PREFACE

One of the earliest and most traditional of the Coast Guard's functions is Search and Rescue (SAR). The SAR program objective, stated simply, is to minimize loss of life, injury and property damage by rendering aid to persons and property in distress on, over and under the high seas and waters under the jurisdiction of the United States.

This report addresses the design, testing and demonstration of a VHF-FM EPIRB which provides the functions necessary to provide quick and reliable distress alerting and locating with a minimum interference to other communications in the coastal maritime region. The primary result of this program consists of a recommended set of operating parameters for a VHF-FM EPIRB. These are:

1. An EPIRB output power of one watt will provide highly reliable reception at a range of 20 nautical miles.
2. The recommended EPIRB modulation consists of a two-tone FSK signal. The tones used are 1300 Hz and 2200 Hz. Each transmission consists of a short (1-2 second) burst of tones on Channel 16, followed by a longer (15 second) burst on Channel 15 after which the Channel 16 transmission repeats.
3. The EPIRB can be equipped to transmit low bit rate (eight bits per second) digital data on Channel 15. Such data transmission can be used to provide features such as user identification and nature of distress.

It is the author's belief that a VHF-FM EPIRB will be highly effective in reducing time of SAR alerting and location of recreational boats in distress. Further, evaluation of the available technology indicates that, the quantity of cost of such a device will be approximately \$100.00, and possibly less. Widespread use of such an EPIRB will make the marine environment a safer place in which to operate.

The authors of this report are Peter D. Engels and Charles J. Murphy of TSC and Howard Salwen of Proteon Associates, Inc.

1. INTRODUCTION

The U.S. Coast Guard in seeking improvements in search and rescue (SAR) capability seeks to (1) reduce the emergency notification (alerting) time for the commercial, military, and general boating public, and 2) provide the capability of detecting and locating the distress. Many areas addressing the SAR mission have been accomplished but insufficient detailed analysis has been done to provide a system approach integrating, in an inexpensive manner, distress alerting with position location. Presently the Coast Guard is actively pursuing the regulatory actions necessary to allow carriage of an Emergency Position Indicating Radio Beacon (EPIRB) compatible with the maritime VHF-FM system by ships and boats operating within the radio coverage of the National VHF-FM Distress System.

This report addresses the design, development and test of an EPIRB which provides the functions necessary to provide quick and reliable distress alerting with a minimum of interference to other VHF communications. In order to ensure this capability, the EPIRB possesses the following features:

- 1) Relatively high power output (1 watt) to ensure reception at shore stations within 20 nautical miles.
- 2) Transmission occurring sequentially on Channels 16 and 15. A short (1-2 second) burst of signal on Channel 16 is followed by a longer (10-15 second) burst on Channel 15.
- 3) A highly recognizable tone modulation consisting of the international distress tones at 1300 and 2200 hertz, alternating four times per second.
- 4) Provision for detection of simultaneous multiple EPIRBs. This capability is provided by terminating RF transmission following each sequence of Channel 16 and Channel 15 transmission, for a time equal to twice the total RF transmission time.
- 5) A flexible prototype design that allows for such desirable features as variable duty cycle, data transmission

for identification or distress situation encoding and automatic turn-off after a pre-set time.

In addition to the above EPIRB features, an automated EPIRB receiver was designed and built as part of this program. This receiver continuously monitors Channel 15. The Channel 15 signal is automatically detected and decoded so as to generate an alarm whenever the alert signal occurs.

The EPIRB itself is packaged in a manner similar to commercially available EPIRBS operating on 121.5/243 MHz. In particular, the EPIRB electronics and power supply can be mounted in a cylindrical container which is approximately 3 inches in diameter and 18 inches long. Furthermore, it is anticipated that the production costs of the VHF marine EPIRB will be comparable to that of the 121.5/243 MHz EPIRB since both systems can employ similar mechanical structures, antennas, VHF electronics, and battery power sources. One of the essential differences between the EPIRB discussed in this report and the existing EPIRBS is found in the modulation design. The objective of the modulation design effort for the EPIRB is to create a modulation format which provides audible alerting for the unsophisticated user and which provides growth potential for future systems which can employ completely automated digital signal processing techniques for distress alerting, vessel identification, direction finding, and homing.

The features provided in this EPIRB result in a design which can benefit from the latest integrated circuit technology. They may be added to, or deleted as desired in a simple fashion so as to optimize the trade-off of cost versus desired performance.

2. DESIGN CONSIDERATIONS

Certain factors are critical to the design of this EPIRB. In the intended mode of operation, it may be floating at the surface of the ocean, and must transmit a signal which can be reliably received at a shore station up to 20 nautical miles distant, which may have an antenna height of 200 feet or less. The critical parameters then become:

- a) Height of transmitting and receiving antennas
- b) Propagation characteristics
- c) Operating frequency and channel usage
- d) Type of signal modulation (and its resultant reception technique)
- e) The EPIRB antenna design

These will now be discussed in more detail.

2.1 ANTENNA HEIGHT

Since this system is essentially a line of sight communications system, reception range is primarily defined by geometric line of sight conditions. This condition is defined by the expression

$$d = (2h_t)^{1/2} + (2h_r)^{1/2} \quad (1) \quad (2-1)$$

d = distance in statute miles

h_t = transmit antenna height (ft.)

h_r = receive antenna height (ft.)

In the proposed system, we assume that the transmitting (EPIRB) antenna is located on the surface of the earth (or ocean) so that $h_t = 0$. Then

$$d = (2h_r)^{1/2} \quad (2-2)$$

Figure 2-1 shows this relationship. As seen from this figure, geometric line of sight, for a range of 20 nautical miles, requires an antenna height of approximately 265 feet.

Figure 2-2 is a plot which shows the height distribution of antennas at 171 Coast Guard shore stations.⁽³⁾ Although 70% are more than 250 feet high, 30% (52 stations total) are less than 250 feet in height. Although it is still possible for these stations to receive signals from a very low antenna height as a result of diffraction effects, increased signal attenuation will result, and there is a higher probability of poor (or no) signal reception.

2.2 PROPAGATION

The required EPIRB output power is determined by the minimum allowable received signal (receiver threshold), and by the signal attenuation. The signal attenuation within the line of sight range is a complex function of distance, frequency, antenna height and antenna aperture (gain). The problem may be analytically structured by considering reception in free space and reception close to the surface. A sufficiently tall receiving antenna can provide free space propagation conditions. When the receiving antenna is relatively close to the earth's surface however, ground or surface wave propagation conditions are dominant. Free space propagation is defined by:

$$\frac{P_r}{P_t} = \left(\frac{\lambda}{4\pi d}\right)^2 g_r g_t \quad (2-3)$$

or,

$$E_o = \frac{(30 g_t P_t)^{1/2}}{d} \quad (2-4)$$

g_r = receiving antenna gain
 g_t = transmit antenna gain
 λ = wave length
 d = distance
 P_r = received power
 P_t = transmit power

E_o = Received field intensity (volts/meter)

When ground wave propagation is the dominant mode, the signal is defined by (2)

$$\frac{P_r}{P_t} = \left(\frac{h_r h_t}{d^2}\right)^2 g_r g_t \quad (2-5)$$

h_r = receive antenna height
 h_t = transmit antenna height

h_1 = Approximate antenna height at Winthrop test site.

h_2 = Antenna height for 20 nm range.

FIGURE 2-1. ANTENNA HEIGHT VS. RANGE FOR TRANSMITTING ANTENNA ON SURFACE

FIGURE 2-2. HEIGHT DISTRIBUTION OF COAST GUARD SHORE STATIONS

Groundwave propagation predominates when both antenna heights are less than h_0 , where h_0 is a parameter called the minimum effective antenna height, and is a function of the surface dielectric constant and conductivity. At the frequency of interest (156.8 MHz), h_0 is 21.55 ft. for a vertically polarized antenna over sea water. When the antenna height is greater than h_0 , attenuation decreases by 6 db for every 2 h_0 increase in antenna height, until free space propagation conditions are reached.

By examination of equations (2-3) & (2-5), we see that there are two important facts about groundwave propagation:

- 1) The attenuation is independent of frequency,
- 2) Attenuation varies as the fourth power of distance.

Furthermore, for a given distance, one can equate the two expressions so as to calculate the antenna heights necessary to ensure free-space propagation conditions. The results of such a calculation are summarized in table 2-1, which shows the receiving antenna height necessary for free space propagation, given a transmit antenna height much less than h_0 (EPIRB on the sea surface).

TABLE 2-1 RECEIVING ANTENNA HEIGHT NECESSARY FOR FREE SPACE PROPAGATION

| DISTANCE (NAUT. MILES) | RECEIVE ANTENNA HEIGHT (FT) |
|------------------------|-----------------------------|
| 0.1 | 14.1 |
| 0.3 | 42.25 |
| 0.5 | 70.4 |
| 1.0 | 140.8 |
| 3.0 | 422.5 |
| 5.0 | 704.2 |
| 10.0 | 1408.3 |
| 20.0 | 2816.6 |
| 30.0 | 5225.0 |

These calculations lead to the following conclusions:

- 1) For the typical case of the EPIRB in or near the water, and a small Coast Guard cutter homing on the EPIRB, the level of the received signal at the cutter is determined by ground wave propagation conditions.
- 2) Although there are nearly 200 Coast Guard shore stations,

only nine have antenna heights greater than 3000 ft., and will provide at least 20 nautical mile range with free-space propagation. The receiving range of the other stations must be calculated individually, assuming groundwave propagation.

3) Search aircraft reception range will, in general, be determined by free space attenuation.

Figure 2-3 graphically depicts the relationship between receiving antenna height, range and the resultant signal attenuation.

We will now calculate the signal level necessary for direction finder operation. A typical good quality direction finder requires a field intensity of 5 microvolts/meter. Assuming a half wave dipole receiving antenna, the antenna aperture is:

$$A = \frac{1.64\lambda^2}{4\pi} \quad (2-6)$$

and the received power on the receiver is

$$P_r = \frac{E_o^2 A}{120 \pi} \quad (2-7)$$

$$P_r = -105 \text{ dBm}$$

E_o = field intensity at the receiver antenna.

For any given transmitter output, now calculate the total loss which will result in a signal level of -105 dBm (assuming an isotropic transmit antenna, and a half-wave dipole receiving antenna). This is shown in Table 2-2.

TABLE 2-2. TOTAL LOSS RESULTING IN A SIGNAL LEVEL OF -105 dBm

| TRANSMIT POWER | TOTAL LOSS TO RECEIVE -105 dBm |
|----------------|-----------------------------------|
| 5 watts | -144 dB |
| 3 watts | -142 dB |
| 2 watts | -140 dB |
| 1 watt | -137 dB |
| 500 mw | -134 dB |
| 300 mw | -132 dB |
| 200 mw | -130 dB |
| 100 mw | -127 dB |

FIGURE 2-3. SURFACE WAVE PROPAGATION

This information can be combined with Figure 2-3 to determine the necessary EPIRB transmitter power. For example, assume that a given Coast Guard station has an antenna height of 400 feet, what EPIRB power is required to give a range of 20 miles? Figure 2-3 says that for these conditions, the attenuation will be less than -126 dB so that 100 mw will be sufficient. However, a conservative calculation must assume additional loss in the system. Typically the system should operate 10 dB above threshold, with an allowance of 6 dB for signal fluctuation due to sea effects. This equates to an EPIRB power of 1 watt.

The surface wave analysis presented so far is based on a smooth plane earth model. Strictly speaking therefore, this analysis is only valid under geometric line-of-sight conditions. In order to calculate signal levels anticipated beyond the horizon, the analysis must be modified to consider a spherical earth. In addition, the effects of surface roughness, due to varying sea state, should also be considered. This analysis was performed by GTE Sylvania Communications Systems Division, under contract to TSC. The details of the analysis are included in Appendix A, together with computer drawn curves of field strength versus distance and sea state. The computer program will also generate printouts of signal level at discrete ranges and sea states, with antenna height also a parameter.

A summary of the predicted signal level is presented in Table 2-3. For this data, range was held constant at 21.6 nautical miles, which is the (approximate) maximum range anticipated for EPIRB reception. The data agrees within 1dB, with the level predicted from Figure 2-2 out to the geometric horizon; Figure 2-2 does not apply beyond this point. The pertinent facts from Table 2-3 are as follows:

- 1) Sea State does not significantly affect the received signal until the range begins to approach the geometric horizon or seas become quite large.
- 2) The most important factor in maximizing received signal is antenna height.

