PREFACE

The second Maurice Ewing Symposium was devoted to the implications of deep drilling results in the Atlantic Ocean. This subject was chosen for two reasons. First, Maurice Ewing was one of the leaders of JOIDES (Joint Oceanographic Institutions For Deep Earth Sampling), the association of oceanographic institutions that was formed to organize and sponsor drilling in the deep ocean, and which has continued to provide scientific advice to the Deep Sea Drilling Project. Second. the first phase of International Program of Ocean Drilling in the Atlantic was finished and it seemed a good time to assess the implications of drilling results in the Atlantic that had been obtained over almost a decade.

During the time this volume was being prepared, discussions were taking place about a new initiative in oceanic drilling, in which a drilling vessel with much enhanced capability might be used. The results presented in this volume thus represent the base on which new drilling plans can be built.

The Maurice Ewing series is based on papers presented at the Maurice Ewing symposia. Two volumes resulted from the second symposium, which was held at Arden House, Harriman, New York on March 19-25, 1978. The symposium was co-sponsored by the Lamont-Doherty Geological Observatory, by JOIDES, and by the Inter-Union Commission in Geodynamics. Financial support for the symposium was provided by the G. Unger Vetlesen Foundation, the U. S. Office of Naval Research, and the U. S. National Science Foundation.

Abstract. With the increase in resolution and the number of measurements, the early seismic model of the igneous crust composed of a 5 km/ sec Layer 2 and a 6.8 km/sec Layer 3 evolved into one with at least two subdivisions for each layer. Recent work, in which arrival amplitudes have been given higher diagnostics priority than travel times in the data analysis, has suggested a further modification of the early model in which velocity gradients, with no distinct discontinuities, replace the layered model. Although the gradient model appears to be generally acceptable, there remains much to learn about the degree, scale and pattern of lateral variations in the velocity structure. Both seismic and drilling results indicate a substantial amount of inhomogeneity, particularly in the upper crust.

There is substantial evidence that several features of crustal structure are age-dependent, including:

(1) Topographic roughness of the upper crust diminishes with increasing age.

(2) Low velocity zones, possibly corresponding to magma chambers, are apparently confined to young lithosphere.

(3) The thickness of the low-velocity upper crust (Layer 2A) decreases and/or its wave velocity increases with increasing age. This effect may be due to cementation and lithification of rubble zones and to filling of fractures by mineralization, possibly associated with hydrothermal circulation in the crust.

(4) Total crustal thickness increases with increasing age.

(5) Because of greater sediment accumulation on older crust, and associated higher wave velocity in the basal sediments, the impedance discontinuity at the sediment-basement interface tends to decrease with increasing crustal age; although the effect may be partially or totally counterbalanced by higher velocities in the upper part of the older crust.

(6) Reflections from the crust-mantle transi-

tion have been observed often in airgun-sonobuoy profiles and in multi-channel reflection profiles in regions of old crust; much less frequently in young regions. It is not certain whether this is also an age-dependent effect or whether it is related to the difference in crustal topography and interference from diffracted arrivals.

Introduction

The model, or models, of the velocity-depth structure and the inferred composition of the ocean crust have had high priority for testing by the crustal drilling program of JOIDES-IPOD. Other papers in this volume deal specifically with relating the drilled samples to the seismic and to the retrologic and geochemical models. This paper will focus on the development of seismic methods and on the precision of the results.

Our efforts to understand the oceanic crust through seismological studies have been going on for almost thirty years. The first crustal refraction measurement made in the deep sea in 1949 by M. Ewing and others (1950) was initially interpreted as indicating a P wave velocity of 7.58 km/sec directly underlying the sedimentary layer. These data were later re-interpreted by Ewing et al (1954) to give 7.05 km/sec overlying a 7.80 km/sec mantle, a model in closer agreement with measurements made later in 1949 and in the early 1950's, eg., Hersey, et al, 1952; Officer, et al., 1952, Raitt, 1956, Gaskell, Hill, and Swallow, 1958. The main feature of the early model was a crust-mantle discontinuity at a depth of 10-12 km, with the oceanic crust being mainly represented by a wave velocity of 6-7 km/sec and the mantle, like that under continents, represented by a velocity in the vicinity of 8 km/sec. Even though this was a crude model, it had great significance because it demonstrated a fundamental 20 to 30 km difference in crustal thickness between continents and oceans.

Following those earliest results we focused

EWING 1

Fig. 1. Upper part shows the refraction data and the derived crustal section based on widely spaced shots. In the lower part, shot spacing has been decreased to about one third, and although the original points are unchanged, the additional data reveals the existence of a 4 km/sec layer.

considerable attention on such question as: 1. Do all oceans have the same structure

urderneath them? 2. Is the structure under mid-ocean ridges the same as under the basins?

3. What is the structure under aseismic ridges and submarine plateaus?

4. What is the structure under various types of ocean-continent boundaries and in marginal interior basins?

In looking for the answers to these questions, we naturally came up against the need to refine our seismic models, and the refinement has been going on steadily. The refinements have come about by improvements in hardware and techniques, by larger numbers of people working on the probles, and has certainly benefitted from the increase of overall knowledge about the earth, 2 EWING through guidance on where and what to investigate.

Models With a Layered Crust

The first efforts in refinement were largely directed toward increasing the number of measurements, i.e., recording a larger number of shots per kilometer. A simple demonstration of this refinement is shown in Figures 1 and 2. The upper refraction time-distance graph of Figure 1 would probably be interpreted conservatively as indicated, producing the velocity vs. depth model shown underneath. With the larger number of observation points shown in the lower time-distance graph, it is easy to see that an additional layer should be included in the velocity-depth model. The advantage of additional observation points in reflection seismology is obvious. Thus, increasing data density was an important improvement to make. As resources and data handling procedures permitted, we progressed from data points miles apart to data redundancy through the development of singlechannel reflection profiling, airgun-sonobuoy

Fig. 2. Solid lines in travel-time graph represent a typical two layer crustal model. Its solution appears under (a). With increased data density additional layers 2A, 2C, and 3B (shown with dashed lines) can be recognized. The solution obtained by incorporating the extra layers is shown in (b). Note that the intercepts of the 5, 6, 7, and 8 km/sec lines remain unchanged in both cases, but that the section thickens as a result of introducing additional layers.

raph repre-L. Its reased data 3B (shown The e extra e internes ret the ducin5 refracti n profiling, and multi-channel reflection and expanding opread refraction measurements. These refinements required a substantial amount of time, effort, and hardware.

