#### PREFACE

This research was conducted under project 7719, Air Force Development of Selection, Assignment, Performance Evaluation, Retention and Utilization Devices; task 771915, Perceptual and Computer managed measurement.

The author wishes to extend his appreciation to Dr. Vern Urry, United States Civil Service Commission, and to Dr. Frederick M. Lord, Educational Testing Service, for making their computer programs available and for their suggestions concerning the simulation and analyses. James R. McBride, Naval Personnel Research and Development Center, James B. Sympson, University of Minnesota, and Vincent Maurelli, Army Research Institute, provided much appreciated assistance in the conduct of this study.

#### ESTIMATING ITEM CHARACTERISTIC CURVES

#### I. INTRODUCTION

Increased interest in computer-driven adaptive testing, automated item banking, and automated test construction has made the estimation of the Item Characteristic Curve (ICC) important. This curve describes the relationship between the ability of individuals and the probability of their answering a test question correctly. It is useful in estimating test scores, equating the scores of various tests, and scoring responses during adaptive testing. There are several methods for estimating ICC within available computer programs. Selection and implementation of the appropriate program becomes a task for the practitioner. The objective of this study is to compare the merits of four available computer programs.

#### The Research Problem

In order to estimate an ICC, a conceptual model must be defined and item parameters must be estimated. The three-parameter logistic model of Birnbaum (Lord & Novick, 1968) is the most frequently used for relating item responses to subjects' ability. The three parameters, a, b, and c, are item discrimination, item difficulty (or location), and probability of chance success (or lower asymptote), respectively.

The curve described by these parameters takes the shape of an (cumulative frequency) ogive or an "s" with the upper asymptote approaching a probability of 1.0 and usually a lower asymptote of a probability greater than 0.0. The ogive describes the probability of obtaining a correct answer to an item as a monotonic increasing function of ability.

The item discrimination parameter (a) is a function of the slope of the ICC and generally ranges from .5 to about 2.5. The value of a equal to about 1.0 is typical of many test items, while a values below .5 are insufficiently discriminating for most testing purposes, and a values above 2.0 are infrequently found.

The item difficulty parameter (b) describes the point of inflection of the ICC and is usually scaled between -2.5 and +2.5 although the metric is arbitrary.

The item guessing parameter (c) is the lower asymptote of the ICC and is generally conceived to be the probability of selecting the correct item-option by chance alone. Most test items have c parameters greater than 0.0 and less than or equal to .30.

Figure 1 shows three ICCs. The horizontal axis is scaled in units of ability ( $\Theta$ ), and the vertical axis is the probability of answering the item correctly. The solid curved line shows an ICC for an item of average difficulty with acceptable discrimination and the lower asymptote appropriate for a five-item multiple-choice item. The dashed line shows an item of identical difficulty, c value of .28, but with a lower a value. Note how the slope of the curve is less steep. The third curve, dot-dash line, shows an item with a c value of .30, an a parameter of 1.0, and the b parameter equal to 1.0. As the b parameter changes, the location of the inflection point of the curve is displaced along the horizontal axis.

In most cases the test constructor is faced with the task of estimating three parameters for the *n* items and one ability parameter ( $\Theta$ ) for every examinee (*N*) so that *N* + 3*n* parameters must be estimated for each group of test items. For a group of 2,000 examinees taking 80 items, 2,240 [2,000 + (3 x 80)] parameters must be estimated simultaneously. In an iterative procedure, this estimation must be repeated several times which leads to long computer runs with more precise estimates. Three of the four ICC estimation procedures evaluated in this study are iterative. The fourth is a monotonic increasing function of the biserial correlation between the item and raw score.

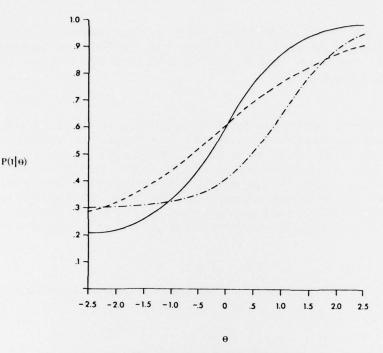

Figure 1. Item characteristic curves.