TABLE 2-3. PREDICTED SIGNAL LEVEL AS A FUNCTION OF ANTENNA HEIGHT AND SEA STATE

| Receiver Antenna Height | Sea State 0 | Sea State 1 | Sea State 2 | Sea State 3 | Sea State 6 | Sea State 9 | Fresh Water Sea State 0 |
|-------------------------|-------------|-------------|-------------|-------------|-------------|-------------|-------------------------|
| 0 | -125dBm | -126.3 dBm | -127.6 dBm | -128.8 dBm | -131.8 dBm | -134.1 dBm | -140.5 dBm |
| 100 meters (328 ft.) | -101 dBm | -101.7 dBm | -102.3 dBm | -102.8 dBm | -104.2 dBm | -105.3 dBm | -108.3 dBm |
| 300 meters (984 ft.) | -83.4 dBm | -84.1 dBm | -84.6 dBm | -85.2 dBm | -88.0 dBm | -89.1 dBm | -95.0 dBm |
| 3048 meters (10,000 ft) | -76.3 dBm | -76.3 dBm | -76.3 dBm | -76.3 dBm | -76.3 dBm | -76.3 dBm | -76.3 dBm |

- 3) Antennas of 100 meters, or more, in height should provide satisfactory reception at a range of 20 nautical miles.
- 4) The present design may be marginal in fresh water areas, e.g., The Great Lakes, unless antenna heights are 200-300 meters (alternately, craft operating in the Great Lakes could be equipped with a special, higher-power EPIRB).

2.3 CHANNEL SELECTION

The primary EPIRB operating frequency will be channel 16 (156.8MHz) which is reserved as the distress, safety and calling frequency for maritime mobile VHF-FM radio telephone service. Ships licensed to transmit in the VHF-FM marine band are required to monitor channel 16 when in service. Similarly, the USCG monitors channel 16 for maritime safety and distress communications in the coastal zone. Thus, in the event of an emergency it is possible that a nearby vessel (private, commercial, or government) may hear the distress transmission on channel 16. The basic system concept assumes periodic transmission of a short alerting audible signal on channel 16. Unfortunately, the requirements of the EPIRB operation and the normal operation of channel 16 are not compatible. Specifically, during heavy traffic density periods the range of the EPIRB would be severely limited by the existence of simultaneous transmissions on channel 16 from ship or shore located transmitters which have higher power outputs and more advantageous antenna mounting configurations. The presence of co-channel interference is a significant problem in any FM communications system. The so-called "FM" capture effect results in a weak signal being suppressed by any stronger signal that appears in the receiver pass band. Since nearly all the VHF-FM radio-telephones presently in use transmit at the legal maximum output power of 25 watts, an EPIRB with only one watt output operates at a significant power disadvantage when there is substantial co-channel traffic. This affect can only be lessened in impact by either using a linear demodulation system (such as a phase-locked demodulator) or by use of a modulation-demodulation scheme that is designed to minimize

interference effects (such as spread spectrum). Such techniques result in complex and expensive receiver designs. On the other hand, given that the channel 16 EPIRB transmission is adequately heard by a number of vessels, the presence of the transmission would preempt the use of channel 16 for calling purposes and other distress and safety traffic. As will be discussed below, direction finding and homing equipment will require longer periods of transmission than those required for audible alerting purposes. Therefore, it is proposed that the EPIRB should transmit, alternately, first on channel 16 then automatically switch to channel 15 which would be reserved for EPIRB use. The transmission on channel 15 is proposed to be of longer duration than that on channel 16. The longer duration transmission on channel 15 allows time for the communication of status data, identification codes or a distress message, as desired.

2.4 SIGNAL MODULATION

A variety of modulation waveforms were considered for this system. These included the following:

- 1) Swept frequency tones, such as that used by 121.5/243 MHz EPIRBS.
- 2) Single-frequency tones
- 3) Multiple alternating tones
- 4) Spread spectrum

The criteria for selection were as follows:

- 1) Audibility to a human listener when detected by a conventional FM receiver.
- 2) Detectability in the presence of co-channel interference and background noise
- 3) Feasibility of automated detection.

All the tone modulation systems examined were found to be highly audible with simple discriminator-type demodulation. Both the swept-frequency tone and the multiple alternating tone system are clearly audible and quickly identifiable to the human listener.

Spread spectrum modulation however cannot be demodulated by the narrow-band IF/discriminator demodulation technique found in all commercial FM receivers, as in general the bandwidth of the spread spectrum modulated carrier will extend well beyond the IF filter skirts. Consequently, a majority of the signal energy will be outside the discriminator bandwidth. In addition the nature of the spread spectrum modulation is such that correct demodulation by conventional receivers is impossible. Therefore, when an EPIRB transmits a spread spectrum signal, no one would be aware of the signal unless they were equipped with a special purpose receiver. Since it is considered essential that any VHF-FM equipped craft that is within range of the distress be able to hear the distress signal, spread spectrum techniques were considered unsuitable for EPIRB use.

In any distress alert system, the desirability of an automated reception system is self-evident. Such a system must operate 24 hours a day, seven days a week, with the utmost of reliability. By incorporating an automatic alarm in the system, triggered by the presence of the EPIRB modulation, we eliminate the requirement for multiple additional personnel to monitor the receiver audio output. In looking at the modulation techniques listed at the beginning of this section, the following conclusions were reached:

- 1) A swept frequency audio tone does not lend itself to an automated monitor without extremely tight specifications on tone frequency variation, period of variation, linearity, etc. These specifications will be difficult to achieve and maintain over the range of operational conditions expected of the EPIRB.
- 2) Single frequency tones are extremely easy to detect - however, with a single tone, the possibility of false alarms due to spurious modulation components is significant.
- 3) Multiple single frequency tone systems are therefore considered to be the logical choice. In particular we have chosen a waveform which consists of two tones, 1300 Hz

and 2200 Hz, alternating four times per second. This waveform is simple to detect, is highly audible under all conditions, and minimizes spurious false alarm problems.

The choice of specific tone frequencies at 1300 Hz and 2200 Hz was made partly on the basis that this waveform is already in use as an international distress waveform--indeed, some ships already carry automated monitor equipment for this waveform. Therefore, this choice is quite rational, in that these frequencies are already used for distress alerting and the choice both maximizes system acceptability and minimizes the proliferation of different distress alerting systems.

2.5 EPIRB ANTENNA CONSIDERATIONS

The provision of a well-matched, efficient transmit antenna, with good radiation characteristics at very low elevation angles is critical to proper EPIRB signal reception. With these requirements, some form of vertically polarized antenna is essential. Thus, the classic antenna which has been used for this application is either a 1/2 wavelength dipole, or (to minimize length) a 1/4 wavelength antenna with a suitable ground plane. It should be noted that the presence of a ground plane, either as part of the antenna structure or in the form of sea water will inevitably tilt the radiation pattern up about 10° away from the local horizon; this can sometimes be alleviated by an angled ground plane.⁽⁷⁾

In addition to the requirements listed above, the present application imposes a new set of operating constraints: the EPIRB antenna must perform well under three separate conditions --

- 1) When floating free near a distress vessel - where the liquid medium is sea water.
- 2) Hand held, or otherwise mounted on the deck (or higher) of a distressed vessel.
- 3) When floating free in a fresh water medium - a situation typical of the Great Lakes. Although a 1/4 wavelength antenna will function well in condition (1), where sea

water, because of its high conductivity, provides an excellent ground plane, in either of the other two situations its performance will deteriorate substantially.

Since fresh water is a poor conductor of electricity and hence a poor ground plane, both conditions 2 and 3 will result in a degraded signal if a $1/4$ wavelength antenna is used. The actual antenna performance is difficult to quantify, as performance is very much dependent on the specific location. Nevertheless, we know that in general the antenna efficiency will decrease because of variation in the antenna impedance, and its main lobe may tilt upwards in poor signal at low elevation angles.

These considerations dictate that some other antenna design is essential for adequate performance. Specifically, the chosen antenna must meet the following criteria:

- 1) No ground plane and well decoupled from its physical surroundings.
- 2) High efficiency and simple impedance match.
- 3) Good radiation characteristics at low elevation angles.

Several designs were evaluated in a search for the ideal EPIRB antenna. The basic approach is to make the antenna appear to the outside world as a half-wave dipole isolated from its surroundings. Such an antenna does not require a ground plane, has a known, fixed impedance value, and provides a pattern with good coverage at low angles.

The antenna design which would ordinarily be specified, in view of the previous discussion, is a coaxial center-fed half-wave dipole incorporating a shorted, quarter-wave section as a choke to prevent current flow down the feed cable and thus isolate the antenna from its environment. The chief drawback of this approach for our application is its complexity and cost.

An extremely simple and inexpensive approximation to this design, widely-used in the amateur radio community, was chosen as the EPIRB antenna.^(5,6) This is the so-called "J" antenna which

consists of a half-wavelength rod attached to a shorted quarterwave section of two-wire line. Fig. 2-4 illustrates the arrangement and shows the "J" shape of the conductors. The antenna is fed by tapping into the shorted quarter-wavelength section at the 50 ohm point. In commercial antennas the connection is made by attaching inner and outer conductors of a coaxial cable to the two-wire line; in an integrated EPIRB design a balanced (two-wire) feed could be preferable and even less expensive.

The operation of the antenna is straightforward, although a little unusual. The dipole is fed from the base at point "A" in figure 2-4 current flow down the antenna along the feed cable which could interact with water or surrounding structures and cause impedance and pattern variations is suppressed by the choke, which at point "A" presents an open-circuit to such currents. The resulting radiation pattern is that of a half-wave dipole.

The primary drawback of the J antenna is its physical length. An antenna length of $3/4$ wavelength at 156 MHz is 1.4 meters or 4.7 feet. Although much of the matching section could be packaged inside the EPIRB, the antenna length is still over 3 feet, resulting in a rather cumbersome design. Further decrease in antenna length may be possible by loading the antenna, either with a disc-shaped hat, or with a small helical structure.⁽⁸⁾ In both instances, the effect is to make a physically short antenna into one with greater electrical length. Further investigation of this technique was considered beyond the scope of this task and therefore was not pursued.

2.6 DURATION OF TRANSMISSION

As discussed in section 2.4, it was decided to adopt the 1300/2200 Hz two-frequency scheme for the EPIRB because 1) this audible tone scheme has international recognition as a distress call, 2) some vessels are currently equipped with automated detection equipment for this tone signaling pair, 3) the signal has good audible detection characteristics under high noise conditions, 4) the signal format is compatible with the requirements of automated detection systems.

The two tones, 1300 Hz and 2200 Hz, will be alternately transmitted for one quarter second each. Clearly, the minimum duration transmission would consist of one transmission of each of the tone frequencies. This takes one-half second. In order to determine the optimum Channel 16 transmission time (defined as the minimum necessary for reliable alert), a subjective listening evaluation was conducted. Specifically, the channel 16 sequence consisting of 1300 Hz and 2200 Hz tones of 1/4 second duration was generated and corrupted by additive white gaussian noise. This implementation represents the output of a receiver when it is deep in the threshold region. The duration of the channel 16 transmission pattern was varied from 1/2 second to 3 seconds. The noise was increased to a point where the channel 16 message was barely audible. The detectability of the channel 16 signals at various lengths was compared by several listeners. It was found after numerous trials that detectability was degraded due to the shortness of the message when message duration was less than 2 seconds. On the other hand, it was found that increasing the message duration beyond 2 seconds did not significantly enhance detectability. This test was repeated, using Coast Guard watch standees as listeners, with identical results. It was therefore concluded that a 2 second transmission on channel 16 is probably optimum.

The transmission duration on channel 15 is not constrained by audible detection characteristics. Instead, the transmission duration must be sufficient to meet the operational requirements of direction finding and homing equipment and to provide the transmission of a vessel identification code and a distress message code.

It is anticipated that approximately 10 million independent vessel identification codes may be required by the system. Given that BCD coding of the vessel identification number is used, 28 data bits provides the capability for defining 10 million independent vessel address codes. The same addressing capability can be achieved with 24 bits of binary coding data. Thus for the purposes of design analysis, it is assumed that adequate addressing capability can be provided by 28 data bits.

The distress message code is substantially shorter. For example, the EPIRB could provide for the transmission of fire, sinking, medical emergency and disabled but not immediately in danger. The minimum number of bits for four possible distress codes is two. However, it is reasonable to employ redundancy in this portion of the distress message to enhance the reliability of detection. For this reason, it is assumed that 12 bits will be employed to transmit one of four possible distress messages.

Thus, it appears that 40 bits of data transmission capability is adequate for present and future system applications. The actual EPIRB transmission will consist of more than 40 bits because a preamble bit sequence is required in order to provide for reliable signal detection, bit synchronization, and start-of-message indication. The preamble bit sequence must be long enough to provide a high probability of detection and sufficiently accurate bit synchronization. The system design effort must determine the distress message bit rate and the required length of the preamble bit sequence. This, along with direction finding and homing constraints, will determine the duration of transmission on channel 15.

