, last, result);

1) **word**  This string is the word to be hyphenated. (Input)<br><br>2) **hyphens**  This is the array returned from a call to hyphenate_ that marks characters in word after which hyphens are to be inserted. (Input)<br><br>3) **last**  This is the status code returned from hyphenate_. If negative, the result will be the original word, unhyphenated, with ** following it. If positive, the word will be returned hyphenated, but with an asterisk preceding the last’th character. If zero, the word will be returned hyphenated without any asterisks. (Input)<br><br>4) **result**  This string contains the resultant hyphenated word. (Output)
**Name:** digram_table_compiler, dtc

This command compiles a source segment containing the digrams for the random word generator and produces an object segment with the name "digrams".

**Usage**

```
digram_table_compiler pathname -option-
```

1) `pathname` is the pathname of the source segment. If the suffix ".dtc" does not appear, it will be assumed. Regardless of the name of the source segment, the output segment will always be given the name "digrams" and will be placed in the working directory.

2) `-option-` may be the following:

- `-list, -ls` lists the compiled table on the terminal. The table will be printed in columns to fit the terminal line length. If `file_output` is being used, lines will be 132 characters long.

- `-list n, -ls n` lists the table as above, but uses n as the number of columns to print. Each column occupies 14 positions, thus a value of 5 will cause 5 columns to be printed, each line being 70 characters long. This option is useful when `file_output` is being used, so that the lines produced are not too long to fit on the terminal to be used to print the output file.

**Notes**

The compiler makes an attempt to detect inconsistent combinations of attributes, as well as syntax errors. If an error is encountered during compilation, processing of the source segment will continue if possible. The digrams segment in case of an error will be left in an undefined state.
During compilation, the ALM assembler is used. At that point the letters "ALM" will be printed on the terminal. If compilation was successful, no other messages should appear.

The listing produced by digram_table_compiler is in a format suitable for printing on the terminal -- not for dprinting. This is because blank lines are used for page breaks, instead of the "new page" character as recognized by dprint.

Syntax

The syntax of the source segment is specified below. Spaces are meaningful to this compiler and a space is only allowed where specified as <space>. The new line character is indicated as <new line>.

<digram table>::= <unit specs>;[<new line>]...<digram specs>$
<unit specs>::= <unit spec>[<delim><unit spec>]...
<digram specs>::= <digram spec>[<delim><digram spec>]...
<delim>::= ,[<new line>][<new line>]
<unit spec>::= <unit name>[<not begin syllable>[<no final split>]]
<digram spec>::= [<begin><not begin><break><prefix>]
  <unit name><unit name>[<suffix>[<end>]]
<unit name>::= <letter>[<letter>]
<letter>::= a|b|c|d|e|f|g|h|i|j|k|l|m|n|o|p|q|r|s|t|u|v|w|x|y|z
<not begin syllable>::= <bit>
<no final split>::= <bit>
<begin>::= <bit>
<not begin>::= <bit>
<brace>::= <bit>
<prefix>::= <space>!-
<suffix>::= <space>!-|+
<end>::= <bit>
<not end>::= <bit>
<bit>::= <space>!1

The first part of the <digram table> consists of definitions of the various units that are to be used and their attributes. The units
are defined as one or two-letter pairs, and the order in which they are defined is unimportant. For each unit, the attributes <not begin syllable> and <no final split> may be specified. In addition, if <unit name> is a, e, i, o, or u, the "vowel" attribute is set. If the unit is y, the "alternate vowel" attribute is set. A <bit> is assumed to be zero if specified as <space>, or one if specified as 1.

The second part of <digram table> specifies all possible pairs of units and the attributes for each pair. The order in which these pairs must be specified depends on the order of the <unit specs> as follows:

Number the <unit spec>s from 1 to n in the order in which they appeared in <unit specs>. The first <digram spec> must consist of the pair of units numbered (1,1), the second <digram spec> is the pair (1,2), etc., and the last <digram spec> is the pair (n,n). All pairs must be specified, i.e., there must be n*n <digram specs>. The <bit>s preceding or following each pair set the attributes for that pair as shown. The <prefix> and <suffix> indicators are set to 1 if specified as "-". If <suffix> is specified as "+", the "illegal pair" indicator will be set, and no other attributes may be specified for that <digram spec>.