Significant results of increasing data density were that we learned much more about the configuration of the top of the crust, largely through reflection profiling, and we were able to identify more velocity zones, or layers, in the refraction profiles. The first subdivision in refraction work was to divide the crust into two layers -- layer 2 about 1.5 km thick with an average velocity of about 5 km/sec and Layer 3, about 5 km thick, with an average wave velocity of about 6.7 km/sec (Gaskell, Hill, and Swallow, 1958; Hill, 1952; Raitt, 1956; Ewing and Ewing, 1959). This model seemed to suffic. for a number of years, and appeared to be valid for most of the world's ocean basins. It has been published and referred to many times and is shown once more in Figure 2a.

Underlying the sediments is the upper part of the igneous crust (Layer 2) which has been called variously, basement, lithified sediment, basalt layer, serpentinized peridotite, and volcanic layer. This is underlain by Layer 3 which was generally called the gabbroic layer by those petrologically oriented, and the oceanic layer by seismologists. It seemed to deserve a special name among seismologists, because it was almost always observed. This is because Layer 3 refracted arrivals are first events on seismograms over a long range of shot-to-detector separation. With close enough shot spacing, layer 2 was easy to observe, except in deep basins with a thick sediment cover.

The subdivision of the principal layers was most easily accomplished in dealing with Layer 1, the sediments. Thanks to the ease of observation provided by the seismic profiler (Ewing and Tirey, 1961; Hersey, 1963), we could see early-on that the sediment layer is not just one uniform blanket. In some areas it is acoustically homogeneous; in others it is strongly layered. Its thickness varies enormously. Although there has been some question about how many of the apparent interfaces observed in the reismic reflection profiles may be caused by multiple interference, there is no doubt that a large number of them are bona fide geologic features, many of which have been identified by the Deep Sea Drilling Project.

To a lesser degree, high resolution data have permitted the subdivision of layers 2 and 3. Through the use of seismic reflection profiling, coupled with airgun-sonobuoy reflection and refraction profiles, Houtz and Ewing (1976), have proposed that wave velocities in Layer 2 vary both laterally and vertically between about 3.5 and 6 km/sec, higher values corresponding both to increasing depth and to increasing age. With similar data and similar analytical procedures, Sutton et al., (1971) have subdivided Layer 3 into an upper 6.0-6.7 km/sec zone and a lower 7.0-7.6 km/sec zone. A comparison of the earlier three layer model with a model incorporating these subdivisions is shown in Figure 2b. Notice that as we make more subdivisions, the crust has become thicker even though the intercept times in the original interpretation are unchanged. It is clear that if the subdividing is continued much further, there will be so many layers that a continuous velocity gradient becomes a better approximation to geological reality.

In order to provide a more generalized approach to time-distance analysis of refraction profiles, many experimenters have in recent years used the tau-p approach of Bessonova, et al (1974). This method provides a systematic means of establishing allowable bounding values of velocity vs. depth and has been used to show that marine refraction data sets may be interpreted as convincingly with velocity gradients as with stacks of constant velocity layers, eg. Kennett and Orcett (1976).

Models with Velocity Gradients

The ciscussion up to this point has been concerned with deriving models by using only travel time vs. distance for the various arrivals on the seismograms, without considering the amplitudes of the arrivals or their wave forms. The classical analytical procedures are based on the assumption that the observed refracted arrivals are pure head waves, or interface waves, and on the following assumptions about the model:

1. Velocities are higher in successively deeper layers.

Velocity is constant within each layer.
 Layers are thick compared with seismic wave length.

4. The layers are separated by plane boundaries.

Those who developed the layered models recognized that at least some of these assumptions were unlikely to be realized in the real world, particularly when faced with the low energy levels that head wave theory predicted for criically refracted arrivals. However, it was considered that the deduced models would still be good approximations of the real situation and would still be useful in comparing one region with another.

There is no question that a derived model, and its usefulness in comparing one region with another, will be greatly improved if its developed from arrival time vs. distance relationships plus the information contained in arrival amplitudes and wave forms. In essence, this additional information is utilized in an iterative process where a starting model is first developed primarily from time-distance relationships, then it is tested further by computing synthetic seismograms and comparing the synthetics with the observed data. The model can then be modified in a way that seems likely to reduce disagreement between observed and synthetics;

EWING 3

Fig. 3. East Pacific Rise OBS profile or 5 m.y. crust. Observed seismograms, velocity vs. depth model at the right and the synthetic seismograms computed for the model below (From Orcutt, et al., 1976).

new synthetics are computed, and so on, until satisfactory agreement is achieved. The techniques developed for this more complete type of analysis in marine seismology have largely been based on the work of Cagniard, 1939; de Hoop, 1960; Helmberger, 1968; Helmberger and Morris, 1969, 1970; Cerveny and Ravindra, 1971; Fuchs and Muller, 1971; and Kennett and Orcutt, 1976.

In effect. the model to be tested, which may contain gradient zones as well as discontinuities, is approximated by a stack of layers. The reflection response of the stack is computed for an appropriate cone of rays. The response can include all primary and multiple reflection paths and contributions involving mode transformations. These contributions are summed to produce the theoretical response of the model. The model response for an appropriate range is then compared with the actual seismogram recorded at that range. It is also necessary to have taken into account the source characteristics, as well as those of the receiving apparatus, and to account for geometrical spreading losses and attenuation. An excellent review of recent ideas on inversion of seismic travel time data and on testing with models and synthetic seismograms may be found in Kennett (1977).

It is not difficult to imagine that, particularly for models that need many layers in the approximation, this is an expensive procedure, requiring many computations. However, the re-7 sults seem to justify the effort as demonstrated by the examples in Figures 3, 4, and 5 which are taken from a recent publication by Orcutt, Kennett and Dorman (1976). Note that only the early parts of the arrival trains are shown in the synthetics; the later arriving energy is more complex and more difficult to manage. The refraction arrival amplitudes are related mainly to the steepness of velocity gradient at the appropriate depth for the phase velocities of the arrivals. Reflection ampli-

tudes are primarily a function of the angle of incidence and of the sharpness of impedance contrast between layers. In Figure 3, for example, the refracted arrivals beyond 40 km range were extremely weak, which is an indication of the lack of a positive gradient in the upper mantle. Figure 4 shows slightly stronger mantle arrivals: consequently, a small amount of positive gradient is interpreted to exist. Gradients in the crust account for large amplitudes at ranges of less than 40 km. In both models, substantial discontinuities in the crustmantle transition zone produce relatively strong moho reflections.

