This report presents improved data reduction and analysis procedures for 3DOF data from continuous wind tunnels. The Chapman-Kirk method is employed in the development of programs designed to extract aerodynamic coefficients from 3DOF motion. Noise sources inherent in the 3DOF gas bearing measurement system and found in typical test environments are studied. The validity...
20. ABSTRACT (Continued)

of extracted aerodynamic coefficients in the presence of these noise sources is addressed.
PREFACE

The work reported herein was conducted by the Arnold Engineering Development Center (AEDC), Air Force Systems Command (AFSC), under Program Element 65807F. The results were obtained by ARO, Inc., AEDC Division (a Sverdrup Corporation Company), operating contractor for the AEDC, AFSC, Arnold Air Force Station, Tennessee, under ARO Project Number V32A-A4A. Major K. B. Harwood was the Air Force project manager. The manuscript was submitted for publication on January 5, 1978.

The author wishes to thank G. E. Burt, ARO, Inc., Supervisor, Dynamics Section, Aerodynamics Projects Branch, von Kármán Gas Dynamics Facility, for his assistance in obtaining the experimental data used in this report and for his guidance in this effort.

NOMENCLATURE .................................................. 176
1.0 INTRODUCTION

During the past few years, improvements made on the AEDC von Kármán Gas Dynamics Facility (VKF) three-degree-of-freedom (3DOF) test mechanism have led to greater usage and increased emphasis on data quality and data reduction techniques. These improvements consist primarily of the addition to the original system as reported in Ref. 1 of roll position measurement and increased axial and normal load capacity.

Before the system alterations were made, only a limited amount of data was reduced to final form. This was due primarily to the relatively large computer time involved in the analysis of data and the limitations imposed by the data reduction procedure. The analysis of data for the extraction of meaningful aerodynamic coefficients was hampered by the use of data reduction procedures based on linear aerodynamics and on mass and aerodynamic symmetry properties of the model (Ref. 2). Since the majority of models tested fail to conform to either one or both of these restrictions, more exact data reduction techniques are required.

The capability of the 3DOF system to measure the roll position accurately permits data to be analyzed in the body-axis system. Use of this system allows analysis of the effects of model inertia anomalies and asymmetric aerodynamics on 3DOF motion. Moreover, increased emphasis has been placed on studying the effects of nonlinear aerodynamics for both symmetric (Ref. 3) and asymmetric configurations (Ref. 4).

This report presents improved data reduction and analysis procedures so that the increased capabilities of the 3DOF system may be utilized. A modified Newton-Raphson technique (hereafter referred to as the Chapman-Kirk method, Ref. 5) was employed to develop two programs designed to extract aerodynamic coefficients from 3DOF data. The asymmetric and symmetric programs utilize the full dynamic and kinematic equations and assume mirror plane symmetry and axial symmetry, respectively. Other data reduction methods currently used in aerodynamic parameter extraction are discussed in Section 2.0. The formulation of the mathematical aspects of the Chapman-Kirk method and the development of the governing 3DOF equations to be used in the extraction methods are presented in Section 3.0. Section 4.0 gives a detailed description of the resulting programs. In Section 5.0, the validity of the improved coefficient extraction technique is studied using computer-generated motion and 3DOF data from Tunnel A. In addition, bench test data are used to support error estimates of the extracted coefficients.

2.0 METHODS OF 3DOF ANALYSIS

During the past 20 years, much progress has been made in parameter identification techniques. Early methods were difficult to implement and time consuming in application.
The need for improved techniques was shown by the disagreement found between extrapolated wind tunnel and flight test results (Ref. 6). The following discussion concentrates on several types of identification techniques currently used in processing data, both in the wind tunnel and in full scale. The advantages and drawbacks of each type are addressed.

Parameter extraction methods may be broadly classified into three categories: 1) the so-called equation error methods, 2) output error methods, and 3) advanced methods. The equation error methods assume a performance criterion (i.e., a set of differential or algebraic constraints on the vehicle aerodynamics and/or motion) that minimizes the square of the equation error. All methods that fall into this group are basically least squares methods, and generally all response variables and derivatives must be measured. Application of this method gives a set of n linear equations with n unknowns. Since the equations to be solved are linear, the equation error methods are single-step processes. As such, they are normally used only as a startup method for output error methods. In addition, equation error methods are known to give biased estimates in the presence of measurement noise.

Output error methods minimize the square of the error between the actual system output and the modeled output. Characteristic of these methods is the ability to extract meaningful parameters in the presence of measurement noise. In addition, process noise (modeling errors) produces biased results in the extracted coefficients and may result in lack of convergence of the iterative scheme. Typical output error methods are Newton-Raphson, gradient, Kalman filter, and modified Newton-Raphson. The modified Newton-Raphson method, also referred to as the differential correction or quasilinearization method, can be shown to be identical to the Kalman filter method for the case of no measurement noise.

The maximum likelihood method (as described in Ref. 7) is the most advanced parameter identification technique currently available and is capable of handling both process and measurement noise. This technique may be subdivided into three basic steps. The first step employs the Kalman filter to estimate the magnitude of the states and to generate a residual sequence. A modified Newton-Raphson algorithm is then used for the parameter estimates. The final step uses an algorithm to estimate the noise statistics (the mean and variance of both process and measurement noise). With this approach used for parameter identification, the lower bound on the variances of parameter estimates and the models for the measurement and process noise disturbances may be determined.

The majority of experience gained over the past 20 years in parameter identification in the ballistic range and wind tunnel has been accumulated using some form of the
differential correction method (see Murphy, Ref. 8, and Nicolaides, Ref. 9, for example). The maximum likelihood method has seen limited use in the analysis of free-flight aircraft test data. Thus, even though the maximum likelihood method appears to hold promise for improved data analysis, the differential correction methods as used in the wind tunnel and ballistic range are still of primary interest due to their relative ease of application and proven reliability.

The differential correction method as used by Murphy (Ref. 8), Nicolaides (Ref. 9), and others, is essentially a linear or slightly nonlinear analysis. Under suitable linearizing assumptions, the angular motion equations of a basically symmetric model may be solved in closed form. The coefficients in the analytic solution which are functions of the vehicle aerodynamics are determined by fitting the solution to the data using the method of least squares. This approach can be used only to extract relatively simple aerodynamic coefficients from the experimental data. Furthermore, complex motion must usually be analyzed in small time segments, and thus any cumulative nonlinearities that may be present in the data are destroyed.

In the late 1960's a different approach to the differential corrections method was developed that did not rely on the existence of analytic solutions. This technique, hereafter referred to as the Chapman-Kirk method (Ref. 5), is also based on the minimization of the least squares function. The partial derivatives as required in the method of least squares are determined by numerically integrating parametric differential equations which are derived from the governing equations of motion. This approach can satisfactorily handle highly nonlinear aerodynamic moments and forces, but it requires substantially more computational effort since, in addition to the integration of the governing equations, a set of parametric differential equations must be solved.

The discussion of output error methods thus far has dealt with parameter identification techniques that are deterministic in nature in that the aerodynamic modeling does not account for measurement or process noise. All ballistic and wind tunnel angular motion data contain a finite amount of measurement and process noise, however. The effect of such noise usually appears in the higher order nonlinear coefficients, as pointed out in Ref. 10, in the form of abnormally large variance and bias. The extended Kalman filter method (as discussed in Ref. 11) provides an approach in which measurement noise can be satisfactorily modeled. This method provides direct estimates of the states of noisy systems as well as estimates of the state variable uncertainties. Even though the extended Kalman filter method provides more detailed information on the measurement noise of experimental data, it provides no estimate of process noise, which is a serious noise source in nonlinear systems. In this regard, the extended Kalman filter method has no distinct advantages over the Chapman-Kirk method in processing real 3DOF data.
Thus, the Chapman-Kirk method is used to develop an improved 3DOF data analysis capability for use in continuous wind tunnels. Even though this approach does not yield detailed information on measurement noise, as does the extended Kalman filter method, it does afford sufficient insight into the effects of the measurement noise on the extracted coefficients. In the absence of process (modeling) noise, it may be shown that the probable error of the extracted coefficients for random measurement noise, using the Chapman-Kirk method, is equal to the root-mean-square (RMS) deviation from the true value.

3.0 MATHEMATICAL DEVELOPMENT

The preceding section has dealt extensively with the different types of parameter identification techniques that may be used for 3DOF data analysis. It was concluded that the Chapman-Kirk method as described in Ref. 5 provided the best compromise in mathematical complexity, reliability, and versatility of the methods considered. This section presents in a concise manner the mathematical details of the Chapman-Kirk method as applied to 3DOF data for axisymmetric bodies of revolution taken in continuous wind tunnels. A similar development of the important equations for models with mirror plane aerodynamic and geometric symmetry is given in Appendix A.

3.1 GOVERNING EQUATIONS FOR 3DOF MOTION

The 3DOF governing equations of motion are derived from Newton's second law of motion, which may be written as

$$\vec{M} = \frac{d\vec{h}}{dt} \tag{1}$$

where $\vec{M}$ is the external moment acting at the mass center of gravity (cg) equal to $M_x\hat{i} + M_y\hat{j} + M_z\hat{k}$, and $\vec{h}$ is the moment of momentum referred to the axis system as shown in Fig. 1. For a rigid body, the moment of momentum may be shown (Ref. 12) to reduce to Eq. (2).

$$\vec{h} = h_x\hat{i} + h_y\hat{j} + h_z\hat{k} = (p I_{xx} - q I_{xy} - r I_{xz})\hat{i}$$
$$+ (-p I_{xy} + q I_{yy} - r I_{yz})\hat{j}$$
$$+ (-p I_{xz} - q I_{yz} + r I_{zz})\hat{k} \tag{2}$$

Here $p$, $q$, and $r$ are the components of the angular velocity vector along the $x$, $y$, $z$ axis system (see Fig. 1), respectively, referenced to a space-fixed axis system, and $I_{xx}$, $I_{yy}$, $I_{zz}$, $I_{xy}$, $I_{xz}$, and $I_{yz}$ are the moments and products of inertia as defined in the standard way by Kolk (Ref. 13) and others.
Utilizing Eq. (2) in Eq. (1), the governing Euler moment equations for a plane-fixed axis system may be written in the form of Eq. (3), where the caret denotes the aeroballistic axis system.

\[
\begin{align*}
\dot{\mathbf{M}}_\mathbf{x} &= \dot{h}_x - \dot{q} h_z - \dot{r} h_y \\
\dot{\mathbf{M}}_\mathbf{y} &= \dot{h}_y + \dot{r} h_x - \dot{p} h_z \\
\dot{\mathbf{M}}_\mathbf{z} &= \dot{h}_z + \dot{p} h_y - \dot{q} h_x
\end{align*}
\]

(3)

The dot as used here indicates differentiation of the scalar quantity with respect to time, and \( \dot{p}, \dot{q}, \) and \( \dot{r} \) are the angular velocities of the plane-fixed axis system relative to the space-fixed axis. For the case in which the body axis is a principal axis, the products of inertia, \( I_{x,y}, I_{x,z}, \) and \( I_{y,z}, \) are identically zero. If it is further assumed that the body is axially symmetric about the x axis, then \( I_y = I_z = 1. \)

In order to derive the Euler moment equations in terms of angular measurements, the Eulerian angles \( \psi, \theta, \) and \( \phi \) are defined. Figure 2 illustrates the Euler angles \( \psi, \theta, \) and \( \phi \) for the aeroballistic axis system. Vectors in the space-fixed coordinate system may be transformed to the aeroballistic axis system by successive rotations about the Z axis through the yaw angle, \( \psi, \) and about the \( \hat{y} \) axis through the pitch angle, \( \theta. \)

The Euler angles \( \psi, \theta, \) and \( \phi \) are related to the angular velocities through Eq. (4),

\[
\begin{align*}
p &= \dot{\psi} - \dot{\psi} \sin \theta \\
q &= \dot{\theta} \\
r &= \dot{\psi} \cos \theta
\end{align*}
\]

(4)

with the plane-fixed angular velocities given as follows:

\[
\begin{align*}
\dot{p} &= -\dot{\psi} \sin \theta \\
\dot{q} &= \dot{\theta} \\
\dot{r} &= \dot{\psi} \cos \theta
\end{align*}
\]

(5)

Inserting Eqs. (4) and (5) into the governing moment equations and simplifying, the governing differential equations of angular motion may be shown to reduce to the form of Eq. (6).
\[\ddot{\phi} = \ddot{M}_x - \dot{\phi} \dot{\theta} \cos \theta + \ddot{M}_y \tan \theta - (2 - R) \dot{\phi} \dot{\theta} \tan \theta \sin \theta - R \ddot{\phi} \dot{\theta} \tan \theta \]

\[\ddot{\theta} = \ddot{M}_y - (1 - R) \dot{\phi}^2 \sin \theta \cos \theta - R \ddot{\phi} \dot{\phi} \cos \theta\]

\[\ddot{\psi} = \ddot{M}_z / \cos \theta + \dot{\phi} \dot{\theta} \tan \theta + R \ddot{\phi} \dot{\theta} / \cos \theta\]

Here the definitions \(\ddot{M}_y = \ddot{M}_y / I, \ddot{M}_z = \ddot{M}_z / I, \ddot{M}_x = \ddot{M}_x / I\), and \(R = I_y / I\) have been utilized.