Example

The following is a very short example of a <digram table>. Only four units are defined, "a", "b", "sh" and "e". The letter "e" is given the "no final split" attribute, the pair "aa" is given "illegal pair", the pair "ae" is given the "not begin", "break", and "not end" attributes, etc.

```
a,b,sh,e 1;  
aa+,ab,ash, 11 ae 1  
ba, 1 bb, 11 bsh 1,be  
sha, 11 shb 1,shsh+,she,ea,eb,esh,ee  
```

Assume the above segment was named "dt.dtc". Below is an example of the command used to compile and list the table produced for dt.
digram_table_compiler

MULTICS PROGRAMMERS' MANUAL

Page 4

digram_table_compiler dt -ls

<p>| | | | |</p>
<table>

</tbody>
</table>

The first line of output lists the individual units. The number preceding the unit is the unit index. The four bits following the unit are respectively:

- not begin syllable
- no final split
- vowel
- alternate vowel

Following the unit specifications are the digram specifications. Preceding each digram are three bits and a space (or possibly a " ") with meanings corresponding to those specified in the source segment as follows:

- begin
- not begin
- break
- prefix (if "-" appears)

Immediately following each digram is a field which may be blank, " ", or " +". If " +", the "illegal pair" flag is set. Otherwise, the meaning of the "-" and following two bits are as follows:

- suffix (if "-" appears)
- end
- not end
Name: print_digram_table, pdt

This entry merely prints the digram table on the terminal, assuming that it has already been compiled successfully. The segment "digrams" is assumed to be located in the working directory.

Usage

print_digram_table -n-

1) n is the number of columns in which to print the table. If not specified, the maximum number of columns that will fit in the terminal line will be used. Each column occupies 14 positions. If file_output is being used, the terminal line width is assumed to be 132.

Notes

This entry performs the same function as the -list option of digram_table_compiler.
Subroutine

**Name:** generate_word_

This subroutine returns a random pronounceable word as an ASCII character string. It also returns the same word split by hyphens into syllables as an aid to pronunciation.

**Usage**

```plaintext
declare generate_word_ entry (char(*), char(*), fixed bin, fixed bin);

call generate_word_ (word, hyphenated_word, min, max);
```

1) **word** is the random word, padded on the right with blanks. This string must be long enough to hold the word (at least as long as max). (Output)

2) **hyphenated_word** is the same word split into syllables. The length of this string must be greater than max to allow for the hyphens. A length of \(3\times \text{max}/2 + 1\) will always be sufficient. (Output)

3) **min** is the minimum length of the word to be generated. This value must be greater than 3 and less than 21. (Input)

4) **max** is the maximum length of the word to be generated. The actual length of the word will be uniformly random between min and max. The value of max must be greater than or equal to min, and less than 21. (Input)

**Note**

Each call to `generate_word_` should produce a different random word, regardless of when the call is made. However, as with any random generator, there is no guarantee that there will be no duplicates. The probability of duplication is greater with shorter words.
Entry: generate_word_$init_seed

This entry allows the user to specify a starting seed for generating random words. If a seed is specified, the exact same sequence of random words will always be generated on subsequent calls to generate_word_ providing the same values of min and max are specified. If this entry is not called in a process, the value of the clock is used as the initial seed on the first call to generate_word_, thereby "guaranteeing" different sequences of words in different processes.

Usage

declare generate_word_$init_seed entry (fixed bin(35));
call generate_word_$init_seed (seed);

1) seed is the initial seed value. If zero, the system clock will be used as the seed. (Input)
**Name:** generate_words, gw

This command will print random pronounceable "words" on the user's terminal.

**Usage**

```
  generate_words -control_args-
```

1) *control_args* may be selected from the following:

- **nwords** is the number of words to print. If not specified, one word is printed.

- **-min n** specifies the minimum length, in characters, of the words to be generated.

- **-max n** specifies the maximum length of the words to be generated.

- **-length n, -ln n** specifies the length of the words to be generated. If this argument is specified, all words will be this length, and **-min** or **-max** may not be specified.

- **-hyphenate, -hph** causes the hyphenated form (divided into syllables) of each word to be printed alongside the original word.