Communication with manufacturers of automatic direction finding equipment (ADF) and with USCG personnel who are familiar with the operation of ADF equipment indicates that the transmission of a signal for 2 or 3 seconds is adequate for direction finding purposes. However, when the signal is deeply buried in noise additional time should be provided to enhance distress message recognition by operating personnel. Thus, for the purpose of design analysis it is assumed that direction finding will require transmission on channel 15 for durations in excess of 5 seconds. Homing systems require much longer transmission durations. For example, it may take several minutes to orient a homer equipped vessel in the direction of a distress message when operating in rough seas and/or restricted channels. However, the EPIRB cannot transmit for such long durations and meet the constraints imposed by battery limitation and multiple EPIRB operational considerations. It is possible to operate the homing equipment while transmitting

for relatively short durations provided that the distress message is retransmitted frequently. In this way the helmsman can correct his heading based on the homing indicator reading obtained during each distress message retransmission. In such a mode of operation, initial retransmission should occur at least once per minute so that the helmsman can correct his course and determine the EPIRB bearing as rapidly as possible.

In order to accommodate the operational requirements of the homing process, the EPIRB must transmit for at least 15 seconds during each transmission cycle. The system was designed with a variable duty cycle such that the EPIRB retransmits roughly two or three times per minute at first, and reduces its transmission rate over the 24 hour active interval. The variable duty rate can be designed so that during the first few hours of transmission the retransmission rate does not go below once per minute. However, the constraints placed on system design by available battery power at reasonable cost, and operation in a multiple EPIRB environment dictate that during the latter part of the 24 hour interval the retransmission rate must be significantly lower than once per minute. This problem is addressed in Section 3.0.

FIGURE 2-4. TYPICAL J ANTENNA

3. OPERATIONAL CONSIDERATIONS

3.1 SUMMARY OF THE TRANSMISSION CYCLE

Figure 3-1 summarizes the transmission parameters discussed in this section. Each transmission cycle begins with transmission on channel 16 for 2 seconds. The modulation format used during the channel 16 transmission corresponds to the international distress tones at 1300 Hz and 2200 Hz. These tones are alternated every quarter second as described for the international distress call format. After a channel 16 transmission the EPIRB switches to channel 15 and continues to transmit using the same tone frequencies at 1300 Hz and 2200 Hz. However, the message is not a simple alternating pattern. For the first five seconds on channel 15 a preamble pattern is transmitted. This consists of 20 tone chips each of which is 0.25 seconds long. The code pattern used during this 20 chip preamble is selected to have good correlation properties for detection and synchronization of the channel 15 message. The latter 10 seconds of the channel 15 transmission consists of a 40 bit message which contains the vessel identification and distress codes. The 40 bits are transmitted using the same 1300 and 2200 Hz tone frequencies. Thus, the transmission duration on channel 15 is roughly 15 seconds. Following transmission on channel 15 the EPIRB switches back to channel 16 and repeats the first transmission pattern. Following the second transmission on channel 16 the EPIRB remains off for a variable length of time which is determined by the duty cycle logic. The exact duty cycle to be used will depend on the energy storage capabilities of the battery selected for the EPIRB. However, it is safe to say at this point that the selected duty cycle pattern will be similar to that shown in Fig. B-4.

3.2 MULTIPLE ACCESS

The EPIRB design described herein provides a relatively high power level (1 watt) in order to provide a usable signal with the propagation conditions described in Section 2.2. In order to

FIGURE 3-1. TRANSMISSION FORMAT

minimize the battery requirements, it is reasonable to assume that the EPIRB will transmit bursts of signal, followed by periods of no transmission. This is shown graphically in Fig. 3-2. In addition, when more than one EPIRB is in operation at a given time the detection performance of the system will be degraded by the potential for overlap of the transmissions from two or more of the EPIRBs. It is likely that most EPIRB receiving systems will use frequency modulation detectors (i.e., ordinary FM receivers), in which case the strongest of the received signals will capture the receiver when overlap exists. This means that in order to detect the weaker (more distant) EPIRB signals there must be a high probability of reception without overlap. Appendix B analyzes this problem.

It should be noted here that there will always be a finite (but small) probability that several EPIRBs will turn on nearly simultaneously. In this eventuality, the receiving system will be incapable of distinguishing between EPIRBs, if they are in close proximity to one another. This event, however, will, in general, be quite rare, as the prime cause would be the sudden onslaught of violent weather (such as a line squall). Sudden, severe weather can (and has) caused severe distress to large numbers of small craft, and no communication system however complex, can accommodate such a situation, unless extremely large amounts of unused time are provided in the transmission format which in turn means that each EPIRB will transmit very infrequently. We have chosen instead to design an efficient communications system, with a high probability of reception and low probability of overlap. The primary consideration is that except for the highly unusual conditions mentioned above, the probability of multiple EPIRBs turning on nearly simultaneously, is extremely low.

3.3 BATTERY LIFETIME

The batter power requirements of the two schemes shown in Fig. B-4 were analyzed as typical designs. The results are shown in Table 3-4. The table assumes two possible patterns during each

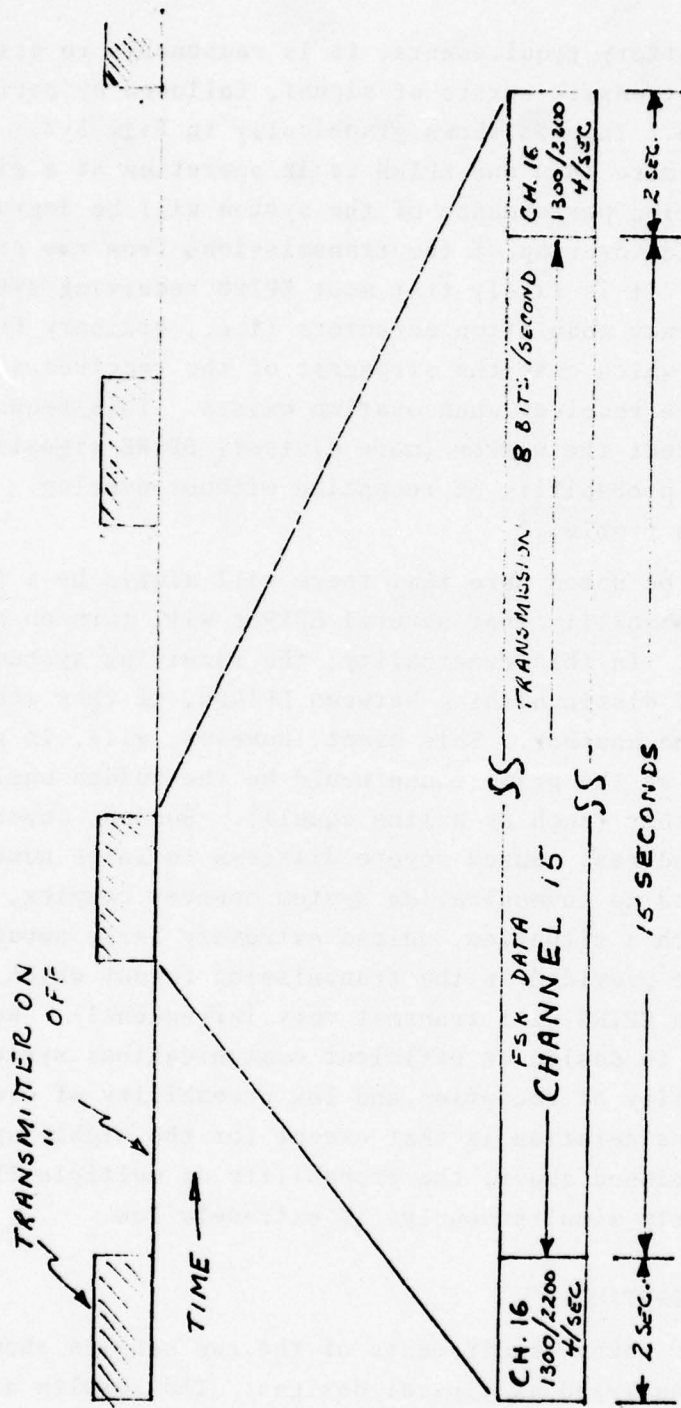

FIGURE 3-2. EPIRB TRANSMISSION CYCLE

cycle: Channel 16 transmits preceding and following channel 15 transmissions. Channel 15 transmissions are always 15 seconds in duration while channel 16 transmissions are either 1 or 2 sec. long. The results of Section 2.2 indicate that 1 watt of transmitter RF power through a 0 dBi gain antenna should be adequate. For this reason, Table 3-4 assumes that the d.c. bus power

TABLE 3-1. BATTERY POWER REQUIREMENTS

| | Cycle A | | Cycle B | |
|----------------------------------|------------|------------|------------|------------|
| | 2 + 15 + 2 | 1 + 15 + 1 | 2 + 15 + 2 | 1 + 15 + 1 |
| No. Trans. in 24 hrs. | 472 | 472 | 399 | 399 |
| Total Trans. Time | 8968 sec. | 8024 sec. | 7581 sec. | 6783 sec. |
| Energy Required for 3 watts d.c. | 7.47 W-hr. | 6.68 W-hr. | 6.32 W-hr. | 5.65 W-hr. |
| ma-hours at 12 volts | 622 ma-hr. | 556 ma-hr. | 526 ma-hr. | 471 ma-hr. |

required during transmission is around 3 watts. The battery capacity required for the various schemes is between 471 ma-hr. and 622 ma-hr. at 12 volts.

Batteries which are typically used in EPIRBs tend to lose their capacity at low temperatures. For this reason, it is necessary to derate the battery when consideration is given to low temperature operation. A derating by 50% is not unreasonable for this application. Table 3-5 summarizes the battery characteristics which are typical of what would be required by the EPIRB using the 2 + 15 + 2 version of Cycle "A."

TABLE 3-2. BATTERY CHARACTERISTICS

| | |
|-------------------------|------------------|
| Voltage | 12 volts |
| Energy Storage | 7.5 W-hours |
| Low Temp. Design Point | -20°C |
| 2.5 Hour Discharge Rate | 250 milliamperes |
| Amp hours at 25°C | 1.25 A-hours |

For the purposes of illustration, it was found that a sealed rechargeable lead-acid battery which roughly meets these requirements is a Globe-Union Gel/Cell Model GC 1215-1. This unit can provide 450 milliamps (to a terminal voltage of 10 V) at 25°C and is derated by 50% at 20°C. The battery is 7.01 x 2.36 x 1.33 inches and weights approximately 1.5 lbs. A nickel-cadmium battery with a similar capability is a GE Model 10 GC W 2.0 ST. This unit is 6.68 x 2.81 x 1.67 inches which is remarkably similar to the sealed lead-acid unit. Of course, this Ni-Cad battery will provide the same performance down to -30°C.

Lithium battery technology offers the highest energy per unit weight and volume of all commercially available batteries. The application of this relatively new technology to the EPIRB application was investigated. It was found that a lithium primary battery capable of delivering 250 ma at 12 volts for 2.5 hours at -20°C was quite small. In fact, 5 "3/4 C" cells will produce 270 ma for 2.5 hours at -28.8°C (-20°F). The voltage at the start of discharge is approximately 11.5 volts and reduces to 11.0 volts after 2.5 hours. The battery unit size is 1.63 high by 0.95 inches in diameter. Five units are required. Total weight for the 5 units is 5.75 oz. (163 grams). Recent cost estimates for a lithium battery pack consisting of 5 "3/4 C" units is \$11.75 (200 and up).

The purpose of reviewing the capabilities of commercially available batteries is not to select a type and style for a production EPIRB. Rather, it is to demonstrate that the assumed design requirement of 3 Watts of D.C. power for 2-5 transmitting hours (24 operating hours) are reasonable and that substantial increases may not be possible within the context of the EPIRB size and cost constraints. At the same time, it is observed that substantial decreases in battery energy storage capability are not required either. For these reasons, it is concluded that duty cycle patterns like those shown in Fig. B-5 are suitable for the EPIRB mission.

4. PROTOTYPE EPIRB DESIGN

This section describes the design and construction of the prototype EPIRB. Five prototypes were built and tested during this program.

4.1 EPIRB DIGITAL DESIGN

The experimental EPIRBs implemented as part of this program were intended to provide maximum flexibility to the experimenters. The following parameters were controllable.

- power output
- antenna type
- duty cycle variation
- duration of channel 16 transmission
- duration of channel 15 transmission

This was achieved using the system shown in Fig. 4-1 which shows the EPIRB block diagram.

Transmitter operation is controlled by the contents of a read only memory (ROM). In particular, the memory determines whether the transmitter is ON or OFF at a given time. If it is ON, the memory determines whether the transmitted frequency is on channel 15 or channel 16. The memory also determines which of the two FSK tones is used to modulate the output frequency.

