40,465 compounds were screened for antimalarial activity in the period from June 1, 1967 through May 31, 1968.

Our contractual commitment under Contract No. DA-49-193-MD-2218 was the screening of 37,500 compounds. However, in keeping with the policy set by WRAIR, the number specified in a contract is considered as the minimum. This year, as in past years, the final number of compounds screened has exceeded the minimum indicated.

Since our new quarters were not ready for occupancy until February 1, 1968, we continued to function in our old quarters during the first eight months of this contract year. Optimum points of efficiency and safety had long been passed, and the limitations and difficulties endured might have presented serious problems if our test system had been more complicated or less flexible.

Tables 1, 2, 3 and 4 list, month by month, the number of compounds tested and the number of mice used in the tests from June 1, 1964 through May 31, 1968.

Table 5 is a summary of the total number of compounds screened from the inception of this program to date.

All compounds tested were obtained from the Department of Medicinal Chemistry at the Walter Reed Army Institute of Research and included: (1) compounds structurally related to chemicals of known value as antimalarial agents; (2) compounds structurally unrelated to compounds known to have antimalarial activity; (3) structural analogues of compounds found active in our test system and representing several novel chemical groups.

Our own breeding colony of 129/HA Swiss mice supplied the large number of animals needed in our tests.

We have continued to use the original test system which was designed specifically to give relatively fast but reliable evaluations from stand-points of antimalarial effect and host toxicity.

This test is based on the responses to candidate compounds by Plasmodium berghei malaria in mice as expressed in comparisons of maximum survival time of treated malaria-infected animals and survival time of untreated malaria-infected controls.

Using young ICR/HA Swiss mice and a standard inoculum of Plasmodium berghei, it has been possible to produce a consistently uniform disease that is fatal to 100% of untreated animals within 6 to 8 days.

Since an established disease is less responsive to treatment than a disease in the early stages of development, treatment is withheld deliberately until a high degree of parasitemia has become evident.

Test compounds were administered parenterally in a single dose on the third day post-infection by which time a 10-15% parasitemia has developed.

To be classified as active, a compound must suppress the disease and produce an unquestionably significant increase, 100% or more, in the life-span of the treated animals over that of the untreated controls.

The severity of the challenges set up in our test system enhances the reliability of our evaluations and the antimalarial potential of the compounds selected for intensive preclinical studies.

M E T H O D

ANIMAL HOSTS. The total supply of animals needed to screen candidate compounds was obtained from our own breeding colony of ICR/HA Swiss mice. Test animals weigh from 15 to 18 grams, weight variations in any given experimental or control group being carefully limited to 2-3 grams. In any given test all animals are of a single sex and approximately the same age.

Animals on test are housed in metal-topped plastic cages, fed a standard laboratory diet and given water ad lib.

TEST PROCEDURE. Test animals receive an intraperitoneal injection of 0.5 ml. of 1:100 dilution of heparinized heart's blood with a minimum of 90% parasitized cells, drawn from donor mice infected one week earlier with Plasmodium berghei. The donor strain is maintained by weekly passages in separate groups of mice inoculated with 0.5 ml. of a 1:500 dilution of heparinized heart's blood.

In order to check factors such as changes in the infectivity of our Plasmodium berghei strain or in the susceptibility of the host or to detect technical errors, a group of infected animals treated with pyrimethamine at dose levels known to produce definite increases in survival time is included in every experiment as a positive control.

DRUG ADMINISTRATION. Test compounds are dissolved or suspended in peanut oil before they are administered.

Treatment consists of a single dose given subcutaneously 3 days post-infection. At the time of treatment a 10-15% parasitemia has developed. Although the disease is well established, it has not yet caused sufficient debility to affect an evaluation of the test compound's toxicity.

Deaths that occur before the 6th day, when untreated controls begin to die, are regarded as the result of a compound's toxic effects and not as the result of action by the infecting parasite.

In each experiment the compound on test is administered in graded doses. Increases in the dose levels of highly active compounds usually are followed by increases in the survival time of the treated mice.

If an active drug is toxic for the host, the toxicity of this compound may become a limiting factor to changes in dose levels.

Treated animals alive at the end of 60 days are considered as cured.

DRUG ACTIVITY. Acceptance of a drug as being sufficiently active for detailed studies is predicated on the margin between the maximum tolerated dose (MTD) and the minimum dose producing a significant effect (MED). A maximum tolerated dose is defined as the highest dose causing no more than one of five animals to die. The minimum effective dose is defined as the minimum dose increasing the life span of treated animals by 100% over the life-span of untreated controls.

An increase of 100% in survival time is considered the minimum significantly effective response for a candidate compound.