- **-seed SEED** On the first call to `generate_words` in a process, the system clock is used to obtain a starting "seed" for generating random words. This seed is updated for every word generated, and subsequent values of the seed depend on previous values (in a rather complex way). If the **-seed** argument is specified, SEED must be a positive decimal integer. For a given value of SEED, the sequence of random words will always be the same providing the same length values are specified. When no **-seed** argument is specified, the last value of the updated seed from the previous call to
generate_words will be used. To revert back to using the system clock as the seed, specify a zero value for \texttt{SEED}, i.e., \texttt{-seed 0}.

\textbf{Notes}

If neither \texttt{-min}, \texttt{-max}, nor \texttt{-length} are specified, the defaults are \texttt{-min 6} and \texttt{-max 8}. In all other cases, the defaults are \texttt{-min 4} and \texttt{-max 20}.

If \texttt{-length} is not specified, the lengths of the random words will be uniformly distributed between \texttt{min} and \texttt{max}. Words generated are printed one per line, with the hyphenated forms, if specified, lined up in a column alongside the original words.
**Name**: get_line_length, gll

This command or active function returns the current length of a line on the stream user_output. When used as a command, the line length is printed on the terminal. When used as an active function, the line length is returned as a character string.

**Usage**

```
get_line_length
[get_line_length]
```

**Notes**

The length of the line is obtained from the modes supplied to the tw_IOSIM. If user_output is attached through some other interface module (such as file when using file_output) the line length may be undefined. If the line length can not be obtained, a default length of 132 will be returned.
MULTICS PROGRAMMERS' MANUAL

**get_line_length_**

**Subroutine**

**Name:** get_line_length_

This subroutine returns the current length of a line on the stream user_output.

**Usage**

```dcl get_line_length_ entry returns (fixed bin);
ll = get_line_length_ ();
```

1) `ll` is the length of the line.

**Notes**

The length of the line is obtained from the modes supplied to the `tw_IOSIM`. If `user_output` is attached through some other interface module (such as `file_output`) the line length may be undefined. If the line length cannot be obtained, a default length of 132 will be returned.
hyphen_test

Command

Names: hyphen_test, ht

This command uses the random word generator (the same one used by generate_words) to divide words into syllables. Words are printed on the terminal with hyphens between the syllables.

Usage

hyphen_test -control_arg- -word1- ... -wordn-

1) control_arg may be -probability (-pb), specifying that the probability of each of the words that follows be printed alongside the hyphenated word.

2) wordi are one or more words to be hyphenated. A word may consist of three to twenty alphabetic characters, only the first of which may be uppercase.

Notes

The control argument may appear anywhere in the command line. However, it only applies to words that follow. Words preceding the option will be hyphenated but no probabilities will be calculated.

If a word contains any illegal characters, or is not of three to twenty characters in length, the word will be printed unhyphenated, followed by **.

If the word could not be completely hyphenated because it was considered unpronounceable, an asterisk (*) will be printed out in front of the first character that was not accepted. The part of the word before the asterisk will be properly hyphenated.

The calculated probability is the probability that the word would have been generated by generate_words, assuming generate_words was requested to generate a word of that length only. If a range of lengths is requested of generate_words, each length has equal probability. For example, if generate_words is called to generate words of 6, 7, or 8 characters, there is a 33% probability that a
given word will have 8 characters. If hyphen_test is then asked to calculate the probability of a given 8 letter word, that probability should be divided by 3 to obtain the correct probability for the case of three possible lengths.
**Name**: hyphenate_

This subroutine attempts to hyphenate a word into syllables.

**Usage**

dol hyphenate_ entry (char(*), (*)) bit(1) aligned, fixed bin);
call hyphenate_ (word, hyphens, code);

1) **word** This is a left justified ASCII string, 3 to 20 characters in length. This string must contain all lowercase alphabetic characters, except the first character may be uppercase. Trailing blanks are not permitted in this string. (Input)

2) **hyphens** This array will contain a "1"b for every character in the word that is to have a hyphen following it. (Output)

3) **code** This is a status code, as follows:

- 0 word has been successfully hyphenated.
- -1 word contains illegal (non alphabetic or uppercase) characters.
- -2 word was not from three to twenty characters in length.