The most dramatic feature in Figure 5 is the offset in travel times and energy partitioning near 20 km range, interpreted as a low velocity zone at about 5 km depth, which Orcutt, Kennett, and Dorman suggest may be indicative of a partial melt region or magma chamber.

Although the comparison between the observed and synthetic seismograms is not exact, the use of new analytical techniques such as these is a refreshing development in the attempt to derive better crustal models. The work is being actively pursued by many research groups, and a substantial number of measurements have been reported, eg., Fowler, 1976; Helmberger, 1977; Lewis and Snydsman, 1977; Reid et al., 1977; Stephen et al., in press. The use of a cight fixed receiving array to better determine phase verocities as a function of range, hence additional opportunity to discriminate between layered vs. gradient models, is reported in Lewis and Snydsr (1977).

Evidence from Reflection Seismology

Perhaps the single most significant result of the recent work has been a consistent indication that Layer 2 is a zone of strong positive velocity gradient and that there is usually no prominent discontinuity between layer 2 and layer 3.

A strong gradient in the upper crust, changing to a weaker gradient in the lower crust seems to be an appropriate model. The lack of any consistent velocity discontinuity in the crust is in agreement with observations in reflection seismology as well. It should be noted that both the reflection and refraction observations have been made with wave lengths of the order of 1 km. and do not definitely rule out the possibility of discontinuities on a finer scale.

We have had considerable success in observing reflections from the crust-mantle boundary, even at normal incidence, but reflections from within the crust are rare. This is demonstrated in Figure 6 which is from an IPOD-USGS multichannel line southeast of Cape Hatteras reported by Grow and Markl (1977). Mantle reflections have also been observed clearly in CDP profiles over wide areas of the western Pacific basin (Buhl, et al., 1978), and apparently also under the crest of the East Pacific Rise (Paul Stoffa, personal communication). Thus it seems that although velocity vs. depth may vary smoothly in the crust, the crust-mantle transition is in many places a first order discontinuity. In some regions. OBS and surface hydrophone data require a relatively gradual transition at the Moho, (e.g. Helmberger, 1977).

We have been observing for some time what we take to be critical, or near-critical angle reflections from the crust-mantle transition in airgun-sonobuoy profiles. An example is shown in Figure 7. In this profile we not only see very strong arrivals near the critical range, marked CR, but we also observe sub-critical arrivals almost at normal incidence. The subcritical reflections are particularly useful because they permit us to calculate interval velocities and also, are diagnostic of the presence of a first order discontinuity. Houtz (1977) has utilized interval velocity data from a number of such profiles along with measurements of the critical range, to make a case for the presence of a high velocity zone, 7-7.5 km/s in the lower crust.

Lateral Variability of Crustal Structures

Given that we have made significant advances in our ability to record seismic data, to invert it, and to refine the model by the use of synthetic seismograms, the question arises about how representative is any model for a substantial portion of a lithospheric plate. What is the degree and scale of lateral inhomogeneity? How does crustal structure vary with age?

The answer to the first question is difficult to find in seismic data alone, because not encugh closely-spaced measurements have been made. In the few places where a substantial r mber of measurements have been made within a few tens of kilometers of each other, the data have been analyzed only from time-distance relationships, but the velocity-depth values determined from slope-intercept analysis vary locally almost as much as they do on a regional scale. For example, groups of 10-20 sonobucy profiles, all within a 1° square (Naini and Ewing, unpublished) have produced velocity histcgrams not significantly different from histograms of entire ocean basins. These results, whether interpreted in terms of layers or gradients, suggest lateral variations on the scale of a few kilometers to a few tens of kilometers.

Deep sea drilling results have also given evidence of lateral heterogeneity in the upper crust, even on the scale of hundreds of meters, from closely-spaced drilling sites. Observations from deep submersible investigations on accreting plate margins have suggested models of volcanic and tectonic processes that would be consistent with significant lateral variations in upper crustal structure on the scale of a few kilometers, eg. Ballard and van Andel (1977).

Ocean bottom seismometer (OBS) and other seismic studies of the crustal region of the East Pacific Rise and Mid Atlantic Ridge have not as yet produced a consistent picture of the structure of those features. Some refraction measurements on the axis of the East Pacific Rise have indicated the presence of low velocity zones (magma chambers?) within the crust, eg. Urcutt et al., (1976). Herron et al., (1978) appear to have recorded reflections from the zone at one location. Figure 8 shows a record section from Herron et al., with reflector R4 at the appropriate time (depth) to correspond to the top of the low velocity. Other refraction profiles have not produced evidence for low velocity zones, however, indicating a variability in structure and processes along the ridge axis. Fowler (1976) found no evidence for a low velocity zone in the FAMOUS area of the Mid Atlantic Ridge. Analysis of data on both ridges has given an inconsistent picture with respect to deeper structure. In some cases, strong amplitude arrivals corresponding to phase velocities <8 km/sec suggest appreciable velocity gradients in lower crustal material, while in others the amplitude data suggest strong gradients in velocity >8 km/sec.

Fig. 6. IPOD multichannel data (from Grow and Markl, 1977) showing reasonably consistent moho reflections in the vicinity of 12 km. depth along a line from Cape Hatteras to the crest of the Mid Atlantic Ridge. The moho reflections were observed only in the older part of the basin; intracrustal reflections at the right are rarely observed.

How much of the apparent variability in axial zone structure remains as the material ages and is moved out into the basins is an important question, and the answer will require a considerable amount of further work. The topography of the crust, which is an important manifestation of lateral variability, appears to be related to age, particularly in the Atlantic, as shown in Figure 9. The upper section is a seismic reflection traverse across the Mid Atlantic ridge. The lower section is partly over the western Bermuda rise and partly over the Hatteras abyssal plain. Each section is about 400 km long and each has approximately 25:1 vertical exaggeration, Some of the apparent topographic smoothing of the old crust can be explained by high velocities in the basal sediments, but the young crust is significantly rougher . A comparison of young and old Pacific crust is shown in Figure 10; the contrast between young and old is much less obvious (vertical exaggeration 25:1). The two types of mid-ocean ridge topography (Pacific vs. Atlantic) probably accounts, at least in part, for the fact that Atlantic seismic data are more scattered than Pacific data. The extremely

rough topography of the Mid-Atlantic ridge is usually attributed to the slow spreading rate, resulting in a more brittle (cooler) accreting margin that is more likely to fracture. It is difficult, with the existing data base to make a convincing case for a different seismic structure between the rough and smooth parts. This difficulty comes about partly because seismic measurements made from drifting ships or sonobuoys, particularly in rough terrain, are subject to considerable inaccuracy, and most of the data base were acquired in that way. We simply do not yet have a sufficient amount of tightly-controlled data to make a definitive comparison. To stress this point, it is ___portant to emphasize that the crustal topography, which can be recognized rather easily by the seismic profiler, was not known in detail for many of the earlier refraction profiles, particularly drifting profiles; and even when it is measured, there is no assurance that the topography is mirrored in interfaces or transition zones within the crust.