The address of the ROM is determined by a counter which is incremented at a rate which is obtained by dividing down a stable reference frequency from the tone generator. Thus, as the counter counts up to its maximum and overflows, the entire content of the ROM is continuously scanned. Each cycle of the address counter corresponds to one transmission cycle.

In the absence of the divide ratio control, the system as described thus far is capable of constant duty cycle operation. A duty cycle counter is included which is incremented once each transmission cycle. This counter controls a divide ratio logic subsystem which reduces the address counter update rate during

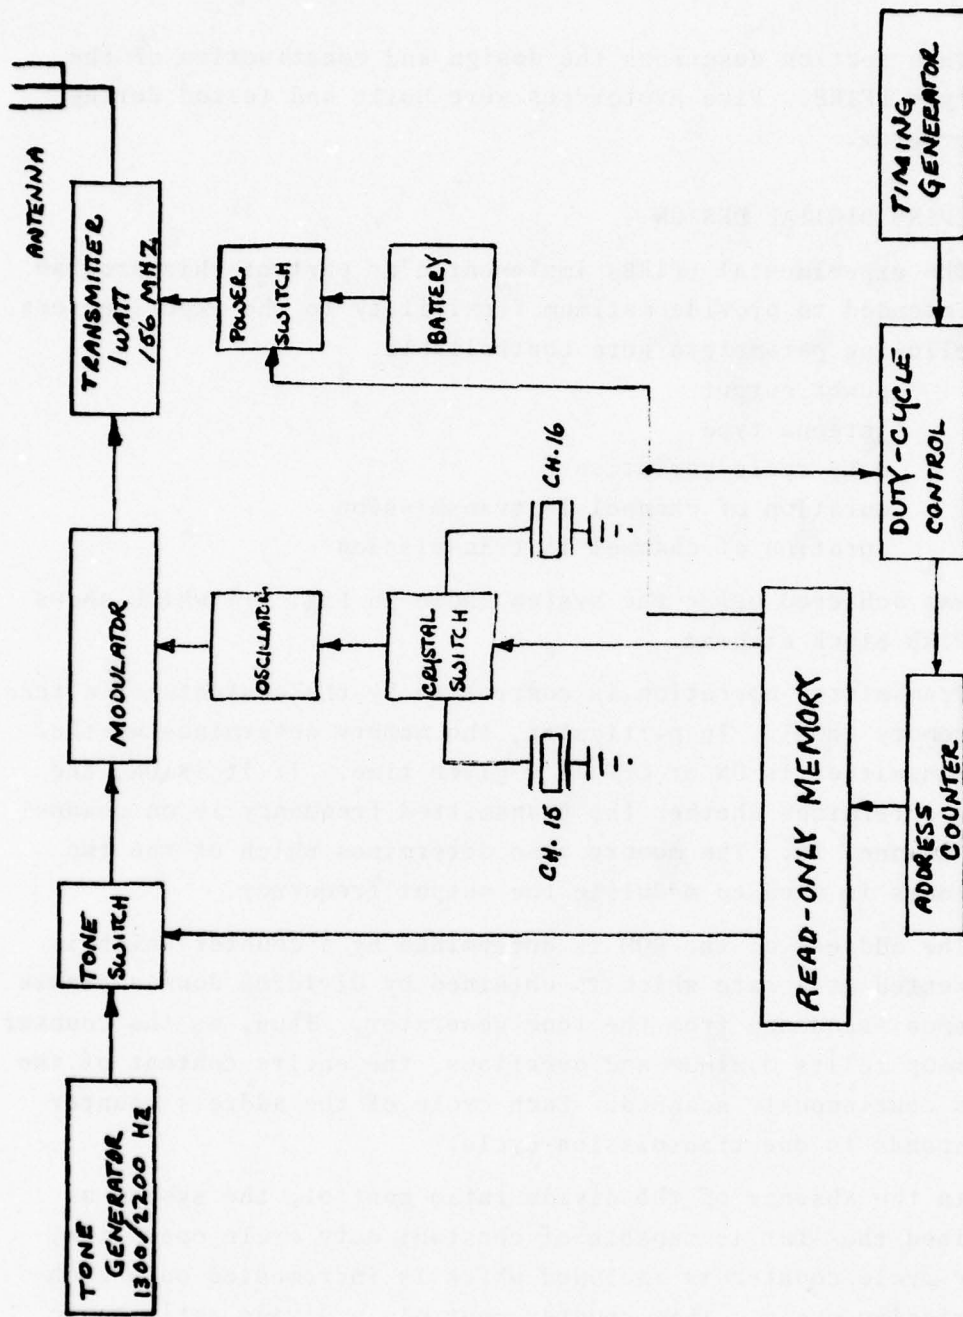

FIGURE 4-1. EPIRB TRANSMITTER BLOCK DIAGRAM

the OFF periods. As the number of executed transmitter cycles increases and the duty cycle counter content increases, the update rate of the address counter during the OFF periods becomes slower and slower. In this way the desired variable duty cycle is implemented. The system also includes a means for randomizing the OFF period from unit-to-unit. This is achieved by perturbing the divide ratio control subsystem by one of the ROM outputs. A unique ROM content would be implemented for each production unit.

4.2 TRANSMITTER DESIGN

The VHF transmitter portion of the system was implemented using a VHF Electronics Model TX144B commercial transmitter module. This unit provided the VCO, and power amplifier functions. It was necessary to modify the unit in order to provide Ch. 15/Ch. 16 capability and logic controlled ON/OFF functions, and to provide an output power of 1 watt.

Two types of antennas were used. A 5/8 wavelength whip antenna was mounted on one of the EPIRBS. Four other EPIRBS were implemented with a "J" antenna (Antenna Specialities Model ASM177).

The tone generator was implemented by a MC14410 integrated circuit (IC). For the purposes of experimentation, the read only memory was implemented using a 2101 random access memory with an attached battery pack. The rest of the logic was implemented in CMOS.

Tables 4-1 and 4-2 show two different duty cycle arrangements which were implemented for experiment purposes. Method "C" provides a 10 second Ch. 15 transmission. Method "D" provides a 15 second on Ch. 15.

4.3 MECHANICAL DESIGN

The prototype EPIRBS were all packaged in identical containers. The container consisted of a right circular cylinder, fabricated from 3 inch (inside diameter) PVC pipe, with suitable endcaps. The container is approximately 18 inches long. Two aluminum rails are fastened to the top cap, and the two printed circuit boards are

TABLE 4-1. DUTY CYCLE PATTERN "C"
(10 Seconds on Channel 15)

| Duty Cycle | Duration | Cum. Time |
|------------|------------|-----------|
| 42.9% | 18.6 min. | - |
| 23.3 | 34.4 min. | 53.1 min. |
| 14.6 | 54.9 min. | 1.8 hrs. |
| 11.3 | 70.6 min. | 2.9 hrs. |
| 8.8 | 91.2 min. | 4.5 hrs. |

| 6.3 | 127.5 min. | 8.4 hrs. |
| 5.6 | | 24 hrs. |

TABLE 4-2. DUTY CYCLE PATTERN "D"
(15 Seconds on Channel 15)

| Duty Cycle | Duration | Cum. Time |
|------------|------------|-----------|
| 31.3% | 17.1 min. | - |
| 13.5 | 34.1 min. | 51.2 min. |
| 8.3 | 64 min. | 1.9 hrs. |
| 6.2 | 86.4 min. | 3.4 hrs. |
| 4.8 | 110.9 min. | 5.2 hrs. |
| 4.0 | 133.3 min. | 7.43 hrs. |
| 3.5 | 151.8 min. | 9.96 hrs. |
| 3.0 | - | 24.0 hrs. |

These two patterns can be separately implemented with only minor wiring and programming changes. The digital electronics was specifically designed to emphasize flexibility. Specifically, all timing patterns could be quickly and simply modified over a wide range.

fastened between these rails (see figures 4-2, 4-3 and 4-4). The antenna is a 50-inch whip, also fastened to the top cap with its matching section contained within the package. One circuit board (fig. 4-3) contains the VHF transmitter and its associated RF circuitry. The other circuit board (fig. 4-4) contains the digital circuitry. The batteries were mounted in the bottom of the container for ballast; rechargeable Gel cells were used. The container was sealed and pressurized (3 psi) to ensure watertight integrity. On the outside of the top cap were mounted the pressure valve and two switches--the on-off switch and another to choose the identification code.

The prototype floated with the antenna base about 3 inches above the surface. The output power was about 1 watt into the antenna.

5. AUTOMATED EPIRB RECEIVER/PROCESSOR DESIGN ANALYSIS

This section considers the performance of the receiver to be used for high performance detection of the channel 15 message and for code processing to extract vehicle identification and distress level.

5.1 SIGNAL CONSIDERATIONS

The EPIRB design described in this report is intended to provide coverage within 20 nautical miles of the coastline. Therefore, the system should provide coverage for slant ranges well in excess of 20 nautical miles. Table 5-1 shows the receiver power level for 1 watt transmitted EIRP at ranges of 24 nm and 30 nm. The transmitter height is assumed to be at sea level, and the receiver antenna height is assumed to be either 100 ft or 200 ft above sea level. Three wind conditions are given: no wind, 7.7 m/s, and 15.6 m/s. The latter two wind speeds correspond to sea-state 3 and sea-state 6, respectively. Also given in the table are the received power levels predicted by the classical smooth spherical earth propagation model.

Table 5-1 shows that the weakest signal strengths anticipated for this system should be about -126 dBm when the transmitted power is 1 watt and the receiving antenna has 3 dB of gain at the heights shown in the table. Of course, somewhat higher antenna gains are readily achieved and the transmitter may put out more than 1 watt especially at initial turn-on. In order to determine performance we must also have an estimate of the receiver noise characteristic. At frequencies in the vicinity of 150 MHz, the noise in the receiver is often the result of man-made ambient noise rather than receiver front-end noise. The level of man-made noise is a function of population density. For example, Fig. 1 of Section 29 of Ref. 1 shows that the equivalent noise figure of urban man-made noise at 150 MHz is approximately 36 dB. The equivalent noise figure of suburban man-made noise at 150 MHz is about 20 dB. For the purposes of analysis, we will assume the latter

TABLE 5-1. RECEIVED SIGNAL LEVEL (dBm) FOR 1 TRANSMITTED EIRP
(transmitter height = 0, antenna gain = +3dBi)

| range (nm) | wind speed (m/s) | sea-state | antenna height (ft) | received power (dBm) |
|---------------|------------------------|-----------|---------------------------|----------------------------|
| 24 | 0 | 0 | 100 | -116 |
| 24 | 0 | 0 | 200 | -109 |
| 30 | 0 | 0 | 100 | -123 |
| 30 | 0 | 0 | 200 | -116 |
| 24 | 7.7 | 3 | 100 | -118 |
| 24 | 7.7 | 3 | 200 | -111 |
| 30 | 7.7 | 3 | 100 | -125 |
| 30 | 7.7 | 3 | 200 | -118 |
| 24 | 15.6 | 6 | 100 | -119 |
| 24 | 15.6 | 6 | 200 | -112 |
| 30 | 15.6 | 6 | 100 | -126 |
| 30 | 15.6 | 6 | 200 | -119 |
| 24 | smooth spherical earth | | 100 | -115 |
| 24 | smooth spherical earth | | 200 | -109 |
| 30 | smooth spherical earth | | 100 | -122 |
| 30 | smooth spherical earth | | 200 | -116 |
| 24 | F(50) ht = 15 ft. | | 100 | -114 |
| 24 | F(50) " | | 200 | -110 |
| 30 | F(50) " | | 100 | -118 |
| 30 | F(50) " | | 200 | -114 |

operational environment. Thus, with 1 Watt EIRP from the EPIRB, the worst-case received carrier-to-noise density will be approximately 29 dB-Hz. If it is assumed that the transmitted EIRP is 1.5 Watts then worst-case signal-to-noise density will be 30 dB-Hz. Such signal levels are well below the threshold of a conventional FM receiver designed for Maritime Mobile Service. Therefore, we must investigate the performance of FM receivers when operated below threshold.