The above equations describe the angular motion of an axially symmetric body about its cg caused by aerodynamic moments \(M_x, M_y,\) and \(M_z\) in the aeroballistic axis system.

The solution of Eq. (6) depends on the form chosen for the moments as functions of the dependent variables. In order to provide the most general form of the moment coefficients for axially symmetric bodies, the ideas of Tobak, Ref. 14, have been utilized. The moments are written as functionals of the parameters that directly influence the moments. Thus, it is assumed that the moment coefficients, \(C_\ell, C_m,\) and \(C_n\) are functions of the velocity ratios \(v/U_\infty\) and \(w/U_\infty\) and the angular velocities \(p, q,\) and \(r\) as shown in Eq. (7).

\[\hat{M}_x = q_s S d C_\ell (\alpha, \beta; p, q, r)\]

\[\hat{M}_y = q_s S d C_m (\alpha, \beta; p, q, r)\]

\[\hat{M}_z = q_s S d C_n (\alpha, \beta; p, q, r)\]

The variables \(\alpha\) and \(\beta\) are the velocity ratios \(w/U_\infty\) and \(v/U_\infty\), respectively, as depicted in Fig. 1. The dynamic pressure, reference area (base area), and reference length (base diameter) are denoted by \(q_\infty, S,\) and \(d,\) respectively. By expanding the moment coefficients about \(\alpha\) and \(\beta\) and dropping nonlinear coefficients in \(\alpha, \beta, p, q,\) and \(r,\) the coefficients of Eq. (7) may be reduced to

\[C_\ell (\alpha, \beta; p, q, r) = C_\ell (\alpha, \beta) + \frac{d}{2U_\infty} \left[ p C_{\ell p} (\alpha, \beta) + q C_{\ell q} (\alpha, \beta) + r C_{\ell r} (\alpha, \beta) + \dot{\alpha} C_{\ell \alpha} (\alpha, \beta) + \dot{\beta} C_{\ell \beta} (\alpha, \beta) \right]\]

\[C_m (\alpha, \beta; p, q, r) = C_m (\alpha, \beta) + \frac{d}{2U_\infty} \left[ p C_{mp} (\alpha, \beta) + q C_{mq} (\alpha, \beta) + r C_{mr} (\alpha, \beta) + \dot{\alpha} C_{m\alpha} (\alpha, \beta) + \dot{\beta} C_{m\beta} (\alpha, \beta) \right]\]

\[C_n (\alpha, \beta; p, q, r) = C_n (\alpha, \beta) + \frac{d}{2U_\infty} \left[ p C_{np} (\alpha, \beta) + q C_{nq} (\alpha, \beta) + r C_{nr} (\alpha, \beta) + \dot{\alpha} C_{n\alpha} (\alpha, \beta) + \dot{\beta} C_{n\beta} (\alpha, \beta) \right]\]
As can be seen, the new coefficients as defined in Eq. (8) are functions of the parameters $a$ and $\beta$ only. Before the expansion of the new coefficients about $a$ and $\beta$ equal to zero is accomplished, the relations describing $a$ and $\beta$ and their derivatives as functions of the Euler angles will be presented. Using this information will result in simplifications which ultimately will reduce the number of unknown parameters. Noting that the only component of velocity that exists in a continuous wind tunnel situation in the space-fixed coordinate system is $-U_\infty$ along the X axis, transformation to the aeroballistic axis system results in

$$
a = \frac{w}{U_\infty} = \cos \psi \sin \theta
$$

$$
\beta = \frac{v}{U_\infty} = -\sin \psi
$$

(9)

with rates of change of $a$ and $\beta$ given by

$$
\dot{a} = -\dot{\psi} \sin \psi \sin \theta + \dot{\theta} \cos \psi \cos \theta
$$

$$
\dot{\beta} = -\dot{\psi} \cos \psi
$$

(10)

A comparison of Eqs. (10) and (4) makes it evident that for small pitch and yaw angles, $\dot{a}$ is approximately equal to $\dot{\theta}$. This of course assumes that $\theta$ and $\psi$ are of the same order, a valid assumption for bodies with axial symmetry or with relatively small asymmetries. Thus, the rates $\dot{a}$ and $\dot{\beta}$ are approximate linear combinations of the angular rates $q$ and $r$ and approach exact linear combinations in the limit as $\psi$ and $\theta$ approach zero. Moreover, in Section 5.1 it is shown that for reasonable levels of measurement noise, the effects of the rate terms $\dot{a}$ and $\dot{\beta}$ cannot be satisfactorily separated from the angular velocities $q$ and $r$. Thus, to avoid over specification of the aerodynamics, it is assumed that $\dot{a} = e_1 r$ and $\dot{\beta} = e_2 r$ where $e_1$ and $e_2$ are constants. This reduces the coefficient expansion as given in Eq. (8) to the form

$$
C_i(a, \beta; p, q, r) = C_i(a, \beta) + \frac{d}{2U_\infty} \left[ pC_{ip}(a, \beta) - qC_{iq}(a, \beta) + rC_{ir}(a, \beta) \right]
$$

(11)

where $i$ equals $k$, $m$, or $n$.

In order to allow for a high degree of versatility in the coefficient expansions in terms of $a$ and $\beta$, while at the same time retaining functional simplicity, Taylor series expansions are made about $a$ and $\beta$ equal to zero for each of the coefficients $C_i$, $C_{ip}$, $C_{iq}$, and $C_{ir}$. Terms involving the magnitude of $a$ and $\beta$ have also been included in the expanded coefficients. Retaining terms cubic and lower in $a$ and $\beta$, for $C_i(a, \beta)$, and
quadratic and lower for $C_{t\rho}$, $C_{t\varphi}$, and $C_{tr}$, the expanded form of the coefficients is given in Eq. (12).

\[ C_i(\alpha, \beta) = a_{i0} + a_{i1}\alpha + a_{i2}\beta + a_{i22}\alpha \beta + a_{i3}\alpha^2 + a_{i4}\beta^2 + a_{i5}\alpha\beta + a_{i6}\alpha^3 + a_{i7}\beta^3 + a_{i8}\alpha\beta^2 + a_{i9}\alpha^2\beta^2 + a_{i10}\alpha^3\beta^2 \]

\[ + a_{i11}\alpha\beta^3 + a_{i12}\alpha^2\beta^3 + a_{i13}\alpha^3\beta^3 \]

Here, the coefficients $a_{i1}$, $b_{i1}$, $c_{i1}$, and $f_{i1}$ are independent constants that are functions of the free-stream conditions (such as Mach number and Reynolds number) and body geometry.

Further simplification of Eq. (12) is not possible unless flow-field symmetry arguments are employed. The primary justification for implementation of the symmetry conditions is based on small angular motion about $\psi$ and $\theta$ equal to zero. Since the maximum angular displacement of the 3DOF gas bearing system is 10 deg, flow-field symmetry that is compatible with geometric symmetry is implied. Thus, symmetry arguments as given by Maple and Synge, Ref. 15, are used to reduce the number of unknown constants in Eq. (12). To reduce the coefficients as given in Eq. (12) to those for a body symmetric about
the x axis (see Fig. 3), two covering operations are required. A covering operation for mirror symmetry about the x, z plane is performed first and is followed by a covering operation for 90-deg rotational symmetry about the x axis. The mirror symmetry condition results in

\[
\begin{align*}
C_m(a, -\beta; -p, q, -r) &= C_m(a, \beta; p, q, r) \\
C_n(a, -\beta; -p, q, -r) &= -C_n(a, \beta; p, q, r) \\
C_g(a, -\beta; -p, q, -r) &= -C_g(a, \beta; p, q, r)
\end{align*}
\]

Under the restrictions of Eq. (13), the moment coefficients as given by Eq. (12) reduce as follows:

\[
\begin{align*}
C_m(a, \beta) &= a_{m0} - a_{m1} a - a'_{m1} a|a| + a_{m2} a^2 - a''_{m2} a|a| \\
&
- a_{m3} a^3 + a'_{m3} a^2 |a| + a'_{m4} |a|^2 - a_{m5} \beta^2 \\
&- a'_{m6} \beta |a| a^2 + a'_{m7} a |a|^2 - a'_{m8} a |\beta| \\
&+ a''_{m8} \beta a^2 + a_{m9} a \beta^2 + a''_{m9} a a
\end{align*}
\]

\[
C_{mq}(a, \beta) = b_{m0} - b_{m1} a + b'_{m1} |a| + b_{m2} a^2 + b''_{m2} a|a| \\
+ b'_{m3} |a| + b_{m4} \beta |a|^2 - b''_{m5} a |\beta| + b''_{m5} a |\beta|^2
\]

\[
\begin{align*}
C_{mr}(a, \beta) &= C_{m3} \beta + C_{m4} \beta |\beta| + C_{m5} a \beta + C_{m5} a |\beta| \\
C_{mp}(a, \beta) &= f_{m3} \beta + f'_{m4} \beta |\beta| + f_{m5} a \beta + f'_{m5} a |\beta| \\
C_{ic}(a, \beta) &= a_{i0} + a_{i4} \beta + a_{i5} \beta |\beta| + a_{i6} \beta^2 + a_{i7} \beta \\
&+ a'_{i7} |a| + a_{i8} a^2 \beta + a''_{i9} a |\beta| \\
C_{iq}(a, \beta) &= b_{i3} \beta + b'_{i4} \beta |\beta| + b_{i5} a \beta + b'_{i5} a |\beta| \\
C_{ir}(a, \beta) &= c_{i0} + c_{i1} a + c_{i1} |a| + c_{i2} a^2 + c_{i2} a |a| \\
&+ c'_{i3} \beta |a| + c_{i4} \beta^2 - c''_{i5} a \beta |a| - c''_{i5} a \beta |a|
\end{align*}
\]

\[
\begin{align*}
C_{ip}(a, \beta) &= f_{i0} + f_{i1} a - f_{i1} |a| + f_{i2} a^2 - f_{i2} a |a| \\
&- f'_{i3} \beta + f'_{i4} \beta^2 + f'_{i5} a \beta |a| + f'_{i5} a \beta |a|
\end{align*}
\]
Here, \( i = n, \ell \). The coefficient expansions as given in Eq. (14) are valid for asymmetric configurations with the symmetry plane of the body in the \( x, z \) plane of the body-fixed axis system. A 90-deg rotational symmetry requirement will result in a four-fold symmetry of the body. The four-fold symmetry coupled with mirror plane symmetry is sufficient for the specification of axial symmetry. A covering operation performed on a 90-deg rotation of the axis system results in the coefficient constraints as given in Eq. (15).