#### II. METHOD

A simulation was run in order to have known values for ability level ( $\Theta$ ) and for the item parameters. Three distributions of ability ( $\Theta$ ) with differing shapes were generated on which to test the procedures for ICC parameter estimation. Each  $\Theta$  is equivalent to a "subject." The generated item parameters (a, b, c) remained constant across the three distributions of ability ( $\Theta$ ).

Four methods of assessing the adequacy of the ICC estimation procedures were used. First, the estimated item parameters  $(\hat{a}, \hat{b}, \hat{c})$  were correlated with the known item parameters: second, the  $\Theta$  estimated by using  $\hat{a}, \hat{b}$ , and  $\hat{c}$  from each estimation procedure was correlated with the known  $\Theta$ . Third "true scores" and estimated "true scores" from the  $\hat{a}, \hat{b}$ , and  $\hat{c}$  were compared (Lord, 1975). Finally, the test information curve was compared with estimates of the test information curve using the item parameters estimated in the three data sets. Table 1 shows the means, standard deviations, and minimum and maximum  $\Theta$  for the three data sets.

<i>Table 1.</i> Descriptive Statistics for the Distribution of $\Theta$ for the Three Data Sector	Table 1.	Descriptive	Statistics f	or the	Distribution of	f \varTheta fa	or the	Three Data S
---	----------	-------------	--------------	--------	-----------------	----------------	--------	--------------

Data Set	Mean	Standard Deviation	Minimum	Maximum	Skew	Kurtosis
1	0012	1.4437	-2.50000	2.4975	.0000	1.7991
2	.4957	.6998	5064	2.3791	.6359	2.7302
3	.0126	1.0191	-3.8445	3.6685	0050	3.1144

#### Data Set 1 (DS1)

The distribution of  $\Theta$  for DSI was generated by dividing the interval between -2.5 and +2.5 into 2,000 equal intervals and assigning each resultant number as a value of  $\Theta$ . This data set is similar to those sometimes produced for item analytic studies for tests such as the Armed Services Vocational Aptitude Battery (Jensen, Massey, & Valentine, 1976).

#### Data Set 2 (DS2)

The distribution of  $\Theta$  for DS2 was generated by obtaining 3,000 cases from a unit normal random number generator. Two thousand values for  $\Theta$  were selected by administering a "test" and generating a sum of the number-right scores for the 3,000 based on ICC parameters of a 30-item subtest used in military selection and classification. A cutting score was set which would yield the upper two-thirds of the population. This method, rather than just cutting at a  $\Theta \equiv 33.3$  percentile equivalent, was used to emulate actual selection practices which involve errors of measurement. The resultant distribution does not have a sharp truncation of  $\Theta$  but is asymmetric with few scores below a specified level. DS2 is similar to samples frequently available to organizations which must work with samples selected for inclusion in training or education.

#### Data Set 3 (DS3)

The distribution of  $\Theta$  for DS3 was generated by accessing the unit normal random number generator for 2,000 numbers.

#### **ICC Parameters**

The distributions of ICC parameters were generated to simulate 80 five-option multiple-choice test questions. A normal distribution was specified for each ICC parameter. The means and standard deviations of these distributions were set to produce item parameters similar to those likely to be obtained in actual practice. Table 2 describes these distributions.

Table 2. Descriptive Statistics of the Generated ICC Parameters

ICC Parameter	Mean	Standard Deviation	Minimum	Maximum
a	.9504	.2837	.4647	1.6136
Ь	.1635	.9286	-1.6530	1.9745
с	.2009	.0458	.0872	.3479

Note. - These ICC parameters were used for all three data sets.

#### **Generation of Item Responses**

In order to generate a vector of item responses for each "subject" the  $\Theta$  values were used in equation (1) to compute the likelihood of "passing" each item. The three parameter logistic model is given by:

$$P(\Theta)_{j} = c_{i} + (1 - c_{i})(1 + e^{(-1.7a_{i}(\Theta - b_{i}))}) - 1$$
(1)

where  $P(\Theta)_i$  is the probability of "subject" j answering the test item correctly and  $a_i$ ,  $b_i$ , and  $c_i$  are item parameters for item i.