Any positive value of code means that the word couldn’t be completely hyphenated. In this case, code is the position of the first character in word that was not acceptable. The part of the word before code will be properly hyphenated. (Output)

**Notes**

This subroutine uses random_word_ to provide the hyphenation. It does this by calling random_word_$give_up and supplying its own version of random_unit and random_vowel that return specified units (of the particular word to be hyphenated) instead of random units.
The word supplied to hyphenate_ is first transformed into units by translating pairs of letters into single units if a 2-letter unit is defined for the pair, and then by translating the remaining single letters into units. See the write-ups of random_word_ and random_unit_ for a description of units. If any units of the word are refused by random_word_, hyphenate tries to determine if the refused unit was a 2-letter unit. If this is the case, then the 2-letter unit is broken into two 1-letter units and random_word_ is called again. In rare cases, hyphenate_ is not able to determine which 2-letter unit is at fault, and will return a status code indicating that the word is unpronounceable, when, in fact, it could have been properly divided by breaking up a 2-letter unit.

**Entry: hyphenate_**$probability

This entry returns information as above, but also supplies the probability of the word having been generated at random by generate_word_ or random_word_generator_. The assumption is made that generate_word_ or random_word_generator_ was asked to supply a word of exactly the same length as the word given to hyphenate_, rather than a range of lengths. If a range of lengths was asked of generate_word_, the probability must be divided by the number of different lengths (all lengths are equally probable).

**Usage**

dcl hyphenate_ entry (char(*), (*), bit(1), aligned, fixed bin, float bin);

call hyphenate_ (word, hyphens, code, probability);

1) to 3) are as above.

4) probability is the probability as defined above. (Output)
Notes

If the supplied word is illegal (i.e. code is not zero), the probability will be returned as zero.

Entry: hyphenate_$debug_on, hyphenate_$debug_off

These entries set and reset a switch that causes hyphenate_$probability to print, on user_output, all units (see random_word_ and random_unit_ for a description of units) that are illegal in a given position of the word. This entry is useful for debugging a digram table for random_word_.

Usage

dcl hyphenate_$debug_on entry;
dcl hyphenate_$debug_off entry;
call hyphenate_$debug_on;
call hyphenate_$debug_off;

Notes

An example of the output produced is as follows. The assumption is that hyphenate_$probability is invoked by the hyphen_test command using the -probability option.

hyphenate_$debug_on
hyphen_test -probability fish
x,ck,f; b,c,d,f,g,h,j,k,m,n,p,s,t,v,w,x,y,z,ch,gh,ph,
   rh,sh,th,wh,qu,ck,i_; i,rh,wh,qu,sh;
fish 6.04127576e-5

In the above example, the units x and ck are shown to have been illegal as the first unit of the word, and the unit f_, (underlined) is the first unit of the word that was accepted. All other units that were not printed are legal as the first unit of the word. Following the semicolon after f_ are the units that are illegal in the second position of the word (assuming that f is the first unit). Then i_ is shown as the legal unit that is taken from the word "fish". This repeats for each position of the word, ending in the legal unit sh (note only one underline).
If the supplied word is illegal, the last underlined letter in the output is (usually) the letter that was not accepted. In cases where hyphenate_ has to split up a 2-letter unit, the word will be shown to start over from the beginning.
Subroutine

**Name:** random_unit_

This subroutine provides a random unit number for random_word_ based on a standard distribution of a given set of units. It is referenced by the generate_word_ subroutine as an entry value that is passed in the call to random_word_. This subroutine assumes that the digram table being used by random_word_ is a standard table. The digram table itself is not referenced by this subroutine.

**Usage**

```fortran
declare random_unit_ entry (fixed bin);

call random_unit_ (unit);
```

1) *unit* is a number from 1 to 34 that corresponds to a particular unit as listed in **Notes** below. (Output)

**Notes**

The table below contains the units that are assumed specified in the digrams supplied to random_word_. Shown in the table are the unit number, the letter or letters that unit represents, and the probability of that unit number being generated.

Entry: random_unit_$probabilities

This entry returns arrays containing the probabilities of the units as listed in the table on the previous page. This entry is provided for hyphenate_$probability and any other program that might require this information. The probabilities must be computed when this entry is called, so it is suggested that the call be made only once per process and the values saved in internal static storage.