\[
C_n(\beta, -\alpha) = C_m(\alpha, \beta) \\
C_m(\beta, -\alpha) = C_m(\alpha, \beta) \\
-C_n(\beta, -\alpha) = C_m(\alpha, \beta) \\
-C_q(\beta, -\alpha) = C_q(\alpha, \beta) \\
C_q(\beta, -\alpha) = C_q(\alpha, \beta) \\
-C_n(\beta, -\alpha) = C_m(\alpha, \beta) \\
C_n(\beta, -\alpha) = C_m(\alpha, \beta) \\
C_n(\beta, -\alpha) = C_m(\alpha, \beta) \\
C_n(\beta, -\alpha) = C_m(\alpha, \beta)
\]  

(15)

Employing these constraints with the additional restriction that, for zero spin rate, an axially symmetric body will have no moments in the plane normal to the total angle-of-attack plane, the aerodynamic coefficient expansions as shown in Eq. (16) will result.

\[
C_{m0}(\alpha, \beta)/a = a_1 + a_2 (|a| + |\beta|) + a_3 (a^2 + \beta^2) + a_5 |a\beta| \\
C_{mq}(\alpha, \beta) - c_5 \beta^2 = b_0 + b_1 (|a| + |\beta|) + b_2 (a^2 + \beta^2) + b_5 |a\beta| \\
C_{mr}(\alpha, \beta) = c_5 a\beta \\
C_{mp}(\alpha, \beta)/\beta = d_3 + d_5 |a| + d_4 |\beta| \\
-C_{n0}(\alpha, \beta)/\beta = C_{m0}(\alpha, \beta)/a \\
-C_{nq}(\alpha, \beta) = C_{mr}(\alpha, \beta) \\
C_{np}(\alpha, \beta) - c_5 a^2 = C_{mq}(\alpha, \beta) - c_5 \beta^2 \\
C_{np}(\alpha, \beta)/a = d_3 + d_5 |\beta| + d_4 |a| \\
C_{q0}(\alpha, \beta) = e_0 \\
C_{q}(\alpha, \beta)/a = f_0 + f_1 (|a| + |\beta|) + f_2 (a^2 + \beta^2) \\
C_{q}(\alpha, \beta)/a = g_3 - g_5 |\beta| + g_4 |a| \\
C_{q}(\alpha, \beta)/a = g_3 + g_5 |a| + g_4 |\beta|
\]  

(16)
The above expressions as used in Eq. (11) yield the required moment coefficients.

It is important to note here that the expansions as given in Eq. (16) are not unique in describing axially symmetric body aerodynamics. Indeed, other expansions, such as those in terms of the total angle of attack as used by Whyte (Ref. 16) and others, are also valid. The "correct" expansion of coefficients describing the aerodynamics of a body, in the parameter identification sense, is that which yields the "best" fit to the experimental data and does not violate established symmetry constraints. With the establishment of the required aerodynamic coefficients, the governing equations of motion, Eq. (6), may be solved.

3.2 FORMULATION OF PARAMETER EXTRACTION METHOD

In order to determine the coefficients describing the aerodynamic model as given in Eq. (16) for axial symmetry or in Eq. (14) for mirror plane symmetry, a parameter extraction technique must be used. The 3DOF gas bearing as described in Ref. 1 yields angular position measurements in yaw, pitch, and roll which provide the experimental data necessary to extract the unknown parameters. In Section 1.0 the Chapman-Kirk method was selected as the parameter identification technique to be employed here. This technique is an output error method and, as such, uses the method of least squares to minimize the cumulative error between observed and calculated motion.

Normally when one is fitting data with a least squares method, the function to be fitted is given with constant coefficients that appear linearly in the function. This results in a set of simultaneous linear equations that may be solved in a noniterative fashion for the unknown coefficients. For nonlinear functions, the coefficients must be evaluated by the differential corrections method. This technique provides corrections to improve the estimates of the unknown parameters and, as a result, is an iterative process.

Since the 3DOF governing equations as given in Eq. (6) are nonlinear and the unknown parameters as given in Eq. (16) are complicated functions of the Euler angles, $\phi$, $\theta$, and $\psi$, the differential corrections method will be used. Consider the problem of fitting the 3DOF motion of a model to known functions of the unknown parameters. If the variables $\phi_m$, $\theta_m$, and $\psi_m$ are defined as the experimental values of the roll, pitch, and yaw positions at each time point $t$, residuals $(u, v, w)$ yielding the difference between the measured and calculated data may be expressed by Eq. (17).

$$
\begin{align*}
    u_t &= \phi_t - \phi_m t \\
    v_t &= \theta_t - \theta_m t \\
    w_t &= \psi_t - \psi_m t
\end{align*}
$$

(17)
Here, $\phi$, $\theta$, and $\psi$ are the calculated values of the roll, pitch, and yaw, respectively, which are functions of a set of independent constants, $a_i$. These constants are the aerodynamic coefficients to be determined as shown in Eq. (16). In order to determine the change in the coefficients, $\Delta a_i$, required to reduce the residuals in the least squares sense, a Taylor series expansion of the calculated solution is made. Expanding $\phi$, $\theta$, and $\psi$, and discarding second and higher order terms and using the definitions as given in Eq. (17), one obtains Eq. (18).

\[
\begin{align*}
\phi_i + \phi_{m} &= \phi_{i0} + \sum_{i=1}^{N_c} \Delta a_i \frac{\partial \phi_i}{\partial a_i} \\
\theta_i + \theta_{m} &= \theta_{i0} + \sum_{i=1}^{N_c} \Delta a_i \frac{\partial \theta_i}{\partial a_i} \\
\psi_i + \psi_{m} &= \psi_{i0} + \sum_{i=1}^{N_c} \Delta a_i \frac{\partial \psi_i}{\partial a_i} 
\end{align*}
\]

The functions $\phi_{i0}$, $\theta_{i0}$, and $\psi_{i0}$ correspond to the values of $\phi$, $\theta$, and $\psi$, respectively, evaluated at each time point for the given constants $a_i$, and $N_c$ is the total number of parameters $a_i$ to be determined. The best fit of $\phi$, $\theta$, and $\psi$ to the experimental data is established by minimizing the sum of the squares of the residuals for all time points considered. Thus,

\[
\sum_{k=1}^{N} (u_k^2 + v_k^2 - w_k^2) = \sum_{k=1}^{N} \left[ \left( \sum_{i=1}^{N_c} \Delta a_i P_{1ik} - R_{1k} \right)^2 + \left( \sum_{i=1}^{N_c} \Delta a_i P_{2ik} - R_{2k} \right)^2 + \left( \sum_{i=1}^{N_c} \Delta a_i P_{3ik} - R_{3k} \right)^2 \right] 
\]

is subject to the minimization condition as given in Eq. (20).

\[
\frac{\partial}{\partial \Delta a_i} \sum_{k=1}^{N} (u_k^2 + v_k^2 + w_k^2) = 0
\]

where

\[
P_{1ik} = \frac{\partial \phi_k}{\partial a_i}, \quad P_{2ik} = \frac{\partial \theta_k}{\partial a_i}, \quad P_{3ik} = \frac{\partial \psi_k}{\partial a_i}
\]
N is the total number of time points considered, and

\[ R_{1\tau} = \phi_{\tau - \theta_{\tau - \phi}} \cdot R_{2\tau} = \theta_{\tau - \phi} \cdot R_{3\tau} = \psi_{\tau - \psi} \]

Performing the indicated partial differentiation in Eq. (20) and combining terms results in

\[ C_{ij} \Delta a_i = D_j \]  

(21)

where \( C_{ij} \) is a symmetric \((N_c \times N_c)\) matrix of parametric influence coefficients given by

\[ C_{ij} = \sum_{\ell=1}^{N} \left( P_{1\ell}^2 P_{1\ell}^2 - P_{2\ell}^2 P_{2\ell}^2 - P_{3\ell}^2 P_{3\ell}^2 \right) \]  

(22)

and \( D_j \) is a residual influence matrix with the form

\[ D_j = \sum_{\ell=1}^{N} \left( R_{1\ell}^2 P_{1\ell}^2 - R_{2\ell}^2 P_{2\ell}^2 + R_{3\ell}^2 P_{3\ell}^2 \right) \]  

(23)

Since Eq. (21) is linear in \( \Delta a_i \), it may be inverted, yielding the required correction to the coefficients, \( a_i \). Thus, given a set of initial estimates for the independent constants, determination of \( \Delta a_i \) will result in corrected values of \( a_i \) which will cause the computed motion to more closely approach the experimental data. In the limit of no process or measurement noise, iteration on \( a_i \) will provide the best fit in the least squares sense of the computed to the experimental motion.

Implied in this development are two important facts that can seriously disrupt or destroy the convergence of \( a_i \) to the "best" values. If measurement noise exists, the definition of the residuals, Eq. (19), assumes that the dependent variables \( \phi, \theta, \) and \( \psi \) have the same relative uncertainty. For practical applications, the relative uncertainty of the measurements \( \phi, \theta, \) and \( \psi \) may differ by as much as an order of magnitude. This effect can be accounted for in the parametric influence coefficients by redefining \( C_{ij} \) as

\[ C_{ij} = \sum_{\ell=1}^{N} \left( \frac{P_{1\ell}^2 P_{1\ell}^2}{\sigma_{\phi}^2} + \frac{P_{2\ell}^2 P_{2\ell}^2}{\sigma_{\theta}^2} + \frac{P_{3\ell}^2 P_{3\ell}^2}{\sigma_{\psi}^2} \right) \]  

(24)

and \( D_j \) as

\[ D_j = \sum_{\ell=1}^{N} \left( \frac{R_{1\ell}^2 P_{1\ell}^2}{\sigma_{\phi}^2} + \frac{R_{2\ell}^2 P_{2\ell}^2}{\sigma_{\theta}^2} + \frac{R_{3\ell}^2 P_{3\ell}^2}{\sigma_{\psi}^2} \right) \]  

(25)
where \( \sigma_\phi \), \( \sigma_\theta \), and \( \sigma_\psi \) are the standard deviations of the relative uncertainty in the roll, pitch, and yaw measurements, respectively (see Ref. 17). Also implied in Eq. (18) is the assumption that the coefficients \( a_i \) used to generate \( \phi_\circ, \theta_\circ, \) and \( \psi_\circ \) are close to the best values. If a significant difference exists between the initial value of the coefficients and the actual or best values, the expansions as given in Eq. (18) are not valid and will result in divergence of the corrections, \( \Delta a_i \), or convergence on invalid solutions. The closeness of the initial values of the coefficients to the best values for correct convergence is a function of the character of the motion fitted.