ations, we have systematically examined a large number of airgun-sonobuoy profiles and have arrived at a statistical interpretation that seems to show a definite aging effect in the upper crust (Houtz and Ewing, 1976). The results from that work are summarized in Figures 11, 12, and 13. In Figure 11 upper crustal velocities from all oceans are plotted as a function of crustal age. There were a number of profiles, mainly in young crust, in which refracted arrivals from the uppermost material were not observed, even though the deeper crustal arrivals were observed. Figure 11 does not include such profiles; only recorded values for the top of the crust are plotted. The large amount of scatter in the data is obvious, and it is noteworthy that the values vary about as much in the old, smoother

crust as in the young, rough crust. Nevertheless, the mean velocity in the uppermost crust is significantly lower (3-4 km/sec) in young crust. The measured velocities increase gradually with age and stabilize at about 5 km/sec.

We have used only Pacific data in Figure 12, and have divided the crust into layers on the basis of seismic velocity. Velocities below about 4.5 km/sec are put in layer 2A, those between 4.5 and 5.5 are put in 2B and those up to 6 km/sec are called 2C. We have not simply pigeon-holed seismic velocities and put them into layers; we have also considered the observed superposition of layers. The results of these studies have suggested that the low 2A velocities are produced by a badly fractured mixture of pillows, flows, rubble, and sediment.

layors. R4 is interpreted as the lid of a low velocity zone (From Herron, et al., 1978).

As this material ages, the cracks and pores are gradually filled by mineralization, possibly associated with hydrothermal circulation, until the whole mixture becomes a competent rock with a wave velocity close to that of its major component, namely basalt. We do not hold strongly to the layered aspect of this model. Instead of pinching out layer 2A on the ridge flank, we would prefer to consider this as analogcus to a facies change in seismic velocity, where 3-4 km/sec velocities grade laterally into higher values. Also our data do not require an interface betwee 2B and 2C and layer 3, as we have derived the models using only arrival time

vs. distance. A continuous velocity vs. depth section is not inconsistent with our data. However, we would say that in young crust the velocity vs. depth relationship has different bounding values than it does in old crust.

Figure 13 is a similar demonstration for the North Atlantic. It is dominated by a large amount of layer 2A material in the crestal region, with poor data on the deeper parts of layer 2 and none on layer 3. We consider our data in the older Atlantic to be good but are less satisfied with that in the young part, where the large thickness of layer 2A is indicated. The crestal regions of the Mid Atlantic ridge are

EWING 8

not well suited for good sonobuoy measurements. It is difficult to find a suitable topographic setting for recording a profile, and the upper crust appears to attenuate seismic energy much more than it does elsewhere. Nevertheless, a similar thickness of material with 2A velocity is measured on the Reykjanes ridge (Talwadi et al., 1971), where the topography is not excessively rough.

Refraction data indicating a thickening of the oceanic layer 3 with increasing age were presented by Shor, et al., (1970) and more recently by Lewis and Snydsman (1977). These data are complicated in many instances by the difficulty of identifying mantle arrivals in the crestal regions of the spreading ridges. In these regions, particularly, the crustal structure is extremely difficult to fit into a simple layered model.

Summary

The crustal models, both layered and nonlayered have not yet been thoroughly tested by drilling because of insufficiently deep penetration. The results, from the holes on legs 37, 45 and 46 all in young crust, appear to confirm that the low velocity of layer 2A is primarily due to the physical state of the basalt, a substantial percentage of the whole rock being composed of rubble and fracture zones. (Aumento, F., Melson, W.G. et al., 1977; Rabinowitz, P.A., Melson, W.G. et al., 1976; Dmitriev, L.V., Heirtzler, J.R. et al., 1976) These sites also demonstrate great lateral variability. At Sites 417-418 in crust of Mesozoic age, the drilling results indicate that the upper few hundred meters initially had much the same structure as the crust cored near the ridge axis, but that mineralization had largely sealed up the * actures and voids. (Donnelly, Francheteau, et al., 1977; Bryan, Robinson, et al., 1977; Flower, Salisbury, et al., 1977). Downhole sonic log measurements to depth of about 500 m into basement have given values that are in general agreement with our sonobuoy measurements of 2A velocities near the ridge axis and 2B velocities in old crust (Salisbury, this symposium volume).

A further comparison of marine seismic velocities with sonic velocities measured on laboratory samples from the Eay of Islands ophiolite suite is made possible through the recent work of Salisbury and Christensen (1978). Figure 14 shows their sonic velocity measurements along with the layered crustal model derived from sonobuoy refraction data. Allowing that 2A and possibly most of 2B are apparently missing from the ophiolite suite, the agreement is quite satisfactory. It is clear also that a gradient model would offer good agreement. The sharpness of the transition between the gabbroic and ultramafic rocks is compatible with seismic reflection

studies, which indicate that the principal discontinuities associated with the oceanic crust are at its top and its base.

1.000

We think that the seismic model of the oceanic crust that has been developed and refined over the past 25 years is a good one in a gross sense. The gradient model is an important modification of the layered model, because it accounts for arrival amplitudes as well as travel times. Further, it is consistent with reflection seismic data, which rarely require discontinuities within the crust. One of the principal shortcomings in our state of knowledge is lack of sufficient data on the degree and scale of lateral heterogeneity at all depths. This is not only an impediment to a more complete analysis of vertical variations, but also of critical importance in understanding the volcanic, tectonic, and geochemical processes involved in the formation of new crust and in its evolution. Fracture zones are obvious candidates for creating hetergeneity in a direction perpendicular to plate motion, and the style and apparent episodicity of crustal accretion, as deduced 2

ment may be possible through more experience with, and possibly better designed instruments, which will permit more use to be made of shear waves, both in body wave and surface wave analysis. Steps in this direction are being taken through efforts to better understand coupling of the seismographs to the sea floor and to extending the band width of the measurements.