Because equation (1) yields a number  $P(\Theta)_j$  such that  $0.0 < P(\Theta)_j < 1.0$ , a number,  $X_j$ , is drawn from a uniform (rectangular) distribution ranging from 0.0 to 1.0 and compared to  $P(\Theta)_j$ . If  $X_j$  is larger than  $P(\Theta)_j$ , then an incorrect response is specified for the item; otherwise, a correct response is specified for the item. Thus, a "subject" with  $P(\Theta)_j = .90$  gets the item correct 9 in 10 times, and a vector of item responses is developed for each "subject" in each data set. These response vectors are then used to estimate a, b, and c by the four methods.

#### **Estimation of ICC Parameters**

The following four methods of ICC estimation were selected because of their wide availability to practitioners: ANCILLES, LOGIST, OGIVIA, and transformations to the item-test biserial correlation. All are three-parameter models.

ANCILLES and OGIVIA (developed by U. S. Civil Service Commission) are described by Urry (1977, 1978) and LOGIST (developed by Educational Testing Service) is described by Wood, Wingersky, and Lord (1976). The transformations may be found in Lord and Novick (1968). These procedures were implemented on a UNIVAC 1108 and thoroughly checked out by processing the sample data set supplied by each of the authors of the programs. Default options for the programs were specified where possible, and the logistic model was used throughout.

#### III. RESULTS

The first set of analyses consisted of correlating the ICC parameters with the estimated ICC parameters  $(\hat{a}, \hat{b}, \hat{c})$ . Table 3 shows these results for each data set.

		ANCILLE	s		LOGIST			OGIVIA		Tra	nsformati	on

Table 3. Correlations of ICC and Estimated ICC Parameters

\*Constant value of c = .20 precludes calculation of correlation.

\*\* Entries for ANCILLES and OGIVIA based on 75 and 64 items, respectively.

The second set of analyses was of the correlation of  $\Theta$  and  $\widehat{\Theta}$  computed using a maximum likelihood method and the various estimates of a, b, and c from the four procedures. These correlations were analyzed to determine how accurately  $\Theta$  could be estimated from  $\hat{a}, \hat{b}$ , and  $\hat{c}$  as would be done in adaptive testing.

Maximum Likelihood Estimation (MLE) of  $\Theta$  is computed using the likelihood function defined as:

$$L(\Theta) = \Pi(P(\Theta)^{u} Q(\Theta)^{1} - u)$$
<sup>(2)</sup>

where  $Q(\Theta) = 1 - P(\Theta)$  and u is 1 if the item was answered correctly and 0 if answered otherwise. The maximum of the distribution of likelihoods is found by the method derived by Jensema (1974). The use of this procedure is advantageous because it allows the estimation of  $\Theta$  regardless of the sequence of item administration. Other methods, such as Bayesian estimation of  $\Theta$ , are sequence dependent (see Sympson, 1976).

MLE is not sequence dependent but has the problems of possible failure to converge or of reaching an asymptotically infinite estimate. Both of these problems can be rectified by arbitrarily placing a limit on the number of iterations and by placing an upper and lower limit on  $\hat{\Theta}$ . Maximum Likelihood Estimates of  $\Theta$  were computed using the response vectors generated from equation (1), each set of estimated item parameters, and the generated item parameters. The estimation of  $\hat{\Theta}$  using the generated (a, b, c) item parameters indicates the bias involved in the estimation of  $\Theta$  alone. The correlation of  $\Theta$  and the resultant  $\hat{\Theta}$  is a measure of test reliability. No correlation of  $\Theta$  and  $\hat{\Theta}$  using the generated a, b, c. Table 4 shows the results of these analyses. The column headed Population is the analysis using the generated item parameters.

# Table 4. Descriptive Statistics for the Estimates of $\Theta$ Computed<br/>from the Generated and Estimated Item Parameters

(N = 2,000)

<sup>a</sup>Indicates number-right score and the all descriptive statistics referred to the number-right score. The correlation is between  $\Theta$  and S.