As stated previously, in the absence of measurement or process noise, correct application of the differential corrections method will yield parameters with no relative error. In the presence of these noise sources, however, bias may be introduced into the converged parameters. According to Ref. 18, for statistically random measurement noise in the data, it may be shown that the root-mean-square (RMS) deviation between the experimental data and converged solution is given by

\[
\delta a_i = \sqrt{B_i} \sqrt{L_i} \left( \frac{\sum_{l=1}^{N} \left( \frac{R_{ll}^2}{\sigma_\phi^2} + \frac{R_{2l}^2}{\sigma_\theta^2} + \frac{R_{3l}^2}{\sigma_\psi^2} \right)}{3(N - 1) - N_r + 1} \right) \tag{26}
\]

with the corresponding RMS error in each of the coefficients, \( \delta a_i \), equal to

\[
\delta a_i = \delta a_i \sqrt{B_i} \sqrt{L_i} \tag{27}
\]

where \( B_i \) represents the diagonal components of the inverse matrix of \( C_{ij} \). Equations (26) and (27) provide mathematically rigorous estimates of the measurement-noise-generated RMS deviation in the coefficients and solution. They do not, however, give reliable estimates of the RMS deviation or error for measurement noise that is not statistically random. noise which may result when data time samples are too small, or for process noise caused by inappropriate aerodynamic modeling.

The differential corrections method just presented requires the value of each of the partial derivatives, as illustrated in Eq. (18), at each time point. Previous users of the differential corrections method such as Eikenberry (Ref. 2) relied on the use of analytic solutions for the angular motion to generate the required partial derivatives. Since the equations of motion as used here are highly nonlinear and cannot be solved in closed form, the values of the influence coefficients \( \partial \phi/\partial a_i, \partial \theta/\partial a_i, \) and \( \partial \psi/\partial a_i \) are determined by numerically integrating a set of parametric differential equations. These equations are derived by differentiating the governing equations of motion with respect to each parameter, \( a_i \), and inverting the order of differentiation. Performing the indicated operations on Eq. (6) results in the following:
\[ \vec{P}_{1i} = M_{1i} + \dot{\phi} \hat{P}_{3i} \cos \theta + \dot{\psi} \hat{P}_{2i} \cos \theta - \ddot{\psi} \dot{\theta} P_{2i} \sin \theta \]

\[ + M_{3i} \tan \theta + \bar{M}_z P_{2i} \sec^2 \theta + (2 - R) (\dot{\phi} \hat{P}_{3i} + \dot{\psi} \hat{P}_{2i}) \tan \theta \sin \theta \]

\[ + (2 - R) \dot{\psi} \dot{\theta} P_{2i} \sin \theta (1 - \sec^2 \theta) + R \dot{\phi} \dot{P}_{2i} \tan \theta \sin \theta \]

\[ + R \ddot{\phi} \dot{P}_{2i} \tan \theta + R \dddot{\phi} \dot{P}_{2i} \sec^2 \theta \]

\[ \vec{P}_{2i} = M_{2i} - 2 (1 - R) \dot{\psi} \hat{P}_{3i} \sin \theta \cos \theta - (1 - R) \dot{\psi} \hat{P}_{3i} (1 - 2 \sin^2 \theta) \] \hfill (28)

\[ - \bar{M}_z \hat{P}_{2i} \cos \theta - R \dot{\phi} \dot{P}_{3i} \cos \theta - R \dot{\phi} \dot{P}_{2i} \sin \theta \]

\[ \vec{P}_{3i} = M_{3i} \sec \theta + \bar{M}_z \hat{P}_{2i} \tan \theta \sec \theta + (2 - R) \tan \theta (\dot{\psi} \dot{P}_{2i} + \ddot{\phi} \hat{P}_{3i}) \]

\[ - (2 - R) \dot{\psi} \dot{P}_{2i} \sec^2 \theta + R \ddot{\phi} \dddot{P}_{2i} \sec \theta + R \dddot{\phi} \dddot{P}_{2i} \tan \theta \sec \theta \]

where \( M_{1i} = \frac{\partial \hat{M}_\lambda}{\partial a_i} \), \( M_{2i} = \frac{\partial \hat{M}_x}{\partial a_i} \) and \( M_{3i} = \frac{\partial \hat{M}_z}{\partial a_i} \) are evaluated in a similar manner through the moment expansions. The above equations are second order and, thus, require two boundary conditions for the evaluation of each influence coefficient. These are obtained from the boundary conditions on the angular motion given by

\[ \phi (0) = a_{N \phi - 5} \]

\[ \dot{\phi} (0) = a_{N \phi - 4} \]

\[ \theta (0) = a_{N \theta - 3} \]

\[ \dot{\theta} (0) = a_{N \theta - 2} \]

\[ \psi (0) = a_{N \psi - 1} \]

\[ \dot{\psi} (0) = a_{N \psi} \]

If one differentiates the boundary conditions given in Eq. (29), the boundary conditions on the governing equations for the influence coefficients may be derived.
\[ P_{1i}(0) = \delta_{N_{c}-5,i} \]
\[ \dot{P}_{1i}(0) = \delta_{N_{c}-4,i} \]
\[ P_{2i}(0) = \delta_{N_{c}-3,i} \]
\[ \dot{P}_{2i}(0) = \delta_{N_{c}-2,i} \]
\[ P_{3i}(0) = \delta_{N_{c}-1,i} \]
\[ \dot{P}_{3i}(0) = \delta_{N_{c},i} \]  \hspace{1cm} (30)

Here \( \delta_{ij} \) is the Kronecker-Delta function with \( \delta_{ij} = 1 \) for \( i = j \) and \( \delta_{ij} = 0 \) for \( i \neq j \).

In order to utilize the differential corrections method to extract aerodynamic coefficients of interest, one must solve the governing angular motion equations and parametric differential equations simultaneously. With the angular motion and influence coefficient solutions determined for a given set of initial coefficient values, corrections to the coefficients are evaluated through Eq. (21). For example, if there are thirty coefficients to be identified (which include, generally, both the boundary conditions, Eq. (20), and the aerodynamic coefficients, Eq. (16)), a maximum of 186 differential equations must be solved simultaneously.

\textbf{4.0 DESCRIPTION OF COMPUTER PROGRAM}

The computer program as described here extracts aerodynamic coefficients from 3DOF data defined by the measured yaw, pitch, and roll angles as a function of time. The code is based on the Chapman-Kirk technique as detailed in Section 3.0. Both symmetric and asymmetric versions of the program have been developed and are listed in Tables 1 and 2.

The symmetric version is written in double precision Fortran IV for use on the IBM 370/165 computer. In the form listed here, core requirements are 164 K bytes using the G compiler. As many as 30 coefficients may be extracted from 3DOF data with actual computation time proportioned to \( \tau \) as shown in Eq. (31).

\[ \tau = n(N_{c} + 1) \frac{t_{\text{max}}}{\Delta t} \]  \hspace{1cm} (31)

Here \( n \) is the number of iterations, \( N_{c} \) is the total number of constants varied, \( t_{\text{max}} \) is the total integration time, and \( \Delta t \) is the integration time interval.

The program is written in a logical sequence so that changes in internal program structure such as alteration of the functional form of the moment coefficient expansions
can be made easily. A flow chart showing the important logic and branching points is provided in Fig. 4. Table 3 contains a brief description of each of the subroutines employed in the code.

The asymmetric version of the code is functionally the same as the symmetric version. Only the core requirements, coefficient arrays in the main program, and subroutines directly involving the kinematic or dynamic equations for the 3DOF motion are altered. Core requirement for the asymmetric program is 266 K bytes when the G compiler is used. In addition, up to 72 coefficients can be extracted from 3DOF data using this version.

In both programs, integration of the kinematic, dynamic, and parametric differential equations is performed with a fourth-order Runge-Kutta, fixed time step scheme. The coefficients to be extracted from the data are reiterated as outlined in Section 3.2 until convergence is achieved. Convergence is assumed when consecutive iterations yield a change in the probable error of the fit less than a specified error bound.

4.1 INPUT

The input information necessary to execute either version of the coefficient extraction program is very similar. The actual 3DOF experimental data to be analyzed is input to both programs through a direct access input file. Data are stored in this file in 1,003 word records, in which the first three words define the data group number, data block number, and data type indicator, in that order, and are integers. The data type indicator defines the variable being accessed and may take on values from one to four corresponding to arrays of time, $\phi$ versus time, $\theta$ versus time, and $\psi$ versus time, respectively, all of which are single precision variables.

The initial values of the coefficients and the parameters providing branching instructions and body and flow-field information are input using namelist statements. No default value is provided in the program for required variables not defined in the initial namelist statement. The namelist input format was used to provide versatility in constructing sequential runs by updating prior information. Table 4 gives the namelist variables, their meaning, and their nominal values needed for execution of either the symmetric or asymmetric coefficient extraction program.

4.2 OUTPUT

Output variables as used in both the symmetric and asymmetric programs are similar and are compatible with input variable definitions. Only portions of the output data from a typical run which are not self explanatory will be discussed.
During normal data reduction using either program, each iteration of the parameters (aerodynamic coefficients and boundary conditions) is listed with the corresponding change in the parameter (DELTA CON) according to the theory of Section 3.2. The variables defined as the new and old probable error are the previous and present values of the RMS deviation between the experimental data and converged solution, respectively, as defined in Eq. (26). The sum of the residuals is defined as follows:

\[
\text{Sum of Residuals} = \sqrt{\sum_{i=1}^{N} \frac{R_{i}^2}{\sigma_{\phi}^2} + \frac{R_{2i}^2}{\sigma_{\theta}^2} + \frac{R_{3i}^2}{\sigma_{\psi}^2}}
\] (32)

The iterations are continued until convergence of the solution, as discussed in Section 4.0, is achieved or until the input value of the maximum number of iterations is reached. The final values of the parameters are then listed along with corresponding values of the RMS error in each coefficient as defined in Eqs. (26) and (27). A comparison of the fit of the theoretical solution (denoted by FIT) to the experimental data (denoted by EXP) is also shown. The theoretically generated solution of \( \psi \) and \( \theta \) (denoted by PSI and THETA, respectively) and the difference between the theoretical and experimental values of \( \psi \) and \( \theta \) (\( \psi - \psi_m = PSI - PSIM \), \( \theta - \theta_m = THETA - THETAM \)) are stored for later use as data for graphical output.

5.0 RESULTS OF VALIDATION TESTS

Verification of the improved parameter identification technique as presented in Sections 3.0 and 4.0 requires, in addition to checks on the program using computer-generated motion, an assessment of the measurement and process noise inherent in the gas bearing and in typical tunnel test data. This is necessary since the "best" coefficients, as produced by output error methods such as the one discussed here, are directly influenced by the cumulative effects of modeling errors and measurement noise. Thus, this section addresses three areas concerned with validation of the improved coefficient extraction technique: numerically-generated 3DOF motion, including Gaussian noise, is employed to simulate measurement noise effects on the probable error in extracted coefficients; a bench test is used to assess the accuracy of the 3DOF measurement system; and 3DOF data taken in Tunnel A are used to indicate some of the capabilities of the parameter identification technique.