Acknowledgments. We are pleased to acknowledge the support of the Office of Naval Research and the National Science Foundation over a number of years, permitting us to contribute to the overall understanding of the structure of the earth through marine seismological research. We also owe a large measure of thanks to our colleagues at Lamont-Doherty Geological Observatory and Woods Hole Oceanographic Institution who have collaborated in much of the work. Finally, we are grateful to George Sutton, Brian Lewis, Michael Purdy and Paul Stoffa for very helpful reviews of the manuscript.

Abstract. The morphology of four areas of the crestal region of the Mid-Atlantic Ridge has been studied by deep ocean side-scan sonar. This has revealed a consistent pattern of closely spaced normal faults parallel to and, for the most part, facing the spreading axis. An analysis of the statistics of the fault orientation, spacing and amplitude indicates that the median valley, typical of slow spreading ridges, is the result of inwardfacing normal faulting occurring within a few kilometres of the axis of the ridge and concurrent outward rotation of the fault blocks. A model is proposed, combining these tectonic events with axial volcanism and lithospheric thermal contraction, to explain the observed topographic profile across a slow spreading ridge.

Introduction

It is widely recognised that slow spreading $(\sim 1 \text{ cm/yr})$ ridges are characterised by rugged topography and by a median valley, in contrast with the elevated median ridges and comparatively smooth topography of fast spreading ridges $(\sim 7 \text{ cm/yr})$ (e.g. Rea, 1975; Lonsdale, 1977).

The typical cross-sectional profile of a slow spreading ridge comprises an inner valley floor with one or more volcanic ridges and small tension fissures, a complex valley wall consisting of scarps and terraces leading up to the crestal mountains some 10-15 km from the axis, and beyond that a rugged topography with ridge crests which progressively deepen with distance from the axis. The majority of slow spreading ridges exhibit this general profile even though the present time is but a snapshot of their evolution. This indicates that the profile is a steady state characteristic acquired by the generation of oceanic crust in the inner valley, modified by tectonism which is spatially related to the axis of spreading.

This profile can be considered as the summation of fault throws and rotations of the fault blocks.

(A regional uplift or subsidence is equivalent to the sum of a series of progressively varying positive or negative rotations). Harrison and Stieltjes (1977) have summarised the three possible models in which faulting and rotation can be combined to give the observed type profile of median valley and crestal ridge. Their model 1 comprises normal faulting without rotation near the bottom of the median valley walls, followed by reverse faulting along the same faults in the upper part, thereby cancelling, at the crestal ridges, the staircase progression. This model implies no faults observable beyond the crestal ridge, or at least a significant reduction in inward facing fault amplitude beyond this region. This is contrary to our observations to be presented.

Model 2 maintains the amplitude of the initial inward facing faults but introduces outwardfacing normal faults along different fault planes on the upper part of the valley walls, compensating the upwards staircase by a downward staircase. The resulting topography beyond the crestal mountains would then comprise a series of horsts and grabens and the cumulative throw on the outward facing faults would equal that on the inward facing ones. Again our data, contrary to those presented by Macdonald and Luyendyk (1977), suggest that this is not in general the case.

Model 3 allows for inward facing faults with amplitudes increasing with age within the median valley but thereafter constant, combined with a progressively increasing rotation of blocks up to a maximum at the summit of the crestal mountains.

Harrison and Stieltjes reviewed the evidence for and against these models and concluded that all three mechanisms are important and that none is capable alone of explaining the topography.

This paper presents new data on the nature, style, frequency and amplitude of faulting as determined by high resolution morphological studies at a variety of scales. An analysis of these data provides evidence that Model 3 is the main mechanism of median valley formation on the Mid-Atlantic Ridge in the North Atlantic.

Fig. 1. Location of GLORIA surveys on the Mid-Atlantic Ridge. 1. FAMOUS area; 2. Kurchatov Fracture Zone; 3. 45⁰N area; 4. Reykjanes Ridge.

New Techniques For Studying Sea Floor Morphology

Until the last five years, ocean floor morphology was studied either by conventional echosounding from surface ships, with its inherent limitations of resolution due to the wide beam angle of echosounders and the difficulties of accurate relative navigation between adjacent profiles; or by underwater photography which was limited in range by the poor transmission of light in water and by the difficulties or accurate location of the camera relative to the grosser morphology.

Advances in technology can now add the following techniques:-

(1) Multiple narrow beam echosounding from the surface, only rarely available in non-classified projects (Glenn, 1970, 1976).

(2) redium range (2.5 km) and long range (30 km) side-scan sonar operated from near the surface (Tucker and Stubbs, 1961; Rusby and Somers, 1977).

(3) Near bottom observations using short range (500 m) side-scan sonar, echosounding, photography and magnetometry, navigated relative to bottom acoustic beacons on vehicles such as "Deep Tow" (Spiess and Tyce, 1973).

(4) Direct visual observations and selective sampling by manned submiribles (e.g. Arcyana, 1975; Ballard and van andel, 1977a).

The latter two techniques are able to give the sort of data a field geologist on land can obtain by walking over his terrain in misty conditions, while the former bridge the gap between these and the grosser bathymetric charts and give results more analogous to the distant views available to the land geologist from a high vantage point on a clear day. All four techniques were used in the study of the FAMOUS area on the crest of the Mid-Atlantic Ridge, southwest of the Azores (deirtzler and van Andel, 1977).

16 LAUGHTON

The data presented here were obtained from deep ocean side-scan sonars, developed at the Institute of Oceanographic Sciences. They have been used in four separate regions of the Mid-Atlantic Ridge (Fig. 1), largely in areas where the complimentary bathymetric mapping and/or near bottom studies have also been made so that the data can be sensibly integrated and interpreted.

GLORIA (Geological Long Range Inclined Asdic) Mark I (Rusby, 1970) was a long range side-scan sonar (6.4 kHz), used up until 1975, operating from a towed vehicle at 100 m depth. It was able to scan the sea bed out to a range of 27 km to one side of the ship, and could be towed at 7 knots. Mark II (Somers et al., 1978), mounted in a different vehicle and able to be operated in much higher sea conditions, looks both sides simultaneously, covering a swath of sea bed 60 km wide, and has been in operation since summer 1977. GLORIA studies in 1977 on the Mid-Atlantic Ridge were supplemented in depths up to 1500 m by a medium range (2.5 km) side-scan sonar (35 kHz) mounted on a stabilised platform below the hull of the ship. This could also be used with the beam vertical as a narrow beam echosounder (narrow in the fore and aft direction giving high resolution bathymetry when crossing linear features at right angles).