The third set of analyses follows guidance proposed by Lord (1975) to eliminate most of the problems associated with estimating extreme values of  $\Theta$ . These are termed true score ( $\xi$ ) analyses. Because MLE procedures tend to exhibit bias on extreme cases, there may be a piling-up of high values at the minimum and maximum values allowed by the particular estimation routine. There are no empirical rules for setting either minimum or maximum values to be obtained in the MLE process. The limits set depend on judgment. In this study, the values were set at -2.50 and +2.50. Other values might have yielded slightly different values in Table 4. Estimation of true scores avoids these problems. Equation 3 defines true score.

$$\xi_j = \sum_{i=1}^n P_i(\Theta) \tag{3}$$

where  $\xi_i$  is the true score, *n* is the number of items, and  $P_i(\Theta)$  is the probability of a correct response for

the item as in equation (1). Similarly, the estimated true score is given by

$$\hat{\xi}_{j} = \sum_{i=1}^{n} P_{i}(\hat{\Theta})$$
(4)

where  $P_i(\hat{\Theta})$  is computed from equation (1) using  $\hat{a}, \hat{b}$ , and  $\hat{c}$ .

Table 5 shows the means and standard deviations of  $\xi$  and  $\hat{\xi}$ , the average difference between them, and their intercorrelation.

# Table 5. Descriptive Statistics of $\xi$ and $\hat{\xi}$ , the Average Difference Between Them and Their Correlation

<sup>a</sup>75 items only for  $\xi$  and  $\hat{\xi}$ .

<sup>b</sup>64 items only for  $\xi$  ans  $\hat{\xi}$ .

The fourth set of analyses consisted of comparisons of the test information curve using the known a, b, c versus test information computed from  $\hat{a}$ ,  $\hat{b}$ ,  $\hat{c}$  from the four-item parameter estimation techniques.

Item information is defined as

$$I_{g}(\Theta) = \frac{\left(\frac{\partial}{\partial\Theta} P_{g}(\Theta)\right)^{2}}{P_{g}(\Theta)\left(1 - P_{g}(\Theta)\right)}$$
(5)

where  $P_g(\Theta)$  is estimated from equation (1) and the numerator is the squared first derivative (i.e., the squared slope) of  $P_g(\Theta)$  at a fixed value of  $\Theta$ . Test information is the sum of the item information curves making up a test and is defined as

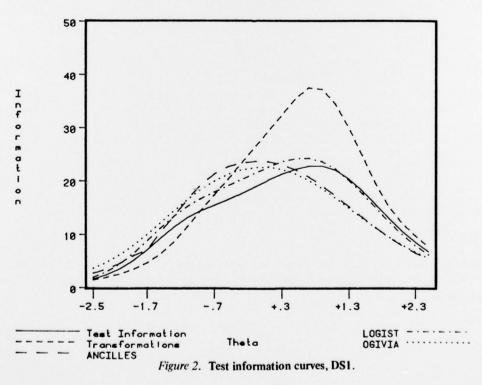

$$I(\Theta) = \sum_{i=1}^{n} I_g(\Theta)$$
(6)

where  $I_g(\Theta)$  is defined in equation (5). Estimates of item information (Î) may be computed by substituting  $\hat{a}, \hat{b}, \hat{c}$  into equation (1) and substituting that quantity into equations (5) and (6).

It is useful to calculate item and test information curves in order to determine the precision of measurement of a test or an item. The height of the item or test information curve at any level of  $\Theta$  may be thought of as being an ICC analog to classical measures of reliability. The higher the information curve the higher the information value and the higher the reliability of the item or test at that level of  $\Theta$ .

Test information curves are frequently used to compare test characteristics (Brown & Weiss, 1977; McBride & Weiss, 1976; Vale & Weiss, 1977; and Weiss, 1975) and to select items for administration during adaptive testing (Jensema, 1974; Ree, 1977). Because test and item information curves are computed using ICC parameters, errors of estimation of the parameters can cause errors in the test and item information curves.