5.1 COMPUTER-GENERATED MOTION

In order to arrive at the final form of the aerodynamic coefficients as given in Eq. (14) for the asymmetric and Eq. (16) for the symmetric analysis, the \( \alpha \) and \( \beta \) coefficients were linearly combined with the q and r rate coefficients, respectively. This was a direct
result of similarity of the $\dot{\alpha}$, $\dot{q}$ and $\dot{\beta}$, $r$ relations [(see Eqs. (4) and (10))] in terms of the Euler angles. In order to verify this hypothesis, 3DOF motion was generated both with and without noise with the $\dot{\alpha}$ and $\dot{\beta}$ coefficients included. The initial conditions and parameters employed to specify the motion are listed below.

\begin{align*}
S &= 0.390 \text{ ft}^2, \quad I_x = 0.0372 \text{ slugs-ft}^2, \quad I = 0.244 \text{ slugs-ft}^2 \\
C_{m\dot{\alpha}} &= -0.236 \text{ l/rad}, \quad C_{mq} = -1.762 \text{ l/rad}, \quad C_{m\dot{q}} = -0.881 \text{ l/rad} \\
\phi_0 &= 0, \quad \dot{\phi}_0 = 641 \text{ deg/sec}, \quad \theta_0 = 5.18 \text{ deg}, \quad \dot{\theta}_0 = -26.356 \text{ deg/sec} \\
\psi_0 &= -2.589 \text{ deg}, \quad \dot{\psi}_0 = -7.77 \text{ deg/sec} \\
U_\infty &= 4,774 \text{ ft/sec}, \quad q_\infty = 150.4 \text{ lbf/ft}^2
\end{align*}

The symmetric version of the parameter identification program was used to extract the variables listed above from the generated data. The parameters $C_{mq}$ and $C_{m\dot{q}}$ were both extracted with nominal values of $-1.74$ per radian and $-0.90$ per radian, respectively, and RMS deviations of $\pm 0.05$ per radian. This deviation is a measure of the character of data fitted and the numerical accuracy of the program. Gaussian noise with one standard deviation equal to 0.01 deg was then added to the generated values of $\phi$, $\theta$, and $\psi$. With noise added, $C_{mq}$ and $C_{m\dot{q}}$ were both extracted from the data and yielded values of $-5.87$ per radian and 3.2 per radian, respectively, with RMS deviations of $\pm 18$ per radian. The noise added is representative of the levels of measurement noise inherent in the 3DOF measurement system. Moreover, the motion examined contained only linear aerodynamics. This should have resulted in the smallest RMS deviations of the extracted coefficients as influenced by modeling. Thus, based on the results of this example, it is not feasible to separate the effects of $C_{mq}$ and $C_{m\dot{q}}$ from typical 3DOF measurements where 1-$\sigma$ measurement errors are 0.01 deg or higher.

The definitions of $\alpha$ and $\beta$ can also play a role in the extraction of the "best" coefficients for a given set of 3DOF measurements. In Tobak's developments, Ref. 14, $\alpha$ and $\beta$ were defined as

\begin{align*}
\alpha_v &= \frac{w}{U_\infty}, \quad \beta_v = \frac{\nu}{U_\infty} \quad \tag{33}
\end{align*}

Much of the past work, however, has employed $\alpha$ and $\beta$ in terms of the angle of attack and sideslip leading to

\begin{align*}
\alpha_a &= \tan^{-1} \frac{w}{u}, \quad \beta_a = \tan^{-1} \frac{\nu}{u} \quad \tag{34}
\end{align*}
Written in terms of the Euler angles in the aeroballistic axis system, $a_v, \beta_v$ may be related to $a_a, \beta_a$, resulting in

$$
a_a = a_v \left[ \frac{1}{\cos \psi} + \frac{1}{6} \frac{a_v^2}{\cos^3 \psi} + \cdots \right]
$$

$$
\beta_a = \beta_v \left[ \frac{1}{\cos \theta \cos \psi} + \frac{1}{8} \frac{\beta_v^2}{\cos^3 \theta \cos^3 \psi} + \cdots \right]
$$

(35)

Thus, for small values of $\theta$ and $\psi$, $a_a \approx a_v$ and $\beta_a \approx \beta_v$. Over a large number of cycles of data, the cumulative effect of these small differences will appear as higher order terms in the coefficient expansions [compare Eqs. (35) and (16), for example]. Both definitions of $a$ and $\beta$ as given in Eqs. (33) and (34) have been incorporated in the parameter identification programs as developed here. Comparisons of generated data using the two definitions of $a$ and $\beta$ were made which confirmed the results derived from Eq. (35).

The accuracy and validity of generated 3DOF motion from the programs as listed in Tables 1 and 2 were examined through comparison with results from an existing 6DOF code, Ref. 19. Calculations were made using the 6DOF code and the asymmetric program as described in this report for two sets of initial body and flow-field conditions as listed below.

CHECK CASE I

$S = 0.3898 \text{ ft}^2$, $d = 0.7038 \text{ ft}$

$I_y = I_z = 0.2444 \text{ slugs-ft}^2$, $I_x = 0.03723 \text{ slugs-ft}^2$, $I_{xz} = 0$

$U^* = 4,774 \text{ ft/sec}$, $q^* = 364.66 \text{ lbf/ft}^2$

$C_{ma} = -C_{n\beta} = -0.2355 \text{ 1/rad}$, $C_{mq} = C_{nr} = -2.6434 \text{ 1/rad}$

$\theta_0 = 5.18 \text{ deg}$, $\psi_0 = -2.589 \text{ deg}$, $\phi_0 = 0$, $p_0 = 641.7 \text{ deg/sec}$

$q_o = -26.356 \text{ deg/sec}$, $r_o = -7.735 \text{ deg/sec}$

CHECK CASE II

$S = 1.228 \text{ ft}^2$, $d = 1.25 \text{ ft}$

$I_y = I_z = 700 \text{ slugs-ft}^2$. $I_x = 20 \text{ slugs-ft}^2$, $I_{xz} = -100 \text{ slugs-ft}^2$
$U_\infty = 1,500$ ft/sec, $q_\infty = 675$ lbf/ft$^2$

$C_{m_a} = -C_{n\beta} = 16.7132$ l/rad

$\theta_0 = 5$ deg, $\psi_0 = 5$ deg, $\phi_0 = 0$, $p_0 = q_0 = r_0 = 0$

Typical results of the calculations are shown below and indicate excellent agreement between the two codes in the computed values of $\phi$, $\theta$, and $\psi$.

To attain the best possible coefficients from 3DOF data with measurement noise, the quantity and character of the data sampled are of fundamental importance. A less than optimum data sample will yield extracted coefficients with high RMS deviations or, in some cases, lack of convergence of the solutions. The extraction of optimum coefficients was studied using the generated motion as discussed previously with 0.05-deg, 1-$\sigma$ Gaussian noise added to the data and $C_{m_a} = 0$, $C_{m_q} = -2.64$ per radian where $\sigma$ is one-standard deviation. Table 5 shows the results of this study where the RMS deviation in percent of $C_{m_q}$ is shown as a function of the number of data points per cycle of data and the total number of cycles of data analyzed. From this table it may be generally concluded that accuracy in the extracted value of $C_{m_q}$ is improved faster by increasing the data sample size than by increasing the number of points per cycle. This same trend and the rate of improvement of the extracted parameter was also found to hold true for $C_{m_a}$ and, moreover, for the nonlinear expansions of $C_{m_a}$ and $C_{m_q}$ [see Eq. (16)].

The effect of the magnitude of the measurement noise on the extracted coefficients was examined by generating noisy 3DOF data for the same conditions as previously used.
but with $C_{m \alpha} = 5.81/\text{rad}^3$, $C_{m \phi} = -4.0$ per radian, and $C_{m \phi \delta^2} = 98.5/\text{rad}^3$. The symmetric version of the parameter identification program was used and yielded the results shown in Table 6. Here the extracted parameters and their RMS deviation are shown as a function of the measurement noise added to the generated values of $\phi$, $\theta$, and $\psi$. The generated data analyzed contained 40 cycles of data with 20 points per cycle. Initial parameter estimates were set at $C_{m \alpha} = -0.2$ per radian and $C_{m \phi} = C_{m \phi \delta^2} = C_{m \alpha \delta^2} = 0$. Typical plots of calculated $\theta$ and $\psi$ values versus time for a measurement noise level of $\sigma = 0.05$ deg are shown in Fig. 5. Residuals showing the difference between the generated data with noise and the calculated values of $\theta$ and $\psi$ and graphs indicating the fit of the computed solution to the generated data are also provided.

Two important conclusions may be drawn from the magnitude and variation of the RMS deviation of each of the coefficients in Table 6. It is apparent that the magnitude of the RMS deviation is approximately a linear function of the measurement noise level denoted by $\sigma$. In addition, the magnitude of the deviation appears to be a good estimate of the actual error in the values of the extracted coefficients. This result is, in fact, verification of those statements made in Section 3.2 concerning the theoretical meaning of $\delta \alpha_i$ [Eq. (27)].

5.2 BENCH TEST DATA

The previous section discussed the effects of measurement noise on the extracted coefficients. The noise source considered was Gaussian and random in nature.

When 3DOF motion including Gaussian noise is viewed in the frequency plane, the noise contributes no distinct frequencies or regions of high spectral density. In most cases, however, the effect of modeling noise on the extracted coefficients is more pronounced than the effect of measurement noise. Most modeling sources occur over finite spectrums with median frequencies occurring near aerodynamic frequencies of interest. Moreover, in such regions modeling noise may have high power levels which may be the same order of magnitude as noise caused purely by aerodynamics. Thus, a critical assessment of the important modeling errors present in typical 3DOF data must be made to gain the optimum capabilities of the improved parameter identification technique.

Some of the important categories of modeling noise are 1) incorrect aerodynamic modeling of the specific configuration, 2) modeling errors introduced through the effects of tunnel flow nonuniformities, and 3) errors associated with nonlinearities and coupling effects caused by the gas bearing. This section will consider modeling errors due to the gas bearing only.
The VKF spherical gas bearing as described in Ref. 1 provides a nearly frictionless pivot in roll, pitch and yaw, and thus is ideal for 3DOF motion simulation. Model oscillations of up to 10 deg in the combined pitch, yaw plane and unlimited roll orientation are possible using this mechanism. Figs. 6 and 7 are photographs of the gas bearing assembly. Details of the balance mechanism and the angular measurement system are shown in Fig. 8. Pitch and yaw angular displacements are measured using an eccentric as shown in Fig. 7 positioned on the outer race of the bearing and two pairs of orthogonal E-cores fixed on the bearing instrument ring. Motion in pitch or yaw causes a change in the distance between the eccentric and the E-core surfaces. The accompanying change of the reluctance of the E-cores provides an analog signal proportional to angular displacement. The measurement of roll position is made using light-emitting diodes and alternating reflective and nonreflective lines affixed to the eccentric as shown in Figs. 7 and 8.

The measurement of angular position in pitch and yaw using the gas bearing is affected by two sources of error. During calibration, adjustments to the bearing are made so that the E-core output varies approximately linearly with the actual angular displacement. Calibration factors are then established for both the pitch and yaw measurements using a linear least squares curve fit. Although this approach provides a very simple and fast technique for reducing raw data into angular displacements, it can introduce error into the resulting measurements. Nonlinearities on the order of 0.02 deg or less for pitch and yaw measurements of up to ±5 deg are typical for bearing calibration. For pitch or yaw measurements approaching 8 deg, the nonlinearity generally increases in magnitude, reaching values as high as 0.1 deg.

An additional source of error is the interaction of roll position on the pitch and yaw measurements. This effect is most probably a result of the machining tolerances of the eccentric and the alignment of the E-cores and has been found to change following reassembly of the bearing. A systematic investigation of this interaction effect was conducted to provide the variation of the measured pitch and yaw angle with roll position. Some typical results of this investigation are shown in Figs. 9 through 12. Data were taken of the variation in ψ and θ as a function of φ and the total angle in the vertical plane for sting roll positions in 15-deg increments. Accuracy of the measurements is within ±0.01 deg in θ and ψ. The sting roll position, Ω, and total angle of attack, δ, are related to the Euler angles for φ = 0 as follows:

\[ \delta = \sqrt{\sin^2 \psi + \cos^2 \psi \sin^2 \theta} \]  (36)

\[ \tan \Omega = \frac{\sin \psi}{\cos \psi \sin \theta} \]  (37)
Figs. 9 through 12 reveal some important facts concerning the roll interaction effect upon \( \theta \) and \( \psi \) measurements. With reference to these figures, the magnitude of the correction approaches 0.1 deg for practically all combinations of \( \delta \) and \( \Omega \). In addition, there is significant variation of the correction as a function of \( \phi \) with no apparent symmetry about particular sting roll positions. If the interaction was caused by imperfections in the eccentric only, symmetry should have appeared as evidenced by matching corrections as a function of \( \phi \) in 90-degree sting roll positions (compare Figs. 9, 11, and 12). Apparently the E-core, bearing alignment, and eccentric imperfections all play a major part in the lack of symmetry of the roll interaction effect.