Clearly inactive compounds are rejected after one test, borderline compounds after two tests. Active compounds are subjected to a dose-response curve so that the spread between the maximum tolerated dose (MTD) and the minimum dose producing a significant effect (MED) may be established.

COMPOUNDS WITH DEFINITE CHEMOTHERAPEUTIC ACTIVITY AGAINST PLASMODIUM BERGHEI IN MICE. Of the 40,465 compounds tested from June 1, 1967 through May 31, 1968, over 888 demonstrated a degree of antimalarial activity sufficient to produce at least 100% increases in the survival time of treated Plasmodium berghei infected mice.

COMBINATION STUDIES. 914 combination tests were done. Although some of these gave results indicating slight increases in antimalarial activity, none was sufficiently remarkable to justify further study.

A second procedure, using a different host and parasite and performing reliably either as a confirmatory test or as another primary screen, is a desirable adjunct to any screening program.

We developed a simple but dependable supplementary test that is done with Plasmodium gallinaceum malaria in chicks.

Tables 6, 7, 8* and 9 list, month by month, the number of compounds tested and the number of chicks used in these tests from January, 1965, through May 31, 1968.

Table 10 summarizes the number of compounds tested and the number of chicks used from the inception of this assay system in January, 1965, to date.

Using 9-12 days old chicks and a standard inoculum of Plasmodium gallinaceum, we have been able to produce a consistently uniform disease that is fatal to 100% of untreated controls within 72-96 hours.

In this test, as in our mouse test, the antimalarial activity of candidate compounds is assessed by comparing the maximum survival time of treated malaria-infected chicks and the survival time of untreated malaria-infected controls.

As in the mouse test, a compound has been considered active against malaria if it has produced increases of at least 100% in the survival time of treated chicks over the survival time of untreated controls.

Again as in the mouse test, acceptance of a test compound's antimalarial activity was further predicated on the margin between the maximum tolerated dose (MTD) and the minimum dose producing a significant effect (MED).

A maximum tolerated dose is defined as the highest dose causing no more than one of five animals to die. A minimum effective dose is defined as the minimum dose increasing the life-span of treated animals 100% over the life-span of untreated controls.

* An outbreak of an avian infectious disease involving entire flocks made it impossible to get the healthy birds that we required, and the chick test was temporarily dropped.

M E T H O D

TEST ANIMALS. 9-12 days old white Leghorn cockerels of uniform stock were obtained from a single breeder.

The animals were delivered to the laboratory when 1 day old and then maintained under standard conditions, including a non-medicated diet, until they were ready for testing.

TEST PROCEDURE. Chicks on test were given an intrajugular injection of 0.2 ml. of heparinized heart's blood infected with Plasmodium gallinaceum and having a minimum of 80-90% parasitized red blood cells.

The parasitized blood was drawn by cardiac puncture from donor birds that had been infected 72 hours earlier with Plasmodium gallinaceum.

Donor strains are maintained in separate groups of chicks, 14-16 days old, that also receive inoculations of heparinized infected heart's blood.

In every experiment 100% of the untreated controls have died within 72-96 hours post-infection.

In order to check factors such as changes in the infectivity of our Plasmodium gallinaceum strain or in the susceptibility of the host or to detect technical errors, a group of infected birds treated with pyrimethamine at dose levels known to produce definite increases in survival time has been included in every experiment as a positive control.

DRUG ADMINISTRATION. Candidate compounds are dissolved or suspended in peanut oil before they are administered.

In this supplementary test treatment consists of a single dose that is administered either subcutaneously or per os immediately after infection.

Each experiment was done with graded doses of the compound on test, and increases in the dose levels of highly active compounds were generally followed by increases in the survival time of the treated chicks.

If an active drug was toxic for the host, its toxicity became a limiting factor to changes in dosages.

Deaths that occurred within 48 hours after infection and treatment were considered as deaths due to the toxic effects of a test chemical, not as the result of the infection introduced by the Plasmodium gallinaceum parasite.

Chicks with survival periods of 30 days were recorded as cured.

DRUG ACTIVITY. In the chick test, as in the mouse test, an increase of 100% in survival time has been considered as the minimum significantly effective response to the antimalarial activity of a compound.

COMPOUNDS WITH DEFINITE CHEMOTHERAPEUTIC ACTIVITY AGAINST PLASMODIUM GALLINACEUM MALARIA IN CHICKS. Of the 2,982 candidate compounds tested in chicks from September 1, 1967, through May 31, 1968, over 380 demonstrated a degree of antimalarial activity that produced a minimum of 100% increase in the survival time of Plasmodium gallinaceum infected chicks.