The performance of an FM receiver above and below threshold was derived based on the work of Davis.⁽⁸⁾ The derivation provided the signal-to-noise density at baseband as a function of signal-to-noise density at IF. The relationship used is given in Eq. (5-1).

$$\left(\frac{S}{N_o}\right)_{\text{base band}} = \frac{\rho B \delta^2}{2e^{-\pi f_m^2/B^2} + \frac{4B^2 \rho e^{-\rho}}{\pi f_m^2 (1-e^{-\rho})^2 [2(\rho+2.35)]^{1/2}}} \quad (5-1)$$

where

$\rho = C/N_o B$, the IF SNR

$B =$ the single-sided noise bandwidth of the IF

$\delta =$ modulation deviation (rads) = $\Delta f/f_m$

$f_m =$ modulation rate (Hz)

Equation (5-1) is plotted in Fig. 5-1 for several choices of parameters. In particular, 2 IF bandwidths are assumed. One is the standard for typical VHF receivers--namely, 12 kHz. The other is 6 kHz. Two tone frequencies are assumed as before, 1300 Hz and 2200 Hz. In all cases analyzed the modulation deviation was assumed to be 2 radians. At 2 radians the best performance is achieved at 2200 Hz in a 7 kHz IF. However, note that a 1300 Hz tone in the same bandwidth could use a larger deviation. When the deviation is optimized, performance at 1300 Hz is similar to that shown for 2200 Hz in the 7 kHz bandwidth. The same argument pertains to the 12kHz IF bandwidth performances shown. Namely, in both cases, at 1300 Hz and at 2200 Hz, the 2 radian deviation assumed is smaller than that which would be allowable by the 12kHz

FIGURE 5-1. BASEBAND SIGNAL-TO-NOISE DENSITY VERSUS RECEIVED CARRIER-TO-NOISE DENSITY

filter. However, in this case, if the deviation were increased by 6 dB and a comparison made with the performances in the 6 kHz bandwidth, it is found that the relative performance of the wider bandwidth system below threshold is inferior to that of the narrower bandwidth system, so that the narrow bandwidth IF always provides the lowest threshold.

The propagation analysis of the previous section indicated that the worst-case received carrier-to-noise density is approximately 28 to 30 dB-Hz. Figure 5-1 indicates that the signal-to-noise density at baseband given this received carrier-to-noise density will be about 20 dB-Hz.

Fig. 5-1 also shows the performances of phase-locked receivers under a variety of operating conditions. The relationship between IF signal-to-noise density and baseband signal-to-noise density in a tone-modulated system with a high signal-to-noise ratio in the phase-lock loop tracking bandwidth is given by Eq. (5-2).

$$\left(\frac{S}{N_0}\right)_{\text{base band}} = 2J_1^2(\delta) \frac{C}{N_0} \quad \text{for } (\text{SNR})_L \text{ high} \quad (5-2)$$

where $J_1(\cdot)$ is the 1st order Bessel function.

Figure 5-1 shows that given high signal-to-noise ratio in the loop bandwidth, the phase-locked receiver provides better performance than the FM receiver when the signal-to-noise density at IF is less than 30 dB. However, a separate set of points is given for the case in which the phase-locked loop noise becomes substantial, resulting in non-linear loop performance. In that case, the effective baseband signal-to-noise ratio is reduced by

$$\frac{S}{N_0} = \frac{C}{N_0} e^{-\phi_{\text{rms}}^2/2} \quad (5-3)$$

where ϕ_{rms} is the rms loop error. It is evident that the PLL demodulator performance will actually be little, if any, better than the conventional demodulator performance with a 6Khz IF bandwidth. The points which are included on Fig. 5-1 to show

the phase-locked demodulator performance assume a 300 Hz tracking loop bandwidth. As a result, the loop can require up to 3 seconds for acquisition when crystal oscillator drifts are at their expected maxima of ± 750 Hz. In order to achieve rapid acquisition at all expected frequency offsets the phase-locked loop tracking bandwidth would have to be so wide that the performance at low signal-to-noise densities would be inferior to that achieved with an FM system. On the other hand, superior performance (indicated by the dotted curves in Fig. 5-1) would be achieved at substantially narrower tracking bandwidths such as 50 Hz or less. In that case, many tracking loops would have to be used in parallel or a sweeping acquisition technique would have to be employed. The latter is undesirable because the transmission time on channel 15 is too short.

It is thus concluded that while a phase-locked demodulator offers the potential for improved performance at low signal-to-noise densities relative to the FM technique, such improvements can only be achieved at the expense of increased complexity. In particular, it is estimated that a bank of 20 or more phase lock demodulators with relatively narrow tracking bandwidths would provide the desired superior performance. However, the advantage is limited to roughly 5-10 dB in the vicinity of 30 dB-Hz. The phase-locked technique does provide an auxiliary advantage relative to the achievable performance in the presence of multiple EPIRB signals. In particular, it is possible for the phase-locked receiver to lock on to one EPIRB signal when another stronger signal is transmitting co-channel. Although this is a desirable feature, we do not feel that it justifies the greatly increased receiver complexity that the phase-locked demodulator would require.

5.2 RECEIVER POST-DETECTION SIGNAL PROCESSOR

Figure 5-2 shows a block diagram of the receiver system. The signal is received and demodulated by a commercial VHF-FM receiver module. The receiver is modified so that the IF bandwidth is 12 kHz. The discriminator output of the receiver drives two bandpass

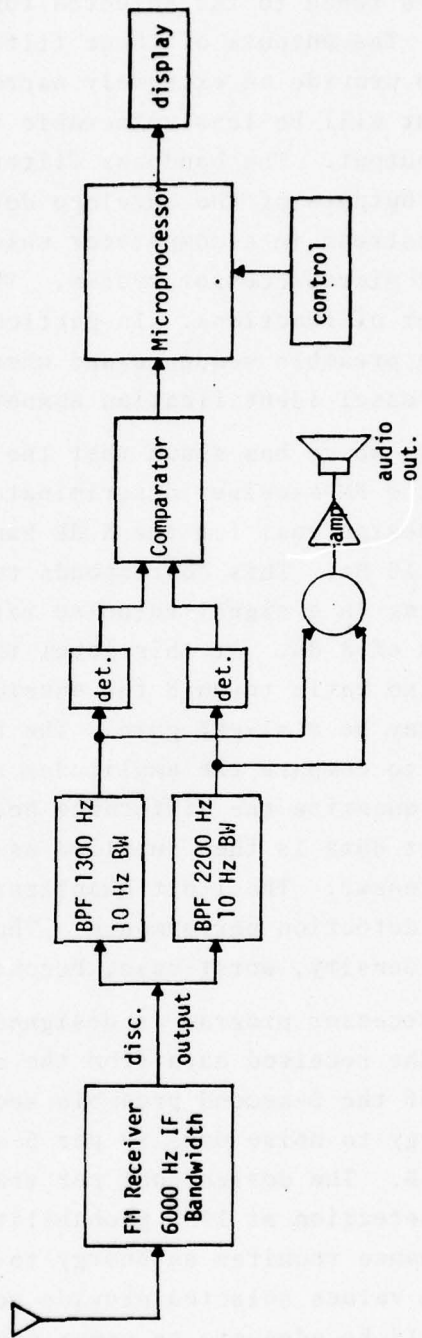

FIGURE 5-2. CODE RECEIVER SYSTEM

filters which are tuned to the selected tone frequencies at 1300 Hz and 2200 Hz. The outputs of these filters are summed together and amplified to provide an extremely narrow filtered audio output. This audio output will be less vulnerable to noise problems than an ordinary FM output. The bandpass filters also drive envelope detectors. The outputs of the envelope detectors are converted to a digital bitstream in a comparator which provides a logic input to a digital microprocessor system. The microprocessor system provides a number of functions. In particular, it searches for the distress message preamble sequence and when it is found, it decodes the distressed vessel identification number and distress status.

The analysis above has shown that the worst case signal-to-noise ratio at the FM receiver discriminator output is approximately 20 dB-Hz. The design goal for the 3 dB bandwidth of the bandpass filters will be 10 Hz. This corresponds to a noise bandwidth of 15.7 Hz, resulting in a signal-to-noise ratio at the output of the bandpass filters of 8 dB. At this level there should be no loss in signal-to-noise ratio through the envelope detection process. In fact, there may be a slight gain. The next stage in the detection process is to compare the amplitudes at the outputs of the detector and to quantize the difference between the amplitudes to 1-bit. The 1-bit data is then supplied as input for processing by the microprocessor. The 1-bit quantization will result in a 1.96 dB loss in detection performance. Thus, the equivalent input signal-to-noise density, worst-case, becomes 18 dB-Hz.

The microprocessor program is designed to carry out a 1-bit correlation of the received data from the comparator against a stored replica of the 5-second preamble sequence. This means that the minimum energy-to-noise density per 5-second detection decision is $18 + 7 = 25$ dB. The design goal per transmission was 90% probability of detection at 10^{-6} probability of false alarm. This level of performance requires an energy-to-noise density of 13 dB. Thus, the design values selected provide nominally 12 dB of margin. This margin should be adequate to cover any anticipated signal fading. For example, if it is assumed that the received signal is Rayleigh fading, the fluctuation loss at probability of detection

of 90% and probability of false alarm of 1×10^{-6} requires only an additional 8 dB. (Ref. 9)

In order to insure accurate data decoding, bit synchronization must be accurate to within 10% of a chip duration. At this level the loss in performance due to synchronization error is nominally 1 dB. The minimum energy-to-noise density per code chip in the preamble is approximately 12 dB given 20 dB-Hz at the output of the discriminator, 2 dB binary detection loss, and one-quarter second chip duration. A recent study of the type of system proposed for the EPIRB receiver has shown that a 10% rms error is achievable when the chip energy-to-noise density is approximately 6 dB. (Ref. 10) This means that the bit synchronization portion of the data detection and decoding operation has a 7 dB margin given the design parameters selected.

During the latter 10 seconds of the channel 15 transmission interval, the vessel identification number and distress code level are transmitted at a 5-bit per second rate. Thus, the energy-to-noise density per bit is 12 dB. This estimate includes the 2 dB binary detection loss. It is reasonable to assume that the performance achievable by this system will be comparable to that achieved by an incoherent FSK data link. Thus, it is estimated that the bit error rate given $E/N_0 = 12$ dB is approximately 1×10^{-4} .

It is possible to improve decoder performance by increasing the channel 15 ON time. This will accentuate the battery energy storage problem and will reduce the multiple EPIRB detection performance. Alternatively, it is possible to redistribute the 15 second channel 15 ON time between the prekey and data transmission intervals. This approach will reduce the distress message automated detection capability and will increase bit synchronization error. Such a trade seems hardly appropriate because the decoding process cannot begin unless detection has been achieved. All things considered, it would appear that the selected system parameters are in the desired ranges for this system. Further refinement should be carried out; for example, the design presented

here incorporates error coding capability for the distress level portion of the message. It does not provide for error correction coding of the vessel identification number. However, this may not be absolutely essential at the beginning of the distress transmission interval. It is probable that through digital combining of a number of distress message transmissions that the correct vessel identification number can be derived without the aid of further error correction coding. In any event, error correction could provide significant improvement in data message detection. The necessary algorithms can easily be handled by the micro-processor already incorporated into the system.

5.3 RECEIVER IMPLEMENTATION

A receiver was designed and built to demodulate and process the Ch. 15 distress signal. The receiver employs sophisticated digital data processing to extract the EPIRB identification number and distress level. This information is displayed on a front panel readout and can also be printed out on a teletype or other hard copy machine.

A block diagram of the receiver is presented in Fig. 5-2. The operation of the receiver is as follows: The EPIRB signal from the antenna is applied to an FM receiver. For the purposes of the experimental system this receiver was implemented using a VHF Engineering Model RX144 Receiver Module. This receiver was modified so that improved IF bandwidth characteristics were obtained. In particular, the IF filter bandwidth for the experimental system was 12 kHz. As indicated in the previous discussion and shown in Fig. 5-1 a 6 kHz filter would provide slightly better performance, however, the necessary filter could not be procured and installed in the allowable time; consequently, a readily available filter was used.

The audio output of the receiver is applied to a pair of bandpass filters at 1300 Hz and 2200 Hz, the FSK tone frequencies. These filters should have 3 dB bandwidths of $1/T$, where T is the bit duration. Since the experiments were conducted using $1/8$

second bit duration, the bandpass filters should have 8 Hz bandwidths. In fact, the experimental system used commercially available filters which were somewhat wider, roughly 18 Hz. The outputs of the bandpass filters are detected to determine a measure of the amplitude in each of the bandpass filters. The detectors in the experimental system were implemented using analog multipliers, which provided nearly ideal square law detection characteristics. Under poor signal-to-noise ratio conditions, it can be shown that square law detection characteristics are optimum with respect to small signal suppression effects.

The envelopes of the two filters are compared in a comparator. The result of the comparison produces a high or low TTL level at the output of the comparator depending on whether the 1300 Hz filter output exceeds the 2200 Hz filter output or vice versa. The bandpass filter outputs are also summed in an analog fashion and applied to a front-panel mounted speaker for audio alerting purposes.

The logic output of the comparator is applied to a microprocessor system. The microprocessor was implemented using an Intel SBC80/10, which is a commercially available module using the Intel 8080 microprocessor chip. The microprocessor interfaces with front-panel control inputs, a Burroughs self-scanned display and in addition a teletype RS-232/C interface is provided on the rear panel.