Usage

declare random_unit_$probabilities entry ((*) float bin, 
   (* float bin);

   call random_unit_$probabilities (unit_probs, vowel_probs);

1) unit_probs This array contains the probabilities of the individual units assuming the random_unit_ entry is called to generate the random units. The value of unit_probs(i) is the probability of unit(i). (Output)

2) vowel_probs This array contains the probabilities of the units when random_vowel is called. Since there are only 6 vowels, most of these values will be zero. (Output)
Notes

A future version of random_unit_ may use different units with different probabilities. The size of the two arrays must be large enough to hold the maximum number of values that may be returned by random_unit_ (which is currently 34). Programs should not depend on the unit_index-to-letter correspondence as shown in the table. This information can be obtained by using the include file digram_structure.incl.pl1.
Subroutine

Name: random_word_

This routine returns a single random pronounceable word of specified length. It is called by generate_word_, and allows the caller to specify the particular subroutines to be used to generate random units. For users desiring random words with an English-like distribution of letters, generate_word_ should be used.

Usage

dcl random_word_ entry ((0:*)) fixed, (0:*bit(1)) aligned, fixed, fixed, entry, entry);

call random_word_(word, hyphens, char_length, unit_length, random_unit, random__vowel);

1) word The random word will be stored in this array starting at word(1) (word(0) will always be 0). The numbers stored will correspond to a "unit index" as described in Notes below. This array must have a length at least equal to the value of "char_length". Unused positions in this array, up to word(char_length), will be set to zero. (Output)

2) hyphens This array must be of length at least "char_length". A bit on in a position of this array indicates that the corresponding unit in "word" (including the very last unit) is the last unit of a syllable. (Output)

3) char_length Length of the word to be generated, in characters. (Input)

4) unit_length This is the length of the generated random word in units, i.e., the index of the last non-zero entry in the "word" array. The actual length of the word in equivalent characters will be the value of char_length. (Output)

5) random_unit This is the routine that will be called by random_word_ each time a random_unit is needed. The random_unit
random_word_

routine is declared as follows:

dcl random_unit entry (fixed bin);

where the value returned is a unit index between 1 and n_units. If an English-like distribution of letters is desired, the "random_unit_" subroutine may be specified here. See Notes below. (Input)

6) random_vowel
This is the routine called by random_word_ when a vowel unit is required. This routine must return the index of a unit whose "vowel" or "alternate_vowel" bits are on. See Notes below. This routine is declared as follows:

dcl random_vowel entry (fixed bin);

If desired, the subroutine "random_unit_$random_vowel" may be specified in this place. (Input)

Notes
The word array can be converted into characters by calling convert_word_.

In order to use random_word, a digram table, contained in a segment named "digrams", must be available in the search path. This table can be created by the digram_table_compiler.

If the user supplies his own versions of random_unit and random_vowel, these subroutines will have to supply legal units that are recognized by the random_word_ subroutine. The include file "digram_structure.incl.pl1" can be used to reference the digram table to determine which units are available. If included in the source program, appropriate references to the following variables of interest in "digrams" will be generated:

dcl n_units fixed bin defined digrams$n_units;
dcl letters(0:n_units) char(2) aligned based(addr(digrams$letters));
dcl 1 rules(n_units) aligned based(addr(digrams$rules)),
   2 vowel bit(1),
   2 alternate_vowel bit(1),
....

where:
n_units is the number of different units.
letters(i) contains 1 or 2 characters (left justified) for the i’th unit.
rules.vowel(i), rules.alternate_vowel(i) One of these two bits are set for the units that may be returned by a call to random_vowel.

When random_unit is called, a number from 1 to n_units must be returned. When random_vowel is called, a number from 1 to n_units, where one of the two bits in rules(i) is marked, must be returned.

Entry: random_word_$debug_on

This entry sets a switch in random_word_ that causes printing (on user_output) of partial words that could not be completed. This entry is of interest during debugging of random_word_ or for checking the consistency of the digram table prepared by the user.

Usage

dcl random_word_$debug_on entry;
call random_word_$debug_on;

Entry: random_word_$debug_off

This entry resets the switch set by debug_on.
Additional notes

The random_word subroutine can be used for certain special applications (such as the application used by hyphenate_), and there are certain features that help support some of these applications. The features described below are of little interest to most users.