In addition to the modeling or process noise resulting from the roll interaction effect and from the methods used for bearing calibration, process noise due to bearing moments can also be present in typical 3DOF data. These bearing moments are small and highly nonlinear and vary with the bearing gas pressure. A special pendulum designed for the gas bearing was used to study nonlinear bearing moments and their effect on 3DOF motion. Assuming that no aerodynamic moments act on the pendulum, the only moment caused by the pendulum is that resulting from the cg displacement from the vertical axis as depicted in Fig. 13. Then, in the aeroballistic system, it may be shown that

\[
\begin{align*}
\hat{M}_y &= -W \ell \cos \psi \sin \theta \\
\hat{M}_z &= -W \ell \sin \psi
\end{align*}
\]  

(38)

where \( \ell \) is the distance between the bearing pivot point and the pendulum center of mass and \( W \) is the pendulum weight. Comparison of Eq. (38) with Eqs. (9) and (16) yields

\[
a_1 = -W\ell/q_\infty S d
\]

Geometric properties of the pendulum and assumed conditions for data analysis are listed below.

- Weight = 10.38 lbf, \( I_x = 0.0305 \text{ slugs-ft}^2 \)
- \( I_y = I_z = 0.04747 \text{ slugs-ft}^2 \), \( \ell = 0.058 \text{ ft} \)
- \( S = 0.3975 \text{ ft}^2 \), \( d = 0.7092 \text{ ft} \)
- \( U_\infty = 1 \text{ ft/sec}, q_\infty = 0.5 \text{ lbf/ft}^2 \)

Experimental \( \phi \), \( \theta \), and \( \psi \) data were taken using the configuration as shown in Fig. 13 for variations in the bearing pressure, total angle of attack of the pendulum, and roll rate. For low bearing pressure equal to 100 psi, analysis of the 3DOF data resulted in excellent fit of the linear moment distribution as given in Eq. (38). Typical plots of the resulting solution and the residuals in both \( \theta \) and \( \psi \) are shown in Fig. 14. Analysis was
performed employing the symmetric version of the coefficient extraction code, Table 1, yielding an equivalent $C_{m,a}$ of -3.70 1/rad. With reference to Fig. 14, all residuals are of the same level as measurement errors caused by the roll interaction effect discussed earlier. In addition, a small rolling-moment coefficient, $C_{f0} = -0.79 \times 10^{-4}$ 1/rad, was extracted from the data.

As the bearing pressure was increased, the resulting 3DOF motion became highly nonlinear. Large differences in the equivalent $C_{m,a}$ for small compared to moderate angles of attack were detected. The extracted values of the equivalent $C_{m,a}$ for the moderate and small angles of attack were -3.79 1/rad and -1.32 1/rad, respectively. The corresponding roll moment coefficient increased from -0.000079 1/rad for moderate angles to -0.00121 1/rad for small angles. Thus, as bearing pressure is increased from 100 to 400 psi, the bearing-induced roll torque increases by an order of magnitude from $-1.1 \times 10^{-5}$ ft-lbf to $-1.7 \times 10^{-4}$ ft-lbf.

Figures 15 and 16 show the fit of the computed solution to the experimental data for a bearing pressure of 400 psi at moderate and small angles of attack, respectively. The moderate angle-of-attack data exhibited large deviations from motion produced by the moments as given in Eq. (38). This is evident when the magnitude and character of the residuals as given in Fig. 15 are compared to those for low bearing pressure, Fig. 14. The results of the small angle-of-attack data, Fig. 16, indicate good agreement between the data and the computed solution based on the moment expressions as given in Eq. (38); however, the magnitude of the equivalent $C_{m,a}$ is a factor of three smaller than the expected value.

Thus, for normal operation of the gas bearing at bearing pressures of 400 psi, nonlinear moments, near $\psi$ and $\theta$ equal to zero, induced by the bearing are present in typical 3DOF data with magnitudes proportional to $\dot{M}_y = 0.330 \alpha$ ft-lbf and $\dot{M}_z = -0.330 \beta$ ft-lbf. As bearing pressure is decreased from 400 psi, nonlinear bearing-induced moments are substantially reduced. For a Mach number 4 test environment with $q_m = 460$ psf and a slightly blunted sphere-cone with reference dimensions of $d = 0.7$ ft and $S = 0.35$ ft$^2$, the contribution of the bearing-induced moment at 400 psi operating pressure is on the order of 1 percent of the model aerodynamic pitching-moment coefficient with $C_{m,a} = -0.22$ 1/rad.

The previous discussion has revealed the existence of pitch and yaw measurement errors caused primarily by the roll interaction effect. In addition, there are errors present in the roll position measurement. The accuracy with which roll position can be measured is directly influenced by the number of alternating reflective and nonreflective lines on the eccentric (see Figs. 7 and 8). Currently, a change in roll orientation is sensed every two degrees by the digital system. Thus, for moderately high roll rates compared to the
median frequency in the pitch-yaw plane, a roll uncertainty of ±1 deg appears in the
data as approximately random noise. As the roll rate is decreased toward the median
pitch-yaw plane frequencies, the roll uncertainty appears less random and can introduce
significant errors in extracted coefficients depending on the duration of the data and the
character of the motion to be fitted.

5.3 TUNNEL A EXPERIMENTAL RESULTS

In Sections 5.1 and 5.2, errors associated with the gas bearing measurement system
were examined. The ability to extract correct aerodynamic coefficients (up to ±0.1 deg
in pitch and yaw) in the presence of random measurement noise caused by the gas
bearing was shown to exist. Even though these errors are not random, successful
analysis of low bearing pressure bench test data indicates that these measurement errors
for linear systems may be treated as random measurement noise. The successful application
of the parameter identification method as developed here, however, also strongly depends
on the precise definition of process noise associated with tunnel flow nonuniformities.
Depending upon the exact form of these flow nonuniformities, extracted aerodynamic
parameters with large bias may result. In order to examine the ability of the present
method to extract "correct" aerodynamic coefficients from typical wind tunnel results,
3DOF data were taken in the AEDC-VKF Tunnel A at a Mach number and Reynolds
number of 4.02 and 3.6 million per foot, respectively.

Tunnel A is a continuous, closed-circuit, variable density wind tunnel with an
automatically driven flexible-plate-type nozzle and a 40- by 40-in. test section (Fig. 17).
The tunnel can be operated at Mach numbers from 1.5 to 6.0 at stagnation pressures
from 29 to 200 psia, respectively, and at stagnation temperatures up to 750°R
depending upon Mach number and pressure level. Minimum operating pressures range
from about one-tenth to one-twentieth of the maximum at each Mach number. The
tunnel is equipped with a model injection system which allows removal of the model
from the test section while the tunnel remains in operation.

The configurations tested were a 6.7-deg sharp and 6.7-deg spherically blunted cone
with mass and geometric properties as listed below (see Fig. 18).

\[ d = 0.6667 \text{ ft}, \quad S = 0.3491 \text{ ft}^2 \]

\[ \text{cg location} \quad = \quad 12.00 \text{ in. from model base} \]

sharp cone: \( I_x = 0.0301 \text{ slugs-ft}^2 \), \( I_y = 0.2583 \text{ slugs-ft}^2 \), \( I_z = 0.2565 \text{ slugs-ft}^2 \)

sphere cone: \( I_x = 0.0304 \text{ slugs-ft}^2 \), \( I_y = 0.2519 \text{ slugs-ft}^2 \), \( I_z = 0.2514 \text{ slugs-ft}^2 \),

\[ d_n/d = 0.2275 \]
These two configurations do not sufficiently challenge the analysis capabilities of the asymmetric or symmetric program in terms of model aerodynamics. They do, however, provide baseline data on bodies whose aerodynamics are known. This information may be used to assess the influence of small tunnel flow-field nonuniformities on the sensitivity of the coefficient extraction technique.

The data analyzed are shown in Figs. 19 and 20 where the variables \( \phi, \theta, \) and \( \psi \) are plotted against time. Figure 19 shows typical data for the sharp cone model. Sphere-cone results are given in Fig. 20 with initial conditions similar to those for the sharp cone. Comparison of \( \theta \) and \( \psi \) versus time in Fig. 19 shows unexpected frequency variations and damping effects normally not associated with motion of a sharp cone. For the flow-field and body constraints listed above, analysis of the sharp cone data should yield symmetric aerodynamic coefficients with

\[
-C_n = C_m = -0.23 \text{ 1/rad}, \quad C_m \beta = -C_n \phi = 1.13 \text{ 1/rad}^3
\]

\[
C_n r = C_m q = -5.5 \text{ 1/rad}, \quad C_q p = 0.0081 \text{ 1/rad} \quad \text{(Ref. 20)}
\]

Analysis of the data as given in Fig. 19 was made using the symmetric program assuming linear aerodynamics and no flow-field-induced process noise. Analysis of 8.44 sec of the data resulted in extracted coefficients with

\[
C_m = -0.225 \text{ 1/rad}, \quad C_m q = -6.0 \text{ 1/rad}
\]

with RMS deviations in the coefficients of

\[
E(C_m) = 0.0003 \text{ 1/rad}, \quad E(C_m q) = 0.23 \text{ 1/rad}
\]

Comparison of the extracted with the corresponding expected value of each of the coefficients reveals good agreement which is reflected in the size of the calculated RMS deviations. However, examination of the residuals and the fit of the calculated solution to the experimental data as shown in Fig. 21 does not substantiate the validity of these coefficients.

Correct aerodynamic coefficients will not be extracted from the sharp cone data until the process noise in the experimental data is properly modeled. Tunnel-fixed flow nonuniformities are the most probable source of the process noise causing the poor fit of calculated and experimental data. Thus, as a first approximation in the modeling of the process noise, tunnel-fixed stiffness and damping moments that may differ in both the X, Y and X, Z planes are assumed as shown in Eq. (39).
In the aeroballistic and body-fixed axis systems, the moments as given in Eq. (39) transform to

\[
\begin{align*}
\hat{M}_x &= M_y T \sin \psi \cos \theta - M_z T \sin \theta \\
\hat{M}_y &= M_y T \cos \psi \\
\hat{M}_z &= M_y T \sin \psi \sin \theta + M_z T \cos \theta \\
M_x &= M_y T \sin \psi \cos \theta - M_z T \sin \theta \\
M_y &= M_y T \cos \psi \cos \phi + (M_y T \sin \psi \sin \theta + M_z T \cos \theta) \sin \phi \\
M_z &= -M_y T \cos \psi \sin \phi + (M_y T \sin \psi \sin \theta + M_z T \cos \theta) \cos \phi
\end{align*}
\]

Thus, tunnel-fixed flow effects as described by Eq. (39) may be extracted from 3DOF data using the symmetric or asymmetric programs by including the moment expansions as given in Eqs. (40) and (41), respectively. In the presence of other unknown process noise, it is not possible to extract the coefficients \( t_1, t_2, t_3, \) and \( t_4 \) and the linear aerodynamic damping and pitching-moment coefficients simultaneously from 3DOF data. This is due to the overspecification of the linear stiffness and damping effects in the moment expansions. This may be shown by considering the linear stiffness terms for moments about the \( y \) axis in the body-axis system. A parallel derivation may be shown for the damping terms. If one substitutes Eq. (39) into Eq. (41), neglecting terms involving \( \sin \phi \sin \theta \), and uses the results of Eq. (14), Eq. (42) results, as follows:

\[
\begin{align*}
C_m &= t_1 \theta \cos \psi \cos \phi + t_3 \psi \cos \theta \sin \phi \\
&\quad + a_{m1} (\sin \psi \sin \phi + \cos \psi \sin \theta \cos \phi) + \ldots
\end{align*}
\]

If one expands terms involving \( \psi \) and \( \theta \) in Eq. (42) and rearranges, Eq. (42) reduces to

\[
\begin{align*}
C_m &= (t_1 + a_{m1}) \theta \cos \phi + (t_3 + a_{m1}) \psi \sin \phi + \ldots
\end{align*}
\]

Examination of Eq. (43) shows that the coefficients \( a_{m1}, t_1, \) and \( t_3 \) for small angular motion are not independent. Thus, only two of the three parameters \( (a_{m1}, t_1, \) and \( t_3 \) can be extracted from 3DOF data simultaneously. Attempts at extracting all three coefficients will lead to divergence of the iteration scheme in the parameter extraction.
technique. As stated previously, similar constraints on the stiffness and damping coefficients in the aeroballistic axis system and on the damping coefficients in the body-fixed axis system may be shown to apply.