When the system is turned on, a front panel pushbutton resets the system, and the program is set to the monitor mode. In this mode, the program samples the output of the comparator and checks for correlation between the noisy bit pattern received from the comparator and a stored replica of the preamble sequence. If and when the correlation score exceeds a set threshold, the program leaves the monitoring mode and proceeds to search for the peak of the correlation function. Once the peak finder locates the correlation maximum, a simple manipulation determines the bit synchronization timing for the digital message which follows the preamble sequence. The program then proceeds to sample and store

the message bits. These are displayed at the end of the message interval on the front panel mounted readout. A separate teletype program is provided which prints out the received message along with time-of-day and the correlation score which triggered the data extraction process.

6. TEST PROGRAM

6.1 TEST SUMMARY

Two prototype EPIRBs were constructed for the initial tests. The first unit was designed as a test bed and reference for comparison. It transmitted a continuous signal which alternated between modulated and CW transmissions. The second unit was the first prototype water-deployable unit with varying duty cycle. Using these two transmitters, a detailed field test was conducted during July and August, 1977. Table 6-1 summarizes the test results. The tests conducted were as follows:

- a. A series of measurements were made at carefully calibrated distances. A 41 foot cutter served as a signal source, carrying the two test units to previously designated positions. The prototype EPIRB was deployed in the water, while the TSC test transmitter stayed on board the cutter. An instrumented TSC Van was used as a shore-based receiving site. At this site, measurements were made of signal level versus range during all tests. These measurements were then compared with two sets of analytical predictions. The measured signal level, in all cases, was the same as, or greater than the predicted level, thus validating the accuracy of the predicted level.
- b. One Coast Guard cutter was equipped with a Dorne and Margolin homing direction finder. Tests of homing ability were then performed using this cutter, and a homer-equipped Coast Guard helicopter. The prototype EPIRB was deployed in the water, at various carefully located sites. The cutter and helicopter then attempted to home on the EPIRB from various distances. The 41 foot cutter consistently homed directly to the EPIRB from a range of 8

TABLE 6-1. TEST PROGRAM RESULTS

| | |
|--|-------------|
| 1. Reception and homing range to 41 foot cutter | 8 miles |
| Reception range to conventionally equipped shore station | 20 miles |
| Reception range to shore station equipped with special EPIRB receiver | 30-35 miles |
| Reception Range to HH-52A Helicopter: | |
| Communications | 30-35 miles |
| Homing | 18-20 miles |
| 2. Channel 17 transmit time of 2 seconds provides reliable audible alert--shorter times unreliable when VHF traffic density is high. | |
| 3. Channel 15 transmit time of 10 seconds is too short for reliable homing under all conditions--recommend 15 seconds. | |
| 4. Two-tone alert signal demonstrated to be highly audible. | |
| 5. Shore-based DF located EPIRB with accuracy of 1-3 degrees. | |

nautical miles. The helicopter homer could not home reliably at a range of more than 10-12 nautical miles, at altitudes of 500-1500 feet. However, when the helicopter receiver was switched out of the "homing" mode, the EPIRB signal could be received at ranges greater than 20 miles. Discussion with the helicopter pilots revealed that it was normal to experience a large loss of sensitivity when operating in the "homing" mode. This is not true of the homers used on cutters, and is believed to be due to a poor antenna design on the helicopter.

- c. Three automatic read-out radio direction finders were then installed at the shore receiving site. These direction finders were selected as typical commercial units available for use in this frequency band. A series of tests were performed at different angles and ranges. These results demonstrated the ability of all three direction finders to make quick, accurate bearing measurements on the EPIRB signal. Typically, accuracies of 1 to 3 degrees were observed.
- d. Four more prototype EPIRBs were designed and built. These units were carefully sealed and pressurized, because of leakage problems and resultant corrosion problems with the first unit. A special purpose EPIRB receiver was also designed and built. This receiver has the capability to receive and process the EPIRB signal, automatically generating an ALERT signal and providing a readout of the identification and situation data if encoded on the EPIRB transmission. This receiver was installed and tested at the shore site. The EPIRB signal was detected and the ALERT signal generated at a range of 30 miles from the shore site.

The complete shore-based facility was then re-installed in the Coast Guard station located at Point Allerton, Hull, Massachusetts. On September 28, 1977, a system demonstration was performed for an audience of personnel from the Coast Guard, FCC and NASA. During the demonstration, EPIRBs were placed in the water at two different locations within the Boston Harbor area. The EPIRB signal was received at the Point Allerton station in a simulated Search and Rescue alert. A Coast Guard cutter equipped with a homing direction finder was dispatched to locate and recover the EPIRBs. The radio direction finders installed at the station provided an initial bearing from the station to each EPIRB. This bearing was used by the rescue cutter to establish an initial heading. The cutter then conducted a search, finally homing on the EPIRB signal, using an on-board homing direction finder.

This demonstration was considered highly successful by all those in attendance. The complete equipment set-up performed normally; the rescue cutter located and recovered both EPIRBs within one hour.

6.2 SIGNAL STRENGTH TESTS

The analysis of propagation and signal attenuation presented in section 2.2 resulted in a recommended EPIRB power output of one watt to achieve a range of 20 nautical miles. In order to verify this prediction and also to quantify the expected signal level versus range, a series of tests were made using a prototype EPIRB. For these tests, a shore station was established on a point of land near Winthrop Highlands, Massachusetts, about five miles north of the entrance to Boston Harbor. The area around the test site consisted of a clear flat field for 200 yards, terminating at a low bluff approximately 20 feet above sea level. At the test site an instrumented equipment van was parked at the edge of the bluff, with the receiving antennas mounted on the van roof. Thus the height of the receiving antenna was about 30 feet above sea level.

The van was equipped with a calibrated reference dipole whose output was fed to the receiving system through a known length of coaxial cable. The received signal was displayed on a Hewlett-Packard spectrum analyzer. Initial signal-level calibration was provided by feeding a known signal level into the antenna-end of the cable from antenna to the receiver.

For the initial tests, two transmitters were used. The first transmitter had an output power of 2 watts, using a dipole antenna and transmitted a signal which alternated between a two-tone modulation and a CW signal. The second transmitter was a prototype EPIRB. The EPIRB was watertight and designed for water deployment. This unit transmitted the chosen EPIRB modulation, as described in sections 2.4 and 4.1.

The test procedure was as follows:

1. The mobile van proceeded to the test site at Winthrop Highlands. When on site, antennas were erected and receiving equipment was calibrated.
2. The two test EPIRBs were placed aboard a Coast Guard 41 foot cutter. The cutter then proceeded to the first test location for the day. All tests were conducted in the vicinity of known navigational marks, principally buoys. Therefore, the distance from the test site to the EPIRB could be measured from the area chart.
3. Communication was established between the shore receiving site and the test cutter. Upon request, the cutter personnel would first energize the test transmitter at a known location aboard the cutter. Reception of this signal established a reference signal level for an unmodulated carrier and for a typical EPIRB modulation, transmitted from a fixed platform. When the reference level had been measured, the test transmitter was turned off; the EPIRB was then turned on and deployed in the water, 10 to 20 feet from the

cutter. The shore station then measured the received level from the EPIRB, also noting the range.

For these tests, all test transmissions were conducted on Channel 15. A series of measurements were made to a number of different locations, corresponding to various buoys around the outer Boston Harbor area (see Fig. 6-1). The data from these tests, in the form of a graph showing signal level versus range, is depicted in Figure 6-2. Also included on this graph are two theoretical curves--one for the plane smooth earth model, and the other a similar model which includes diffraction over a smooth spherical earth.

The data are shown for two receive antenna positions--the top of the TSC mobile van and mounted at the base of the bluff below the van, with a physical antenna height of 5-10 feet (depending on the height of tide). The important thing to note about this data is the excellent agreement with theoretical prediction. In general the data points lie either between the two predicted curves, or directly on the spherical earth curve. From this we conclude that one watt of power, into a well-matched quarter-wave antenna will provide sufficient signal for a reliable alert to 20 nautical miles.

6.3 CUTTER RECEPTION TESTS

The signal strength tests primarily were intended to provide data on reception range at shore stations. However, a 41 foot cutter was also equipped with Channel 15 reception capability. Quantitative signal strength tests were not conducted on board the cutter; instead, the cutter crew merely verified whether or not they had good reception. By this means it was determined that the EPIRB signal could be received by the 41 foot cutter with high reliability out to a range of approximately 8 nautical miles. Signals were occasionally heard at a range of 12 miles, however, the reception was extremely erratic.

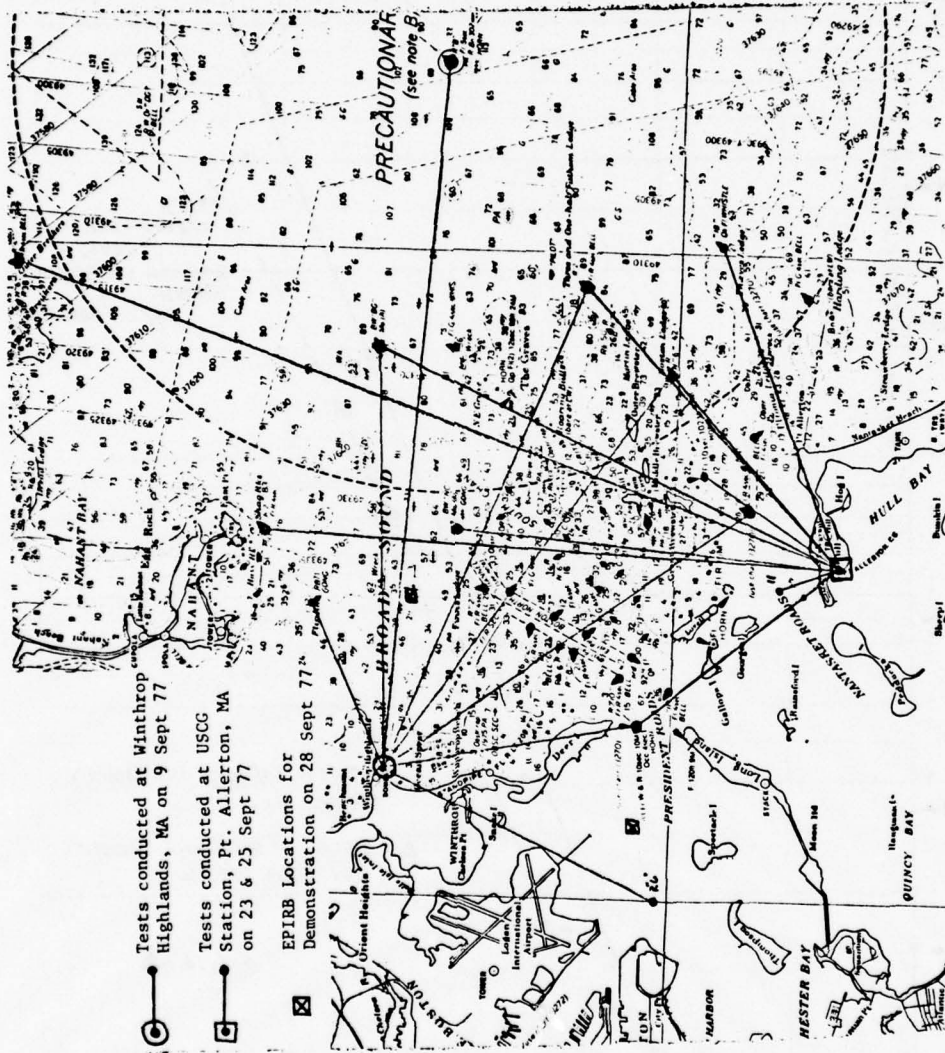

FIGURE 6-1 EPIRB TEST AREA CHART

FIGURE 6-2. RECEIVED SIGNAL LEVEL VERSUS RANGE

6.4 EPIRB RECEIVER TESTS

The next set of tests was designed to verify reception range by the special EPIRB receiver described in section 5. In order to perform this test, the EPIRB was deployed by the cutter at a series of locations with gradually increasing range. Cutter location was determined by reception of Loran-C signals at the cutter with a commercial Loran-C receiver. At each test location, the EPIRB receiver verified correct reception by teletype printout of an identification number transmitted by the EPIRB.

This reception was perfect out to approximately 21 nautical miles. Beyond this range, signal reception was quite erratic, as deep fading was encountered. This was due to the relatively low height (30 feet) of the receiving antenna, plus substantial swells (3-6 feet) in the test location. Accordingly, a directional antenna with approximately 9 dB gain was substituted for the standard dipole receive antenna. This was equivalent to increasing the antenna height by a factor of 2.8 (to approximately 85 feet). With this antenna, the EPIRB receiver received and printed out the correct ID every time, out to a range of 33 nautical miles. This test verified the design range of the EPIRB receiver, as the unit was designed for reception to 30 miles.