The first feature allows the caller-supplied random_unit (and random_vowel) subroutine to find out whether random_word _ "accepted" or "rejected" the previous unit supplied by random_unit. Each time random_unit is invoked by random_word, the value of the argument passed is the index of the previous unit that random_unit_returned (or zero on the first call to random_unit in a given invocation of random_word ). The sign of the argument will be positive if this last unit was accepted. "Accepted" means that the last unit was inserted into the random word and the word index maintained by random_word was incremented. Once a unit is accepted, it is never removed. Thus a positive value of the unit index passed to random_unit means that a unit for the next position of the word is requested.

If the unit index passed to random_unit has a negative sign, the last unit was rejected according to the rules used by random_word and information supplied in the digram table. If the unit is rejected, random_word does not advance its word index and calls random_unit again for another unit for that same word position. With this information random_unit can keep track of the "progress" of the word being generated.

The feature described above is used by the special random_unit routine provided by hyphenate_. Since the random_unit routine for hyphenate_ is not really supplying random units (but is supplying units of the word to be hyphenated), it must know whether any particular unit is rejected by random_word_. Rejection then implies that the word is illegal according to random_word_rules.

The second feature allows random_unit to "try" a certain unit without committing that unit to actually be used in the random word. The sign of each unit supplied to random_word by random_unit is checked. If the sign of the word is positive, random_word will
accept or reject the unit according to its rules, and will indicate this on the subsequent call to random_unit.

If the sign of the unit passed to random_word_ is negative, random_word_ will merely indicate (on the subsequent call to random_unit) whether that unit would have been accepted, but it never actually updates the word index. In other words, random_word_ always rejects the unit, but lets random_unit know whether the unit was acceptable.

This latter feature is used by hyphenate_$probability in order to determine which of all possible units are acceptable in a given position of the word. The random_unit routine used by hyphenate_$probability tries all possible units in each word position, and only allows random_word_ to accept the unit that actually appears in that position.
Subroutine

Name: read_table_

This subroutine is the compiler for the digram table for random_word_. It is called by digram_table_compiler.

Usage

declare read_table_ entry (ptr, fixed bin(24), returns (bit(1));
flag = read_table_ (source_ptr, bitcount);

1) source_ptr is a pointer to the source segment to be compiled. (Input)
2) bitcount is the bit count of the source segment. (Input)
3) flag is "0"b if compilation was successful. It is "1"b if an error was encountered.

Notes

If compilation was successful, the compiled table will be placed in the working directory with the name "digrams". If unsuccessful, the digrams segment may or may not have been created, and may be left in an inconsistent state (i.e., unusable by random_word_). Error messages are printed out on user_output as the errors are encountered, except that file system errors are printed on error_output.

This subroutine uses the ALM assembler for part of its work. As a result, the letters "ALM" will be printed on user_output sometime during the compilation.
APPENDIX VII

MODIFIED SOFTWARE FOR UNIFORM DISTRIBUTION

The following pages contain documentation and source listings for the two modules that have been altered to produce uniformly distributed random words as discussed near the end of Section IV. The two modules are generate_word_ and generate_words. In addition, a listing of the random number generator encipher_ is included for those interested in the algorithm used to obtain random numbers.

Except for generate_words and generate_word_, all other modules are unchanged from those shown in Appendix III and Appendix VI. These two modules have been modified in an upward compatible manner. Thus, when called as described in Appendix VI, they will perform exactly as described. In order to get uniformly distributed words, an additional entry point in generate_word_ and an additional control argument to the generate_words command have been provided.
generate_word_

Subroutine

**Name:** generate_word_

This subroutine returns a random pronounceable word as an ASCII character string. It also returns the same word split by hyphens into syllables as an aid to pronunciation.