GLORIA Survey Operations and Interpretation

On account of the wide swath coverage and high towing speed. GLORIA can insonify a large area in a short time. An areal coverage of about 30,000 km² can be achieved in about seven days. Regional surveys have been made with GLORIA Mk I using parallel tracks spaced so that there is appreciable overlap between adjacent sonographs, allowing the build up of a mosaic, utilising the far range where slant-range distortion is minimal. In later surveys, using the two-sided Mk II, the tracks were chosen to study individual features and trends, viewing from a variety of directions and resulting in a montage rather than a mosaic.

For a more detailed look at selected features, the effective range of GLORIA can be reduced by a factor of two or four, using an increased pulse repetition rate and achieving higher resolution. Detailed studies have been made in this way of the axial volcanic zones of all the areas surveyed.

Sonographs are built up by successive scans of the sea floor at right angles to the ship. The echo strengths vary over a wide dynamic range (60 dB) even after time-varied gain has been used to compensate for range. After linear correlation processing the signals are stored on magnetic tape, either with "fixed gain" (independent of signal strength), or AGC (Automatic Gain Control). Whereas the fixed gain channel allows the amplitude contrasts between high and low reflectivity regions to be displayed, it cannot handle the wide dynamic range. The AGC channel tends to suppress differences in signal level over more than 1-2 seconds of

travel time, but reveals detail throughout the dynamic range. It is, therefore, more suitable for matching adjacent sonographs on a mosaic and has been used in all mosaics presented except on the Reykjanes Ridge. For detailed interpretation of the mosaics, however, it is essential to study both channels.

The GLORIA surveys on the Mid-Atlantic Ridge

have highlighted linear targets parallel to the spreading axis, revealing a texture of the sea floor which i3 superimposed on the grosser morphology indicated by echosounding surveys (Whitmarsh and Laughton, 1976). Detailed comparison between the echoes on the sonographs and reduced (migrated) echosounding profiles (Fig. 2), and an analysis of the acoustic shadows

LAUGHTON 17

Fig. 4. (a) Sonograph mosaic and, (b) interpretation in terms of faults and fracture zones in the FAMOUS area (from Whitmarsh and Laughton, 1976). Positions of DSDP holes 332, 333, 411-413 are shown. Areas of median valley indicated by heavy lines, sediment ponds by hachure and shadows by stipple.

in relation to the computed angles of incidence of the sound at the bottom (Laughton and Rusby, 1975), have shown that the targets are predominantly steep $(40-80^\circ)$ and linear topographic scarps of height varying between 20 and 800 m. The interpretation of these scarps as normal faults has been confirmed by near bottom observations in the FAMOUS area, both visually by submersible (Ballard and van Andel, 1977b), and by echosounding and side-scan sonar from Deep Tow (Macdonald and Luyendyk, 1977).

The sonographs show other more diffuse and less well-aligned echoes. Within the median valley (or median ridge zone on the northern part of the

LAUGHTON 19

Reykjanes Ridge) such echoes have been shown, by submersible observations and by short and medium range sonar, to be extrusive volcanoes aligned approximately lormal to the spreading direction. Remnants of these volcanic edifices, which may be partially destroyed by subsequent rifting and by the tectonism associated with the walls of the median valley, are carried away from the axial region on the fault blocks and give rise to irregular echoes between the fault scarps. When the fault blocks are insonified on the dip slope side, the fault scarps are identifiable only as shadows and the dominant features are the irregularities on the fault blocks (Fig. 3). Away from

sition of DSDP hole 410 is shown.

the axial region, sedimentation progressively covers both the volcanic features and the fault scarps.

In the vicinity of fracture zones, which are not discussed in this paper, additional linear targets are seen, both parallel and oblique to the fracture zones.

Mid-Atlantic Ridge Study Areas

Four separate areas of the Mid-Atlantic Ridge, between 36° and $61^{\circ}N$ (Fig. 1), have been studied

by GLORIA together with other geophysical methods. The most southerly was on the North America-Africa plate boundary, the others on the North America-Eurasia plate boundary. In most cases the survey area included known fracture zones, but these are not discussed here. In some areas the spreading is approximately orthogonal, in others it is oblique. The four surveys are discussed below and in Table I the main faulting characteristics derived from them are tabulated against the spreading parameters.

Fig. 7. Sonograph montage and interpretation on the Reykjanes Ridge. The montage differs from the mosaics in Figs. 4, 5 and 6, due to (a) irregular track orientations, (b) simultaneous port and starboard insonification, (c) sonographs are from the fixed gain channel of GLORIA, not the AGC channel; the extended dynamic range clearly shows the axial high-reflectivity zone.

22 LAUGHTON

(a) FAMOUS Area (Whitmarsh and Laughton, 1976)

The 30,000 km² survey covered the whole of the greater FAMOUS area with a mosaic (Fig. 4) obtained from tracks oriented 055°, separated by 12 km. Insonification was towards the southeast. East of the spreading axis, strong, narrow echoes were observed, whereas on the west side there were broader and weaker echoes and acoustic shadows often with a sharp linear cut-off on the northwest edge. The sharp echoes on the east side and sharp shadows on the west are interpreted as resulting from linear inward facing fault scarps (the wiggles in the linear echoes are artifacts due to yaw), whereas the diffuse echoes on the west side show the rough volcanic terrain riding on the fault blocks. Some outward facing scarps were identified west of the axis, but they are few compared to the inward facing faults.

Detailed sonar studies (Laughton and Rusby, 1975) of the median valley segments between fracture zones A and B (Rift Valley 2), and between B and C (Rift Valley 3), together with the intensive surveys made by submersible and by Deep Tow (Ballard and van Andel, 1977; Macdonald and Luyendyk, 1977), have shown that steep normal faults occur on the flanks of the median valley forming the inner walls and are responsible for the existence of the valley as a morphological feature. The interpretation of the linear echoes and shadows of the FAMOUS sonar mosaic enabled a fault map to be constructed (Fig. 4). The data to the cast of the axis is a more reliable guide to the size and distribution of the inward facing faults since all are adequately insonified. By contrast, on the west side, many such faults may be obscured by the shadows of larger faults, and furthermore, smaller faults may be missed because of the low contrast between the black of a shadow and the sometimes low back-scattering from the dip slope of a fault block.