In addition to the tunnel-fixed stiffness and damping effects, constant bias in the measured pitch and yaw displacements may also be present. These can be caused by imprecise alignment of the zero yaw/pitch axes with respect to the tunnel-fixed axis and/or flow nonuniformities causing tunnel-fixed trim moments. This effect has been included in the form of artificial flow angularity corrections in the pitch and yaw planes ($\theta_T$ and $\psi_1$, respectively).

The asymmetric parameter identification program presented in Table 2 was employed to extract the tunnel-fixed process noise (as described above) from the sharp cone data (Fig. 19). Results of the analysis are shown in Table 7. As indicated in the table, only the tunnel-fixed process noise, $I_{zz}$, $C_{k0}$, and the boundary conditions were allowed to vary. Due to the constraints on the tunnel-fixed process noise, the model aerodynamics were fixed at theoretical estimates given previously. The calculated solution, residuals, and fit of the computed solution to the experimental data are shown in Figs. 22 and 23 for two data sample periods.

Analysis of the results presented in Table 7 indicates the existence of tunnel stiffness effects in both the pitch and yaw planes. In addition, a small product of inertia was extracted from the data. Tunnel-fixed damping effects were also extracted, indicating decreasing magnitudes for increasing data sample intervals. This effect may be caused by higher order coefficients in the tunnel-fixed damping terms. Examination of Fig. 22 shows excellent fit of the computed to the experimental data with residuals in $\theta$ and $\psi$ bounded by $\pm0.1$ deg. The best fit of the experimental data to the calculated solution is bounded by the measurement errors caused by the gas bearing as discussed in Section 5.2. Doubling of the data sample interval as shown in Fig. 23 resulted in larger residuals with a dominate frequency approximately the same as the fundamental frequency of the experimental data (compare Figs. 23c and d with Figs. 19a and b, respectively). This is most probably an effect of frequency mismatch caused by higher order terms not included in the tunnel stiffness model, Eq. (39). Considering the results given in Table 7 and depicted in Figs. 22 and 23, the fit of the calculated 3DOF solution to the experimental sharp cone data is significantly improved over that given in Fig. 21. Thus, tunnel-fixed process noise governed by Eq. (39) and $I_{zz}$ appear to be valid contributions to the parameters to be evaluated.

In order to further evaluate the tunnel-fixed process noise and the ability of the asymmetric program to extract model aerodynamics in the presence of this process noise,
the sphere cone data as shown in Fig. 20 were analyzed. Using the asymmetric program, aerodynamic moment coefficients and tunnel-fixed process noise were extracted from the data as given in Fig. 20 and are shown in Table 8. Since model aerodynamic coefficients were allowed to vary, one damping and one stiffness coefficient describing the tunnel-fixed effects were held constant. Considering the RMS deviations and values of $t_1$, $t_2$, $t_3$, and $t_4$ as given in Table 7, the stiffness term, $t_1$, and damping term, $t_2$, were assumed constant and equal to 0.017 1/rad and 0, respectively. Examination of Table 8 shows large variations in the extracted aerodynamic coefficients for different data sample intervals. Moreover, since the sphere cone is axially symmetric, the relationship given in Eq. (16) should hold. As the data sample interval increases in Table 8, the extracted coefficients tend to become less like those caused by an axisymmetric body. These effects are further illustrated by comparison of the graphical results in Figs. 24, 25, and 26 which correspond to this table. Thus, in addition to those sources of process noise described here, others must exist which cause the significant disagreement in the generated solution and experimental data. Even though the preceding analysis of the sphere cone data as given in Fig. 20 does not yield acceptable extracted aerodynamic coefficients, it does indicate some problem areas encountered in the analysis of 3DOF data taken in continuous wind tunnels as well as concepts for establishing process noise models.

6.0 CONCLUDING REMARKS

The previous sections have presented the mathematical development of coefficient extraction programs and practical application of the programs in continuous wind tunnel flow fields. The programs developed here are based on the principals governing output error methods. As such, extracted parameters are highly sensitive to measurement and process noise. Thus, identification of sources of both process and measurement noise and modeling of these effects were extensively examined.

Noise attributable to the gas bearing, tunnel flow nonuniformities, and inappropriate aerodynamic modeling was categorized as being the most important. Measurement noise caused by the gas bearing was shown to contribute errors in $\psi$ and $\theta$ measurements up to $\pm 0.1$ deg with the magnitude of these errors dependent upon the value of $\psi$, $\theta$, and $\phi$ and the gas bearing pressure. In addition, small, bearing-induced moments were also identified. Even though the magnitude of the bearing-induced errors can be large, it was concluded that these errors for most situations could be modeled as random noise. This allows for accurate parameter identification, assuming sufficiently large data samples and no other noise sources.

In order to define the effects of process noise on the extracted coefficients, sharp and spherically blunted cone data taken in Tunnel A were analyzed.
It was shown that the process noise inherent in the sharp cone and sphere cone data was large and could not be treated satisfactorily as linear, tunnel-fixed stiffness and damping moments independent of the model configuration. In addition, this process noise was of sufficient level to cause significant error in the extracted coefficients. The analysis of the sharp cone and sphere cone data did provide, however, concepts for establishing process noise models in similar situations. Further studies are planned on the definition of process noise in Tunnel A and on the effects of these noise sources on extracted aerodynamic coefficients. Also, more work is planned on the application methods of the programs developed herein.

### Table 3. Subroutine Descriptions for Both Asymmetric and Symmetric Programs

<table>
<thead>
<tr>
<th>Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>NOISE</td>
<td>Adds noise to generated 3DOF motion or to experimental 3DOF motion data. Input values to the subroutine specify the standard deviation and bias to be added to $\phi_m$, $\gamma_m$, $\psi_m$.</td>
</tr>
<tr>
<td>RANDU</td>
<td>Random number generator.</td>
</tr>
<tr>
<td>GAUSS</td>
<td>Gaussian noise evaluated.</td>
</tr>
<tr>
<td>ICS</td>
<td>Computes approximate boundary conditions from the input 3DOF data to be used in place of initial guesses.</td>
</tr>
<tr>
<td>PART</td>
<td>Alters data set to be used in extraction technique.</td>
</tr>
<tr>
<td>DRKGS</td>
<td>Runge–Kutta fourth-order integration scheme for NDIM simultaneous differential equations.</td>
</tr>
<tr>
<td>DUM</td>
<td>Equivalent to the Kroneker–Delta function.</td>
</tr>
<tr>
<td>INV</td>
<td>Provides solution to a set of simultaneous linear equations. Also used to define inverse of a matrix.</td>
</tr>
<tr>
<td>INTGRL</td>
<td>Calling subprogram for integration of parametric, kinematic, and dynamic equations. Evaluates influence coefficient matrix, residual influence matrix, and total residual.</td>
</tr>
<tr>
<td>MBARA</td>
<td>Defines the values of the partial derivatives of the moment coefficients with respect to the parameters.</td>
</tr>
<tr>
<td>MBAR</td>
<td>Defines the moment coefficients.</td>
</tr>
<tr>
<td>TEMP</td>
<td>Defines variables required in moment coefficients and derivatives of moments with respect to the parameters.</td>
</tr>
<tr>
<td>FCT</td>
<td>Values of derivatives as used in DRKGS.</td>
</tr>
<tr>
<td>REGOUT</td>
<td>Conversion of parameters to output form.</td>
</tr>
<tr>
<td>REG</td>
<td>Conversion of input parameters to internal code dimensions.</td>
</tr>
</tbody>
</table>
Table 4. Input Variable Definitions for Symmetric and Asymmetric Programs

a. Namelist Input Common to Both Symmetric and Asymmetric Programs for Namelist/NAM/

<table>
<thead>
<tr>
<th>Namelist Variable</th>
<th>Type</th>
<th>Input Values</th>
<th>Meaning</th>
<th>Units</th>
</tr>
</thead>
<tbody>
<tr>
<td>NSWTCH</td>
<td>Integer</td>
<td>0, 1, 2</td>
<td>Switch indicating type of analysis: = 0, normal data reduction by Chapman-Kirk method as outlined in Section 3.2; = -1, 3DOF data generated from initial values of coefficients; = -2, 3DOF data generated and stored on disk for later analysis.</td>
<td></td>
</tr>
<tr>
<td>NTOT</td>
<td>Integer</td>
<td>1,000</td>
<td>Maximum array size of input and output variables: time, ( \phi ), ( \theta ), ( \psi ).</td>
<td></td>
</tr>
<tr>
<td>NC</td>
<td>Integer</td>
<td>30 symmetric</td>
<td>Maximum number of coefficients allowed to vary.</td>
<td></td>
</tr>
<tr>
<td></td>
<td></td>
<td>72 asymmetric</td>
<td></td>
<td></td>

<sup>b</sup>As used here, $\delta$ is defined as $\delta = \sqrt{a^2 + \beta^2}$.

<sup>c</sup>These coefficients define the effects of tunnel flow nonuniformities on the body motion and are discussed in Section 5.3.

<sup>d</sup>This coefficient is a roll torque produced by the gas bearing and is discussed in Section 5.2.