**Usage**

```plaintext
declare generate_word_ entry (char(*), char(*), fixed bin, fixed bin);
call generate_word_ (word, hyphenated_word, min, max);
```

1) **word** is the random word, padded on the right with blanks. This string must be long enough to hold the word (at least as long as max). (Output)

2) **hyphenated_word** is the same word split into syllables. The length of this string must be greater than max to allow for the hyphens. A length of $3\times \text{max}/2 + 1$ will always be sufficient. (Output)

3) **min** is the minimum length of the word to be generated. This value must be greater than 3 and less than 21. (Input)

4) **max** is the maximum length of the word to be generated. The actual length of the word will be uniformly random between min and max. The value of max must be greater than or equal to min, and less than 21. (Input)

**Note**

Each call to generate_word_ should produce a different random word, regardless of when the call is made. However, as with any random generator, there is no guarantee that there will be no duplicates. The probability of duplication is greater with shorter words.
**Entry: generate_word_$init_seed**

This entry allows the user to specify a starting seed for generating random words. If a seed is specified, the exact same sequence of random words will always be generated on subsequent calls to `generate_word_` providing the same values of `min` and `max` are specified. If this entry is not called in a process, the value of the clock is used as the initial seed on the first call to `generate_word_`, thereby "guaranteeing" different sequences of words in different processes.

**Usage**

```plaintext
declare generate_word_$init_seed entry (fixed bin(35));
call generate_word_$init_seed (seed);

1) seed is the initial seed value. If zero, the system clock will be used as the seed. (Input)
```

**Note**

If the seed is a small integer, the first few words generated may not be quite as random as one might like, i.e., if 5 is specified for the value of seed the first word generated will be almost the same as when some other small integer is specified.

**Entry: generate_word_$uniform**

This entry is the same as `generate_word_`, except that the words produced are uniformly distributed. The probabilities of the words produced by `generate_word_` are not all the same. This entry provides words with equal probability. The method used to generate uniformly distributed words results in a speed degradation that is worse with longer words. For eight letter words, factor of at least 10 should be expected. In addition, the set of words that may be produced is not quite as large (although certainly within 90% of the set produced by `generate_word_`).

**Usage**

```plaintext
declare generate_word_$uniform entry (char(*), char(*), fixed bin, fixed bin);
```
call generate_word_ (word, hyphenated_word, min, max);

Arguments are the same as above.
Name: generate_words, gw

This command will print random pronounceable "words" on the user's terminal.

Usage

generate_words -control_args-

1) control_args may be selected from the following:

nwords is the number of words to print. If not specified, one word is printed.

-min n specifies the minimum length, in characters, of the words to be generated.

-max n specifies the maximum length of the words to be generated.

-length n, -ln n specifies the length of the words to be generated. If this argument is specified, all words will be this length, and -min or -max may not be specified.

-hyphenate, -hph causes the hyphenated form (divided into syllables) of each word to be printed alongside the original word.

-seed SEED On the first call to generate_words in a process, the system clock is used to obtain a starting "seed" for generating random words. This seed is updated for every word generated, and subsequent values of the seed depend on previous values (in a rather complex way). If the -seed argument is specified, SEED must be a positive decimal integer between 1 and 9999. For a given value of SEED, the sequence of random words will always be the same providing the same length values are specified. When no -seed argument is specified, the last value of the updated seed from the previous call to generate_words will be used. To revert back to
using the system clock as the seed, specify a zero value for SEED, i.e., -seed 0.

-uniform, -uf

The probability of the words produced by this command is not the same for all words, i.e., some words are more probable than others. This option changes the way in which the words are generated so that all words are equally probable. The number of different words that can result when this option is specified is a little smaller than the number of words that may be produced without this option. (One result of using this option is that the letter "q" will never appear.) The use of this argument results in a speed degradation by a factor of about 10 for eight letter words, and greater for longer words. This argument is useful when it is desirable to generate words whose probabilities are equal.

Notes

If neither -min, -max, nor -length are specified, the defaults are -min 6 and -max 8. In all other cases, the defaults are -min 4 and -max 20.

If -length is not specified, the lengths of the random words will be uniformly distributed between min and max. Words generated are printed one per line, with the hyphenated forms, if specified, lined up in a column alongside the original words.
This procedure enciphers an array of double words, i.e., fixed bin(71).

using the key that is provided. It has entries to both encipher and decipher:
call encipher_1(key, input_array, output_array, array_length)
call decipher_1(key, input_array, output_array, array_length)

where:
key is fixed bin(71) key for coding
input_array(array_length) is fixed bin(71) array
output_array(array_length) is fixed bin(71) array
array_length is fixed bin(71) length (double words) of array

Coded 1 April 1973 by Roger R. Schell, Major, USAF