6.5 SYSTEM DEMONSTRATION

Upon completion of the test program, the receiving test site was moved to the roof of the Pt. Allerton Coast Guard Station, Hull, Massachusetts in preparation for a system demonstration to be performed for personnel from the Coast Guard, FCC, & NASA. The demonstration included homing and location of EPIRBs from Coast Guard Cutters, and the use of shore-based direction finding as a Search and Rescue aid. Due to the presence of considerable land masses to the east and southeast of the station, which completely blocked line-of-sight paths from the ocean surface to the antenna locations, preliminary testing of DF reception from various azimuths was conducted. Two EPIRB test locations were selected which included significant close-in land blockage in the line of sight to the receiving antenna: 7.6 mi on a bearing of 119°M and approxi-

mately the same distance on a bearing of 068°. No usable DF bearings were attained on either path. This contrasts with the Winthrop/LNB test point, a clear path of the same range, where bearings within $\pm 5^\circ$ of measured bearing were obtained from each of the three DF test units. After this directionality was established further testing was restricted to the areas to the north and northeast of the station (Boston Harbor, Winthrop, Nahant areas) and results similar to the Winthrop results were attained.

On September, 28, 1977, the demonstration was performed. An EPIRB was deployed in the President Roads anchorage area approximately 4 nmi from the Pt. Allerton Station. Immediately upon receipt of the signal by the Pt. Allerton radio watch, the station dispatched a 41 foot cutter and requested a bearing from the DF room. This bearing was then transmitted to the cutter, which was underway but not clear enough to use its homer. Upon reaching open water, the cutter obtained a homer bearing, which was within a few degrees of the initial bearing measured from the station. The cutter proceeded, pausing to search the Southeast shore of intervening Long Island, to home on and recover the first EPIRB. Prior to completion of the first recovery, a second EPIRB was deployed at a point approximately one nautical mile east of Winthrop Highlands (5 nmi from the station) and the cutter was given a bearing to the second EPIRB from Pt. Allerton. This time, since the cutter was not collocated with the land based DF, the cutter's homing bearing was used with the land based bearing to determine the bearing and distance to the EPIRB. Thus, it was not necessary to search the shore of intervening Deer Island on the trip to the second EPIRB. The rescue cutter located and recovered both EPIRBs within one hour after the first alert. Shore bearings taken during the demonstration were within 1° - 3° of the actual bearing to the EPIRB.

7. CONCLUSIONS AND RECOMMENDATIONS

The results of this investigation are best summarized in the following conclusions and recommendations. The recommended EPIRB parameters are summarized in Table 7-1.

1. An EPIRB output power of one watt will provide highly reliable reception at a range of 20 nautical miles, provided that:
 - a. The receiver antenna is located 100 feet or more above sea level.
 - b. The EPIRB transmitting antenna design provides good radiation characteristics at low elevation angles. "Good" is here defined as equivalent to a true isotropic antenna; i.e., a net gain of no less than 2 dB below a dipole.
2. The EPIRB need not transmit continuously. Rather, the transmission should be for short (10-20 seconds) periods, with longer (30-60 seconds) periods of no transmission. This has been shown to provide efficient operation with substantial savings in battery power and no loss of information. Further, it is recommended that the EPIRB transmission should initially be relatively frequent, about once per minute; it should then gradually slow down, so that after approximately eight hours the transmissions will occur only 10-12 times per hour.
3. The EPIRB can be equipped to transmit low bit rate (eight bits per second) digital data on Channel 15. Such data transmission can be used to provide the following features:
 - a. User identification. A 20 bit digital code, with a different code built into each unit at time of manufacture, will provide a unique identity for up to one million users. The number of unique

TABLE 7-1. RECOMMENDED EPIRB PARAMETERS

| | |
|---------------------|--|
| Power Output | 1 watt EIRP |
| Center Frequency | Alternately on VHF channels 15 and 16 |
| Transmission Cycle | 1/minute initially, decaying to 11 times/hour |
| Modulation | 1300 and 2200 Hz tones alternating 4 times/second. (Channel 16); FSK DATA transmission at 8 bits/second using the same tones (Channel 15). |
| Transmit Sequence | Channel 16 (2 seconds), switch to channel 15 (15 seconds, switch to channel 16 (2 seconds) |
| Frequency Stability | ± 5 parts per million, over the temperature range of -20°C to $+50^{\circ}\text{C}$. |
| Battery Life | 2 years storage, 24 hours operating at minimum temperature |
| Initial Turn-on | Manual switch with manually erected antenna. |

Unit shall float upright, with complete watertight integrity over the operating lifetime.

identities is easily increased; a 25 bit code will identify 33 million users and a 30 bit code will suffice for up to one billion users. At 8 bits per second, this will require less than four seconds of transmission time.

b. Situation encoding. A three bit code can generate information as to eight different situations or types of distress, entered by an external switch on the EPIRB. Some knowledge as to the nature of the distress situation would be extremely desirable; however, there is some evidence that most people will exaggerate the seriousness of the distress.

4. The recommended EPIRB modulation consists of a two-tone FSK signal. The tones used are 1300 Hz and 2200 Hz. Each transmission consists of a short (1-2 second) burst of tones on Channel 15, followed by a longer (15 second) burst on Channel 16 after which the Channel 16 transmission repeats. Each Channel 16 signal consists of the two tones alternating four times per second; the Channel 15 transmission utilizes the same two tones to transmit FSK data.

5. In areas of high boating activity and consequent high traffic density on Channel 16, reliable reception of the EPIRB transmission on Channel 16 can be very uncertain. Consequently, the Coast Guard should consider monitoring Channel 15 in high traffic density areas. It was demonstrated on this program that a receiver could be designed to correlate the Channel 15 data transmission so as to provide highly reliable alert detection at low signal reception. This receiver provided the following features.

a. Automated detection of an alert on Channel 15, thus minimizing the requirement for additional watch-standers.

- b. Extended range reception, beyond that provided by commercial VHF-FM receivers.
- c. Automated detection and readout of data (such as identification, etc.) encoded on the Channel 15 transmission.
- d. A simple, low cost implementation, provided by microprocessor control of all post-detection processing.

Accordingly, it is recommended that the Coast Guard implement shore stations with a production version of this receiver, so as to take maximum advantage of the Channel 15 transmission.

identities is easily increased; a 25 bit code will identify 33 million users and a 30 bit code will suffice for up to one billion users. At 8 bits per second, this will require less than four seconds of transmission time.

b. Situation encoding. A three bit code can generate information as to eight different situations or types of distress, entered by an external switch on the EPIRB. Some knowledge as to the nature of the distress situation would be extremely desirable; however, there is some evidence that most people will exaggerate the seriousness of the distress.

4. The recommended EPIRB modulation consists of a two-tone FSK signal. The tones used are 1300 Hz and 2200 Hz. Each transmission consists of a short (1-2 second) burst of tones on Channel 15, followed by a longer (15 second) burst on Channel 16 after which the Channel 16 transmission repeats. Each Channel 16 signal consists of the two tones alternating four times per second; the Channel 15 transmission utilizes the same two tones to transmit FSK data.

5. In areas of high boating activity and consequent high traffic density on Channel 16, reliable reception of the EPIRB transmission on Channel 16 can be very uncertain. Consequently, the Coast Guard should consider monitoring Channel 15 in high traffic density areas. It was demonstrated on this program that a receiver could be designed to correlate the Channel 15 data transmission so as to provide highly reliable alert detection at low signal reception. This receiver provided the following features.

a. Automated detection of an alert on Channel 15, thus minimizing the requirement for additional watch-standers.

APPENDIX A

COMPUTER EVALUATION OF RECEIVED SIGNAL STRENGTH-- SPHERICAL EARTH AND SURFACE ROUGHNESS INCLUDED

NOTE: THIS WORK WAS PERFORMED BY GTE/SYLVANIA
COMMUNICATIONS SYSTEMS DIVISION ON PURCHASE
ORDER NUMBER TS-13-777.

A.1 INTRODUCTION

The performance of the proposed maritime navigational beacon system and of the associated direction finder, to be deployed with surface vessels in the coastal waterways, depends on the precise sizing of the transmitted power if the system is to remain effective in all circumstances and at distances encompassing most of the expected traffic.

To facilitate such a sizing it is necessary to predict the field strength, at the indicated frequency, in the sea environment. That environment implies a propagation path which is, generally, highly conducting and can be, potentially, rough. Furthermore, because of the limitations on antenna heights, much of the service area is expected to be below the horizon and, therefore, accessible only by the groundwave.

A.2 SCOPE OF CALCULATIONS

The propagation prediction is made for an electromagnetic field transmitted at 156.8 MHz over a sea path characterized by the sea state 0, 1, 2, 3, 6, and 9. The transmitting antenna is assumed to be a ground-based quarter-wave monopole. The radiated

power is 1. watt. Reception at heights from 0. to 3048. meters is indicated. The resulting ground distances, dictated by the requirements of constant field of 30., 10., 3., 1., and .3 and .1 $\mu\text{V/m}$, extend to 300. km.

The computation is repeated for a fresh water path but only for "sea state" 0 (i.e., 0. wind velocity). The reason for this limitation is given below.

A.3 LIMITATIONS

The computer codes used in the present computation are based on the results of work done by van der Pol and Bremmer¹, Barrick² and Kaliszewski^{3,4}. So far as their use at VHF and in a sea environment is concerned certain assumptions implied in the above analyses must be scrutinized and, in particular, those defining the limitations on the validity (and use) of the concepts of the surface impedance, of the apparent conductivity and of the roughness criteria.

A.3.1 Normalized Surface Impedance

The implied limitation on that parameter is

$$|\Delta| < 1$$

where

$$\Delta = \frac{1}{\sqrt{\epsilon_r - 160\lambda\sigma}}$$

Here, ϵ_r is a relative dielectric constant of the ground, λ - is a wavelength, in free space, in meters and σ - is conductivity in mhos/m.

In our case we have:

| | |
|--------------|----------------------------------|
| I. Sea Path: | $\epsilon_r = 80$ |
| | $\sigma = 4. \text{ mhos/m}$ |
| | $f = 158.6 \text{ MHz}$ |
| | $\lambda = 1.913 \text{ meters}$ |

Consequently,

$$|\Delta| = 0.0463 \ll 1.$$

and the criterion is satisfied in sea environment.

$$\begin{aligned} \text{II. Fresh Water Path: } \epsilon_r &= 80. \\ \sigma &= 0.01 \end{aligned}$$

$$|\Delta| = .112 < 1.$$

We conclude, therefore, that the implied limitation on the boundary condition is satisfied in both cases.

A.3.2 Apparent Conductivity

Crucial to the use of the concept of the apparent conductivity is the assumption

$$\Delta \approx \frac{1}{\sqrt{60\lambda\sigma}e} + i45^\circ$$

or

$$(60\lambda\sigma) > \epsilon_r.$$

In sea environment:

$$60 \lambda \sigma = 459. > 80.$$

In fresh water environment:

$$60 \lambda \sigma = 1.148 < 80.$$

We conclude, therefore, that without further analysis the concept of an apparent conductivity cannot be used in fresh rough water environment. Consequently, we limit our computation here to $SS = 0$ (i.e., 0. wind velocity).

A.3.3 Roughness Criteria

The assumption underlying Barrick's analysis (and the present prediction program) is that the roughness of the propagation path be "slight", i.e.,

$$(K_0 \xi)^2 \leq 1$$

where

$$K_0 = 2\pi/\lambda$$

and ξ - is the surface height above a mean level.

For a wind driven sea surface we have the following theoretical relation:

$$\bar{h} = 4.345 \cdot 10^{-3} \sqrt{U^5}$$

where U is the wind velocity in meters/sec.

By setting $(K_0 \xi)^2 = 1$ we obtain the upper limit of applicability and, hence,

$$\bar{h} \approx .3045 \text{ meters}$$

and

$$U \approx 5.473 \text{ m/sec.}$$

corresponding, roughly, to sea state 2.

A little more relaxed criterion is obtained from the relation (implied in the program) derived from the Phillips model of the sea surface:

$$(K_0 \cdot \sigma)^2 \leq 1.$$

where

$$\sigma^2 = \frac{1}{2} BU^4/g^2$$

$$B = 0.005$$

$$g = 9.81 \text{ m/sec.}^2$$

Hence, at 158.6 MHz,

$$\sigma \approx .3045 \text{ meters}$$

and

$$U \approx 7.73 \text{ m/sec.}$$

or, roughly, corresponding to sea state 3.

We conclude, therefore, that the existing program can be used readily up to sea state 3. In fact we have exercised it also at sea states 6 and 9 and find the results to be quite agreeable although, as indicated above, we cannot justify the validity of the results at these high sea states.