APPENDIX A
MATHEMATICAL DEVELOPMENT: ASYMMETRIC VERSION

The parameter identification technique as developed in Section 3.0 considered the 3DOF motion of axially symmetric bodies. In order to provide the greatest versatility in the improved analysis technique as developed in this report, an analogous version considering asymmetric bodies has been formulated. The asymmetric analysis considers the 3DOF motion of bodies with mirror plane symmetry about the x, z plane (see Fig. 1). The governing equations as derived from Eqs. (1) and (2) in the body-fixed coordinate system are

\[ J\dot{\theta} = \bar{M}_z + \bar{M}_x J_z - pq (I_x - J_x J_z) - qr (1 + I_x') J_z \]
\[ \dot{q} = \bar{M}_y - (p^2 - r^2) J_y - rp I_y' \]
\[ J\dot{\phi} = \bar{M}_x + \bar{M}_z J_x - qr (J_x J_z + I_x') + pq (1 - I_x') J_x \]

where the following definitions have been used

\[ J_x = I_{xx}/I_x \quad \quad \quad I_x' = (I_x - I_x)/I_x \]
\[ J_y = I_{yy}/I_y \quad \quad \quad I_y' = (I_y - I_y)/I_y \]
\[ J_z = I_{zz}/I_z \quad \quad \quad I_z' = (I_z - I_z)/I_z \]
\[ J = 1 - J_x J_z \]

with \( \bar{M}_x = M_x/I_x, \bar{M}_y = M_y/I_y, \) and \( \bar{M}_z = M_z/I_z. \)

The kinematic relations relating the Euler angles to the body-fixed angular rates are given in Eq. (A-3).

\[ \dot{\phi} = p - \tan \theta (q \sin \phi - r \cos \phi) \]
\[ \dot{q} = q \cos \phi - r \sin \phi \]
\[ \dot{\phi} = (r \cos \phi + q \sin \phi) / \cos \theta \]

Integration of Eqs. (A-1) and (A-3) yields the 3DOF angular motion solution for an asymmetric body assuming that the moment expansions as functions of the Euler angles and angular rates are given. For mirror symmetry about the x, z plane in the body-fixed axis system, the moment coefficient expansions in terms of \( \alpha \) and \( \beta \) as given in Eqs. (11) and (14) are utilized. The variables \( \alpha \) and \( \beta \) are, however, re-evaluated in the body-fixed axis system leading to Eq. (A-4).
The parameter extraction method as discussed in Section 3.2 is applied in an analogous manner to the asymmetric analysis. The parametric differential equations required to evaluate the influence coefficients as used in Eq. (21) are derived from Eqs. (A-1) and (A-3) and are shown in Eq. (A-5).

\[
\begin{align*}
\dot{p}_{1i} &= Q_{1i} + P_{2i} \sec^2 \theta (q \sin \phi + r \cos \phi) \\
&\quad + \tan \theta (\theta_2 i \sin \phi + P_{1i} \quad q \cos \phi + Q_{3i} \cos \phi \\
&\quad - P_{1i} \quad r \sin \phi) \\
\dot{p}_{2i} &= Q_{2i} \cos \phi - P_{1i} \quad q \sin \phi - Q_{3i} \sin \phi - P_{1i} \quad r \cos \phi \\
\dot{P}_{3i} &= (Q_{3i} \cos \phi - P_{1i} \quad r \sin \phi + Q_{2i} \sin \phi + P_{1i} \quad q \cos \phi) \sec \theta \\
&\quad + (r \cos \phi + q \sin \phi) P_{2i} \tan \theta \sec \theta \\
J\dot{Q}_{1i} &= M_{1i} - M_{3i} J_x - (J_x J_x + I'_x) (q Q_{3i} - r Q_{2i}) \\
&\quad + (1 - I'_x) J_x (P_{2i} + q Q_{1i}) \\
\dot{Q}_{2i} &= M_{2i} - J_y (2 p Q_{1i} - 2 r Q_{3i}) - I'_y (r Q_{1i} + p Q_{3i}) \\
J\dot{Q}_{3i} &= M_{3i} + M_{1i} J_x - (I'_x - J_x J_x) (p Q_{2i} + q Q_{1i}) \\
&\quad - (1 + I'_x) J_x (q Q_{3i} - r Q_{2i})
\end{align*}
\]

where \( P_{1i}, P_{2i}, P_{3i}, M_{1i}, \) and \( M_{2i}, \) and \( M_{3i} \) are defined as before and \( Q_{1i} = \partial p / \partial a_i, \)
\( Q_{2i} = \partial q / \partial a_i, \) \( Q_{3i} = \partial r / \partial a_i. \) The initial conditions for the parametric, kinematic, and dynamic equations as given in Eqs. (A-1), (A-3), and (A-5) are listed below.

\[
\begin{align*}
\phi(0) &= a_{N_c-5} \\
\theta(0) &= a_{N_c-4} \\
\psi(0) &= a_{N_c-3} \\
p(0) &= a_{N_c-2} \\
q(0) &= a_{N_c-1} \\
r(0) &= a_{N_c}
\end{align*}
\]
\[ P_{1i}(0) = \delta_{N_{c} - 5, i}, \quad Q_{1i}(0) = \delta_{N_{c} - 2, i}, \]
\[ P_{2i}(0) = \delta_{N_{c} - 4, i}, \quad Q_{2i}(0) = \delta_{N_{c} - 1, i}, \quad (A-7) \]
\[ P_{3i}(0) = \delta_{N_{c} - 3, i}, \quad Q_{3i}(0) = \delta_{N_{c}, i}. \]

Integration of the parametric and angular motion equations and evaluation of the corrections to the parameters, \( a_{i} \), are determined in a manner similar to that discussed in Section 3.2 for the axially symmetric analysis.

In addition to the moment coefficients as given in Eq. (14) and the boundary conditions, the product of inertia, \( I_{zx} \), has also been included in the list of parameters, \( a_{i} \), to be determined. This option was provided in order to circumvent the lack of simple techniques for determining the product of inertia for asymmetric configurations. In Ref. 21, values of \( I_{zx} \) as large as 6 percent of \( I_{y} \) have been extracted successfully from generated motion with measurement noise.
NOMENCLATURE

\( a_i \)  
Aerodynamic coefficients to be extracted, see Section 3.2

\( a_{i0}, a_{i1}, \ldots \)  
Taylor series expansion coefficients as used in Eqs. (12), (14), and (16) \((i = 1, m, n)\)

\( B_i \)  
Diagonal components of the inverse matrix of \( C_{ij} \).

\( b_{i0}, b_{i1}, \ldots \)  
Taylor series expansion coefficients as used in Eqs. (12), (14), and (16) \((i = 1, m, n)\)

\( C_{ij} \)  
\( N_c \times N_c \) matrix of influence coefficients, Eq. (24)

\( C_{lg} \)  
Rolling-moment coefficient, Eq. (7)

\( C_{lq} \)  
Trim roll torque coefficient, see Eq. (16)

\( C_{lp} \)  
\( \partial C_{lg} / \partial (dp/2U_\infty), \text{ 1/rad} \)

\( C_{lq} \)  
\( \partial C_{lg} / \partial (dq/2U_\infty), \text{ 1/rad} \)

\( C_{lr} \)  
\( \partial C_{lg} / \partial (dr/2U_\infty), \text{ 1/rad} \)

\( C_{la} \)  
\( \partial C_{lg} / \partial (d\alpha/2U_\infty), \text{ 1/rad} \)

\( C_{l\delta} \)  
\( \partial C_{lg} / \partial (d\delta/2U_\infty), \text{ 1/rad} \)

\( C_{l\beta} \)  
\( \partial C_{lg} / \partial (d\beta/2U_\infty), \text{ 1/rad} \)

\( C_m \)  
Pitching-moment coefficient, Eq. (7)

\( C_{mp} \)  
\( \partial C_m / \partial (dp/2U_\infty), \text{ 1/rad} \)

\( C_{mq} \)  
\( \partial C_m / \partial (dq/2U_\infty), \text{ 1/rad} \)

\( C_{mq\delta^2} \)  
\( \partial C_m / \partial (dq\delta^2/2U_\infty), \text{ 1/rad}^3 \)

\( C_{mr} \)  
\( \partial C_m / \partial (dr/2U_\infty), \text{ 1/rad} \)

\( C_m \alpha \)  
\( \partial C_m / \partial \alpha, \text{ 1/rad} \)

\( C_m \dot{\alpha} \)  
\( \partial C_m / \partial (d\dot{\alpha}/2U_\infty), \text{ 1/rad} \)

\( C_m \alpha \mid \alpha \mid \)  
\( \partial C_m / \partial \alpha \mid \alpha \mid, \text{ 1/rad}^2 \)
\( C_{m\alpha} \) \( C_m \alpha | \beta | \) \( \partial C_m / \partial \alpha | \beta |, \ 1/\text{rad}^2 \)
\( C_{m\alpha^2} \) \( \partial C_m / \partial \alpha^2, \ 1/\text{rad}^3 \)
\( C_{m\dot{\beta}} \) \( \partial C_m / \partial (\dot{\beta}/2U_\omega), \ 1/\text{rad} \)
\( C_n \) Yawing-moment coefficient, Eq. (7)
\( C_{np} \) \( \partial C_n / \partial (dp/2U_\omega), \ 1/\text{rad} \)
\( C_{nq} \) \( \partial C_n / \partial (dq/2U_\omega), \ 1/\text{rad} \)
\( C_{nr} \) \( \partial C_n / \partial (dr/2U_\omega), \ 1/\text{rad} \)
\( C_{na} \) \( \partial C_n / \partial (d\alpha/2U_\omega), \ 1/\text{rad} \)
\( C_{n\beta} \) \( \partial C_n / \partial \beta, \ 1/\text{rad} \)
\( C_{n\dot{\beta}} \) \( \partial C_n / \partial (\dot{\beta}/2U_\omega), \ 1/\text{rad} \)
\( C_{n\beta \alpha} \) \( \partial C_n / \partial \beta | \alpha |, \ 1/\text{rad}^2 \)
\( C_{n\beta \beta} \) \( \partial C_n / \partial \beta | \beta |, \ 1/\text{rad}^2 \)
\( c_{i0}, c_{i1}, \ldots \) Taylor series expansion coefficients as used in Eqs. (12), (14), and (16) \((i = 1, m, n)\)
\( D_j \) Residual influence matrix, Eq. (25)
\( d \) Reference length (base diameter), ft
\( d'_3, d'_4, d'_5 \) Coefficients as used in Eq. (16)
\( d_N \) Nose diameter, ft
\( E \) RMS deviation between experimental data and converged solution, rad
\( e_0 \) Trim roll coefficient, see Eq. (16)
\( e_1, e_2 \) Proportionality constants relating \( \dot{\alpha}, q \) and \( \dot{\beta}, r \)
\( f_{i0}, f_{i1}, \ldots \) Taylor series expansion coefficients as used in Eqs. (12), (14), and (16) \((i = 1, m, n)\)

RMS deviation in extracted coefficient \( a_i \)

\( \theta \)  
Pitch angle, see Fig. 2

\( \theta_c \)  
Cone semiangle

\( \theta_T \)  
Artificial tunnel-fixed flow angularity correction, pitch, deg

\( \theta_\ell \)  
Calculated pitch angle at time point \( \ell \), deg

\( \theta_\ell_0 \)  
Value of \( \theta_\ell \) for the given constants, \( a_i \), deg

\( \theta_m \ell \)  
Measured pitch angle at time point \( \ell \), deg

\( \sigma \)  
One standard deviation, Gaussian noise, deg

\( \sigma_\phi, \sigma_\theta, \sigma_\psi \)  
Standard deviation of relative uncertainty in \( \phi, \theta, \) and \( \psi \) measurement, respectively, deg

\( \tau \)  
Computer run time of codes, Eq. (31), sec

\( \phi \)  
Roll angle, deg

\( \phi_\ell \)  
Calculated roll angle at time point \( \ell \), deg

\( \phi_\ell_0 \)  
Value of \( \phi_\ell \) for the given constants, \( a_i \), deg

\( \phi_m \ell \)  
Measured roll angle at time point \( \ell \), deg

\( \psi \)  
Yaw angle, see Fig. 2, deg

\( \psi_T \)  
Artificial tunnel-fixed flow angularity correction, yaw, deg

\( \psi_\ell \)  
Calculated yaw angle at time point \( \ell \), deg

\( \psi_\ell_0 \)  
Value of \( \psi_\ell \) for the given constants, \( a_i \), deg

\( \psi_m \ell \)  
Measured yaw angle at time point \( \ell \), deg

\( \Omega \)  
Sting roll position as used in Eq. (36), deg
Coefficients in plane-fixed or aeroballistic axis system

\( \frac{d}{dt} \)

Initial value of coefficient

\( \text{o} \)