(b) Kurchatov Fracture Zone (Searle and Laughton, 1977)

The survey (Fig. 5) of 10,000 km² was planned to study the fracture zone but also gave significant data on the crestal region of the Mid-Atlantic Ridge away from the influence of the fracture zone. Knowing the style of faulting to expect, tracks were made parallel to the spreading axis to minimise problems due to vehicle yaw, and the sonar beam was mainly directed outwards from the spreading axis. Equal resolution of inward facing faults, both east and west of the spreading axis, was therefore obtained. There was inadequate coverage of terrain viewed from both directions to establish everywhere the asymmetry of individual ridges from the sonographs alone, but comparison with echo-sounding profiles, reduced to the equivalent of a narrow-beam profile, suggested the presence of asymmetric, tilted fault blocks (Fig. 2). In the few areas viewed inwards towards the axis,

耄

111

Fig. 8. Part of sonograph from the medium range side-scan sonar extending in direction 261^o from the Reykjanes Ridge axis at about 60 N. (GLORIA sonograph taken along the same track is seen in Fig. 7). Note that the linear fault scarps to the north but not to the south of the track are insonified and give echoes indicating the preponderance of inward facing faults. Note also the asymmetry of individual ridges with steep scarps and gentle back tilts, and the occasional perched volcano forming a volcanic "lip" to the fault block.

LAUGHTON

there was little evidence of outward facing scarps.

(c) 45° North Area

A strip of sea floor across the axis of the Mid-Atlantic Ridge, botween 45° and 46°N, was surveyed and sampled intensively, between 1960 and 1969, as part of the Canadian Hudson Geotraverse (Aumento, Lorcarevic and Ross, 1971). A GLORIA survey (Fig. 6) of 15,000 km² covered most of the

area for which detailed bathymetric charts were available. One objective of the survey was to search for postulated fracture zones, so survey lines were run oblique to the spreading axis and insonification throughout was towards the northwest. Since the median valley lay in the eastern part of the survey area, any inward facing scarps in the western two-thirds of the area would have been insonified, but not those in the eastern third. Linear targets were more prevalent in the western part, although not completely absent in the eastern part, indicating a small, but significant, proportion of outward facing scarps. Beyond 40 km from the axis, sediment accumulations in the valleys progressively obscure some of the basement structure.

(d) Reykjanes Ridge

In 1977, GLORIA Mk II, with its ability to look both sides of the ship simultaneously, was.used in a survey of the Reykjanes Ridge axis to examine the transition between its rifted and non-rifted axial regions and to obtain data on an oblique spreading ridge (Laughton, Searle and Roberts, in press). The survey montage (Fig. 7) of about 35,000 km² was not obtained from a regular pattern of parallel lines but from a series of reconnaissanc lines comprising five oblique crossings of the ridge axis, followed by tracks both parallel and perpendicular to the axial trend. Thus, many parts of the ridge have been viewed from a variety of directions enabling the asymmetry of individual ridges to be assessed (e.g. Fig. 3).

Concurrently with the GLORIA data, medium range

side-scan sonographs, out to a slant range of 2.5 km, were obtained both sides of the ship's track, giving a higher resolution of the fault scarps and an effectively narrow-beam profile beneath the ship (Fig. 8). Both sets of sonar data indicate that inward facing faults are heavily preponderant.

The data showed an axial zone, 13 km wide, consisting of a series of <u>en echelon</u> elongated volcanic ridges trending 010°, approximately orthogonal to the spreading direction of 095° and probably reflecting the orientation of the tension cracks and of the feeder dykes. Outside this zone, and in contrast to it, inward facing normal faults trend between 032° and 022°, subparallel to the axial trend of 36°. These trends may, however, comprise a mixture of a fault trend parallel to the ridge axis (i.e. perpendicular to the direction of lithospheric thickening), and relics of the 010° volcanic trend. In the southern part of the survey area the innermost pair of inward facing faults which delineate the median valley are indeed parallel to the axial trend, i.e. 036°.

Analysis Of Faults Cn The Mid-Atlantic Ridge

(a) Ratio of inward to outward facing faults

The contrast between the inward viewing sonographs on the west side of the FAMOUS area spreading axis and the outward viewing sonographs on the east side, and a study of the geometry of their shadows in relation to the near bottom sound-ray paths led Whitmarsh and Laughton (1976) to conclude that, although there are some outward facing faults, the majority are inward facing. Although correlations have been made with the digitised narrow-beam echosounder profiles obtained by USNS Hayes, it is difficult to determine from these the asymmetry of individual ridges associated with near-vertical fault scarps since the scarps are not easily identified on the echosounder profiles, especially at the rather large vertical exaggerations used.

More detailed profiles have been obtained by Deep Tow which is better able to resolve steep slopes. Macdonald and Luyendyk (1977) and Macdonald and Atw.... (1978) concluded that outward facing faults were generated in the upper part of the median valley wall complex, and that beyond 20 km from the axis, they contributed as much to the relief of the crestal mountains as did the inward facing faults, thereby cancelling the shoaling depths of the median valley wall complex. They also concluded that tilting of blocks contributed less than 20% of the contribution by faulting. Thus, these data are in direct conflict with the sonograph data from GLORIA.

A resolution of this conflict may be possible by the direct comparison of the sonographs with individual faults interpreted from Deep Tow data on both sides of the median valley. It is

26
possible that GLORIA is more sensitive to nearvertical scarps which will give strong echoes at long range when the ray path is nearly horizon.tal, whereas the Deep Tow echosounder, still working in a vertical mode, is unable to distinguish between the steep, but not vertical, flow fronts of relic linear volcances, and nearvertical faults. Furthermore, it is difficult to determine tilt angles of a rough volcanic terrain since there is no obvious reference surface. If the tilt of large blocks is appreciable, say up to 40° as has been suggested from palaeomagnetic studies of irilled basement rocks (Hall, 1978), this might be confused with outward facing faulting. ubmersible observations of the cravity-controlled extrusions from the crests of rotated volcanoes should be able to determine the role of tilting in the crestal mountains and beyond.

There was little data on the ratio of inward to outward facing faults in the Kurchatov Fracture Zone area. However, the high reflectivity of the scarps when viewed outwards and the shortness of the returning echoes (Fig. 2) indicate scarps with a mean slope of 47° on the inward-facing sides of the crestal mountain ridges (Searle and Laughton, 1977), an angle higher than the resolution of the processed echosounder profiles. However, some of these lower-resolution profiles suggest a net asymmetry of the ridges indicating a majority of inward facing scarps. A significant feature found on these profiles, as well as on others on mid-ocean ridges (e.g. in the Gulf of Aden (Laughton, Whitmarsh and Jones, 1970)), and noted by Macdonald and Luyendyk in the FAMOUS area, are the "lips" perched on the uplifted edges of fault blocks (see also Fig. 8). They are interpreted as relic volcanic features and their location indicates that faulting often occurs near the foot of the axial volcanic ridges as shown by Ballard and van Andel (1977b).