A.4 RESULTS

As already noted the results consist of a set of computer printouts and a set of field contour plots. The computer printouts, because of their size, are not included in this report.

Each of the printouts is identified by the following parameters: frequency (in MHz), radiated power (in KW), gain (relative to a short monopole), wind velocity (in meters/sec.), transmitter and receiver height (in meters). In addition we identify the polarization and the model of refractive atmosphere (standard, implying a $4/3$ earth radius). Also listed is the distance to horizon (in km). For definition of this quantity and also of SIG.DBW refer to the enclosed STN.

To construct the field contours an intermediate step consisting of a plot of the field strength versus distance (for constant height) is used. These plots are not shown. Contours of constant field strength are obtained by intercepting all of the constant height curves and noting the corresponding distances. The end results of this procedure are shown in Figs. A-1 to A-7 in which contours of constant field are plotted. The figures are identified only by the sea state but it should be understood that all of the parameters identified in the printouts are implied.

A.5 SOME CONCLUSIONS

The contours, despite some scatter of data point, show great regularity and, as expected at the indicated frequency, show also only small dependence on the sea state. To be more specific let us compare the field strengths at various sea states, zero heights and (an arbitrary) reference distance of 50. km. The comparison is shown in Table A-1.

TABLE A-1. COMPARISON OF CONTOURS AT VARIOUS SEA STATES

| Sea State | Field Strength, $\mu\text{V}/\text{m}$ | Difference, db |
|-----------|--|----------------|
| 0 | 0.222 | 0 |
| 1 | 0.187 | 1.476 |
| 2 | 0.161 | 2.794 |
| 3 | 0.140 | 4.003 |
| 6 | 0.098 | 7.030 |
| 9 | 0.038 | 15.526 |

The comparison would indicate, at the specific heights and distance, a relative decrease in field strength of approximately 1.5 dB per sea state (or 5. knots in wind velocity). Surprisingly, this regularity extends well beyond the sea state which can be justified by the theoretical considerations.

The contours shown in Figs. A-1 to A-7 afford a quick appraisal of the permissible path geometry for a prescribed signal strength. Unfortunately, for low elevations the contours tend to be crowded and, in fact, obscure the intercept points at zero elevation. However, these can be recovered from the printouts. For example, the intercept point for SS = 0, .1 $\mu\text{V}/\text{m}$ (zero elevation) can be read from the printout, at about 60. km.

It should be noted that most (but not all) data points were obtained at reception points below the horizon. This is quite fortunate for the computer fields are then truly radial (i.e., locally vertical). This is not the case with the line-of-sight paths where (1) further decomposition of the field strength may be necessary, and (2) the elevation pattern of the monopole must be considered. A modification of the program to enhance its LOS prediction capability is quite possible but must await a future opportunity.

APPENDIX B
PROBABILITY OF OVERLAP VERSUS EPIRB DUTY CYCLE

For the purposes of this analysis, it is presumed that the probability of EPIRB detection must be very high, say 99.99%, over the first 15 or 20 minutes of transmission. We will assume that during this interval the EPIRB transmits 40 times. Now, the receiver analysis of Section 5 indicates that a probability of detection of 90% in the absence of overlap and with the EPIRB at a range of roughly 20 nm is a reasonable design goal. This means that in order to achieve 99.99% probability of detection, the EPIRB transmission must be received at least 4 times out of 40 without overlap.

B.1 DUTY CYCLE CONSIDERATIONS

Figure B-1 depicts the transmission overlap situation. In particular, it is assumed that the desired signal duration and the interfering signal duration are identical. However, the times between retransmissions are different. The probability of no overlap of the desired signal by one interferer is given by

$$\text{Prob. of no overlap} = \frac{T_{\text{off } b} - T_{\text{on } a}}{T_{\text{off } b} + T_{\text{on } b}} \quad (\text{B-1})$$

But, it is assumed that

$$T_{\text{on } a} = T_{\text{on } b} \quad (\text{B-2})$$

and, the duty cycle of the interferer is

$$\delta_b = \frac{T_{\text{on } b}}{T_{\text{off } b} + T_{\text{on } b}} \quad (\text{B-3})$$

FIGURE B-1. THE OVERLAP PROBLEM

$$\text{Prob. of no overlap} = 1 - 2 \delta_b \quad (\text{B-4})$$

and

$$\text{Prob. of overlap} = 1 - (1 - 2 \delta_b) = 2 \delta_b \quad (\text{B-5})$$

One of the objectives of the EPIRB system design effort is to provide reliable EPIRB detection performance when up to 4 EPIRBs are transmitting simultaneously. Using Eq. (B-4) it is easily found that the probability of no overlap of the desired signal by interferers B, C, or D in Fig. B-1 is given by

$$P = \text{Prob. of no overlap} = (1 - 2 \delta_b)(1 - 2 \delta_c)(1 - 2 \delta_d) \quad (\text{B-6})$$

and

$$Q = \text{Prob. of overlap} = 1 - (1 - 2 \delta_b)(1 - 2 \delta_c)(1 - 2 \delta_d) \quad (\text{B-7})$$

The system will meet its performance objective provided that four or more of the transmissions of the desired signal are not overlapped by one of the potential interferers, B, C, or D. We can compute the probability of at least four unoverlapped transmissions out of 40 transmissions using the following expression:

Prob. of less than 4 "no overlap" transmissions out of 40 transmissions =

$$P_{\text{NO}} = Q^{40} + \frac{40!}{39!1!} Q^{39} P + \frac{40!}{38!2!} Q^{38} P^2 + \frac{40!}{37!3!} Q^{37} P^3 \quad (\text{B-8})$$

For clarity we first assume that all the interferers have the same duty cycle, $\delta_b = \delta_c = \delta_d = \delta$. Using Eq. (B-6), (B-7), and (B-8), the probability of less than 4 "no overlap" transmissions out of 40 is calculated as a function of the interferer's duty cycle. The results are shown in Table B-1.

TABLE B-1. PROBABILITY OF SUBSTANDARD DETECTION PERFORMANCE VS. DUTY CYCLE

| δ = Duty Cycle of Interferers | Prob. of Poor Performance |
|---|---------------------------|
| $\delta = 0.1$ | 4.24×10^{-9} |
| 0.15 | 8.27×10^{-5} |
| 0.2 | 1.64×10^{-2} |
| 0.25 | 2.46×10^{-1} |
| 0.3 | 7.48×10^{-1} |
| 0.35 | 0.978 |
| 0.4 | 0.999 |
| $\delta_b = 0.25, \delta_c = 0.15, \delta_d = 0.0625$ | 4.54×10^{-4} |
| $\delta_b = 0.25, \delta_c = 0.15, \delta_d = 0.15$ | 5.69×10^{-3} |

The table clearly shows that there is a rapid onset of poor performance when the duty cycle of the interferer is in the vicinity of 20%. Moreover, the table shows that if the duty cycle of the interferers is less than 10% there is no chance that less than 4 transmissions out of 40 from a given EPIRB will be overlapped by any of the other three EPIRB transmissions. Table B-1 also shows the more complicated case in which the duty cycles of the 3 potential interferers is not the same. Here again, good performance will be achieved as long as the duty cycles of the potential interferers is less than 20% on the average.

The discussion of this section shows that the system can provide adequate performance with 4 EPIRBs operating simultaneously provided that the duty cycles of the 3 interfering EPIRBs is roughly 20% or lower and that the duty cycle of the desired EPIRB signal is high, i.e. roughly 50%. Figures B-2 and B-3 show candidate duty cycle patterns for the EPIRB system. These patterns are easily generated using low cost digital logic in the EPIRB system. The pattern of Fig. B-2 begins with a duty cycle of 40%. This duty cycle remains for the first 400 seconds (6.66 minutes). Then the duty cycle is reduced to 25% and this persists for the next 640 seconds. The duty cycle is reduced at regular intervals

until it reaches a level of 4% after 9 hours. In the system of Fig. B-2 this low duty cycle would be maintained for the rest of the 24 hour transmission time. The design of Fig. B-2 assumes a transmission time of 10 seconds per transmission. Following the pattern of Fig. B-2 the EPIRB would transmit 40 times in roughly 25 minutes. This corresponds to the assumptions used above in the overlap analysis. The pattern of Fig. B-3 can be generated using the same hardware as that used to generate the pattern of Fig. B-2. It is important to note that at this point that the hardware is sufficiently flexible that a wide variety of duty cycle patterns could be generated using the same hardware. The two patterns of Fig. B-2 and B-3 are given as illustrative examples. In Fig. B-3, the duty cycle begins at 50% and is reduced to 25% after 13.65 minutes. The duty cycle is reduced at regular intervals until it reaches 0.0625 after 6.37 hours. It is assumed that this duty cycle is then maintained for the rest of the 24 hour transmission cycle. The system of Fig. B-3 employs a 12.8 second transmission time. Thus, the transmission is repeated 40 times in roughly 20.5 minutes. Again, these parameters correspond closely to those assumed in the overlap analysis. However, the overlap analysis shows that for reliable detection in under 20 minutes, the final duty cycle need not be reduced much below 20%. By reducing the final duty cycle below 10% as shown in Figs. B-2 and B-3, more rapid detection of an EPIRB is assured, and less battery power is required.

The test phase of the EPIRB design effort indicated that a typical transmission sequence could proceed as follows: Each transmission would begin with 2 seconds of alternating 1300 Hz - 2200 Hz tones on channel 16. Transmission on channel 15 for 15 seconds would follow the channel 16 transmission. Then a 2 second transmission on channel 16 would terminate the sequence.

Thus, total ON time per transmission is 19 seconds. Total time on channel 15 would be 15 seconds. The unit could be implemented to provide a 50% duty cycle on channel 15, at first. (That is, the total transmission cycle would be 30 seconds.) Then

FIGURE B-2. EPIRB VARIABLE TRANSMISSION RATE

 n = 1,2,3 8

FIGURE B-4. DUTY CYCLE PATTERN BASED ON U.S.C.G. SAR STATISTICS

following the same algorithm assumed for Fig. B-3, the EPIRB would provide the transmission pattern shown in Fig. B-4. The characteristics of this pattern are summarized in Table B-2.

TABLE B-2. DUTY CYCLE PATTERN "A"

| Duty Cycle | Rate | Duration | Cum. Time |
|------------|----------|----------|---------------------|
| 50% | 2/min. | 16 min. | 16 min. |
| 25% | 1/min. | 32 min. | 48 min. |
| 16.66% | 40/hr. | 48 min. | 96 min. |
| 12.5% | 30/hr. | 64 min. | 160 min. |
| 10.0% | 24/hr. | 80 min. | 240 min. (4 hrs.) |
| 8.33% | 20/hr. | 96 min. | 336 min. (5.6 hrs.) |
| 7.14% | 17.1/hr. | 112 min. | 448 min. (7.5 hrs.) |
| 6.25% | 15/hr. | - | 24 hrs. |

This pattern provides a very high duty cycle for the first 16 minutes during which time the SAR vessels get under way. Coast Guard data indicates that in 50% of all incidents the rescue vessel will be on the scene in 2 hours or less. At this point, the duty cycle is 12.5%, i.e., transmission for 15 seconds every 2 mins. on channel 15 and 2 transmissions of 2 seconds each every 2 minutes on channel 16. After 8 hours of operation, the duty cycle has been reduced to 6.25% (15/hr.) and it remains at this level until the end of the 24 hour life of the transmission. This duty cycle is designed to conform to data that shows that the SAR vessel is on scene within 2 hours 50% of the time, in 6 hours 95% of the time and in 8 hours, over 99% of the time.

Figure B-4 also shows a second reasonable duty cycle implementation which conforms to available U.S.G.C. SAR statistics. The characteristics of this pattern are shown in Table B-3.

TABLE B-3. DUTY CYCLE PATTERN "B"

| Duty Cycle | Rate | Duration | Cum. Time |
|------------|-----------|------------|-----------------------|
| 26.3% | 1.05/min. | 30.4 min. | 30.4 min. |
| 15.8% | 37.9/hr. | 101.3 min. | 131.7 min. (2.2 hrs.) |
| 8.8% | 21.1/hr. | 364.8 min. | |
| 4.6% | 11.1/hr. | - | 24 hrs. |

Patterns "A" and "B" are quite similar in the region from 1000 sec. to 30000 secs. (8.27 hrs.). The differences between the two patterns occur at the beginning and the end of the duty cycle patterns. Both satisfy the general constraints of the EPIRB multiple access requirement. Namely, the duty cycles are less than 20% most of the time. However, the duty cycle pattern of Table B-3 is the one recommended for implementation. It is the simplest of all those considered, and the changes in the pattern correspond most closely to the available statistics on time to rescue.