Figures 2, 3, and 4 show the test information curve and estimates of the test information curve based on  $\hat{a}, \hat{b}, \hat{c}$  estimated by the four methods in each of the data sets. The item parameters have been made comparable by placing them on common metric via a linear transformation of *a* and *b*. No such transformation of *c* is necessary. Table 6 presents the sum of squared deviations of true test information minus estimated test information as well as the point on  $\Theta$  where information reaches its maximum ( $\Theta_g$ ), the correlation of I and  $\hat{I}$ , and minimum and maximum values of  $\hat{I}$  computed by each method in each of the data sets.

#### Table 6. Information Analysis and Estimated Information Analyses Based on ICC Parameters

<sup>a</sup>75 items only.

<sup>b</sup>64 items only.

#### **IV. DISCUSSION**

The results clearly indicate that no one program functions best in all situations posed by the three data sets. The transformation procedure performed poorly in most instances and is not recommended unless no other procedures are available.

In the rectangular data set (DS1), LOGIST produces results superior to the other procedures except in terms of the average differences between  $\xi$  and  $\hat{\xi}$ . The correlations of estimated item parameters and generated item parameters,  $\Theta$  and  $\hat{\Theta}$ , I and  $\hat{I}$ , and  $\xi$  and  $\hat{\xi}$ , are higher for LOGIST than for any other procedure. LOGIST estimated item parameters also most nearly reproduce the test information curve.

The results from the skewed and selected data set, DS2, call attention to a peculiarity exhibited by ANCILLES and OGIVIA. Under specific conditions, these two programs will not estimate parameters of some items. While this may seem a disadvantage, notice that  $(\xi - \hat{\xi})$  for OGIVIA is the smallest in DS2. Note also that OGIVIA shows (Table 4) an r $\Theta$ . $\hat{\Theta}$  of .937 for 64 items compared to .943 for 80 items using LOGIST. This increase of .006 is very small for the addition of 16 items. LOGIST estimates item parameters for all the items, but inspection of the scatter plot of b versus  $\hat{b}$  indicates several outliers which have the effect of substantially reducing the value of  $rb.\hat{b}$ . All the estimated test information curves computed from DS2 estimates of the item parameters approximate the true test information curve very poorly. The OGIVIA procedure is the most preferable for use in the normally distributed data set, DS3. The correlations of OGIVIA estimated  $\hat{a}$  and  $\hat{b}$  with a and b are higher than for the other procedures; however, its correlation of c and  $\hat{c}$  is less than that of either ANCILLES or LOGIST. The r $\Theta$ .  $\hat{\Theta}$  using OGIVIA is as high as LOGIST and higher than all others. The r $\xi$  for OGIVIA is the highest and simultaneously has the smallest average difference between  $\xi$  and  $\hat{\xi}$ . OGIVIA is built around assumptions of the normality of the distribution of  $\Theta$  and performs very well when these conditions hold true, as in DS3, or approximately hold true, as in DS2. LOGIST estimates of the item parameters produce the highest correlation between I and  $\hat{T}$  and the lowest sum of squared deviants of I minus  $\hat{T}$  and thus the best estimate test information.

The decision as to which procedure to use must be based on a series of criteria. If all the items must be calibrated, then OGIVIA and ANCILLES may present problems in a situation like that represented by DS2. If wide range samples like DS1 and DS3 are available and the estimation of  $\Theta$  is the goal, then calibration with LOGIST or OGIVIA is recommended. Clearly, if the examinees are available, a normal distribution of  $\Theta$  leads to the best estimations of  $a, b, c, \xi, \Theta$ , I and is desirable. These data should then be calibrated using OGIVIA.

A final factor should be considered: cost. The transformation procedure was the quickest because, unlike the others, it is not iterative and its work can be accomplished in about 10 FORTRAN statements. The LOGIST procedure takes the longest on the computer. It ran eight times longer than either ANCILLES or OGIVIA. Central Processor Unit (CPU) times on a UNIVAC 1108 with 262K words of memory for DS3 were for ANCILLES, 296 seconds; LOGIST, 2,061 seconds; OGIVIA, 180 seconds; and transformations, 38 seconds.

The choice of ICC parameter estimation techniques should be consistent with the planned use of the estimates, the characteristics of the distribution of ability in the groups available for item administration, the necessity to calibrate all items, and the computer resources available.