In the 45°N survey, no narrow-beam or near bottom profiles were available to examine the asymmetry of the ridges. A comparison of GLORIA data on either side of the median valley indicates, however, a majority of inward facing scarps.

In contrast, in the Reykjanes Ridge survey considerable data were obtained on this issue. In some areas the same piece of sea floor was viewed from both sides and the contrast is evident in Fig. 3. In addition, the medium range side-scan sonar was well able to distinguish between inward and cutward facing faults and to relate them to a profile beneath the ship (Fig. 8). Throughout the survey, out to a distance of 75 km from the axis, 192 inward facing and only 6 outward facing faults were crossed. This ratio is supported generally by the comparative views of inward and outward looking GLORIA sonographs.

A prependerance of inward facing faults can also be seen on sonographs collected along passage tracks parallel and close to the Mid-Atlantic Ridge axis between 54° and $37^{\circ}N$. One must conclude that this is, therefore, characteristic of much of the slow spreading ridge system in the North Atlantic.

(b) Fault Throws

Model 1 of Harrison and Stieltjes (1976) (faulting followed by 'unfaulting'), implies that the throw of inward facing faults should be at a maximum part way between the axis and the crestal mountains, and should decrease to zero at the crestal mountains. Sonographs have given data on scarp heights (interpreted as fault throws) in the Kurchatov Fracture Zone area and on the Reykjanes Ridge. Searle and Laughton (1977) correlated target widths from sonograph echoes near the Kurchatov Fracture Zone with scarp heights on selected echosounder profilcs and used this relationship to infer scarp heights from the width of the sonar targets over a much

ider area. On the Reykjanes Ridge, inferred fault throws were measured from the medium range side-scan sonar profiles directly. When plotted against distance from the axis (Fig. 9), the data points show no correlation with the theoretical distribution required by Model 1. The data on the Reykjanes Ridge are taken from the southerly section of the survey where the median valley is well developed. The gradual decrease in maximum fault throw and in the mean scarp height near the Kurchatov Fracture Zone (Searle and Laughton, 1977, Fig. 11) out to 60 km from the axis, can be attributed to scarp burial by pelagic sedimentation and the growth of talus slopes.

(c) Fault Spacing

The spacing of faults along lines perpendicular to the spreading axis (not necessarily flow lines) was measured for all four areas on several typical sections, avoiding fracture zones, and was plotted against distance from the axis (Fig. 10). The data for the Reykjanes Ridge include both the southerly rifted section and the northerly unrifted section of the survey area. Since there is no significant difference between the fault spacings in the two sections, the two data sets have been combined. Spaces that included sediment basins exceeding 100 msec (approximately 75 m) in thickness or where there is poor sonar coverage due to extreme range or shadow, were excluded from the data. The spaces between the first inward facing pair of faults were also excluded. The plots show no significant change in the fault spacing beyond 10 km from the axis, implying that no new inward facing faults were generated beyond this range, and that all faults were, therefore, formed within the median valley (or median ridge) zone.

The complete data sets can, therefore, be used to give histograms of fault spacings for each area (Fig. 11), and to compute mean values (Table I). There is no significant difference between the mean fault spacings in the four

LAUGHTON 2

areas. The mean value for all four areas, 2.4 km, agrees closely with that (2.4 km) observed by Macdonald and Luyendyk (1977) in the terrace regions of the FAMOUS area. However, each of the major scarps may in fact consist of a cluster of closely spaced faults producing slivers of crust some tens or hundreds of metres wide as observed on the inner walls of FAMOUS by Deep Tow. We think it likely that each cluster belongs to a single faulting episcde.

(d) Length of Faults

A striking feature of the faults is their considerable length compared with their spacing. In the FAMOUS area, some faults can be traced continuously for as much as 35 km, ending at fracture zones. South of the Kurchatov Fracture Zone, fault scarps with only minor offsets were traced for as much as 60 km, although more commonly a single scarp length is 10-20 km. It is difficult to assess an average length since small apparent discontinuities may arise from problems of vehicle stability and quite commonly faults coalesce or branch at small angles.

Long closely spaced faults result in fault blocks that are long and thin. Assuming that a fault is initiated at one place and propagates as a tear, the close spacing of consecutive faults implies a remarkably uniform stress field or a well defined zone of weakness.

(e) Position of Fault Generation

The analysis of the statistics of fault spacing excluded the spacing of the two central inward facing faults either side of the median valley or ridge. It is widely accepted that the morphology of the inner floor of the median valley on mid-ocean ridges is predominantly due to extrusive volcanism and that the floor is bounded by inner walls of inward facing normal faults. These are the first major faults dislocating the newly formed and recently spread lithosphere and the position at which they occur relative to the spreading axis must be where the shear strength of the lithospheric wedge is exceeded by the vertical shear stress resulting from the accretion process.

28 LAUGHTON

12

Fig. 13. Three stages, before, during, and after the formation of a fault in laterally moving uniform thickness lithosphere.

Since the major fault blocks have a finite width, the present position of the inner walls will on average be further from the spreading axis than the position of their origin. If g represents the distance of the fault generation position from the axis, y_1 the observed distance from the axis to the first inward facing fault and $\overline{\Delta y}$ the mean fault spacing, then

$$=\overline{y}_1 - \frac{\overline{\Delta y}}{2}$$
 (Fig. 12).

ġ

Table II shows observations of the width of the spacing of the inner walls (or first pair of major inward facing faults) for the different survey areas, and the calculated values of g, using the appropriate fault spacing. The wide variation of y_1 between segments of the same survey area, separated by fracture zones, reflects the relative ages of the first fault scarp.

Geometry of Fault Generation on Moving Lithosphere

The observed fault spacing implies an average time interval between the initiation of clusters of new faults of 200,000 years. We believe this characteristic period depends both on the rate of thickening and strengthening of the lithoTILT Fig. 14. obtained uniformly for illus fault blo the zone fault blo lines of sphere, and of vertical ridge cress The avera fault scar not signif scarp heigh grow to the than 200,00 measured fa 1975), Sea continuous events - ab dykes 0.1 t

ZONE OF FLEXURE FAULT GENERATION POSITION PLATE MOVEMENT

Fig. 14. Geometrical construction of profile obtained by repeated faulting and flexure of uniformly moving lithosphere. It is assumed for illustration purposes that the width of a fault block equals one-eighth of the width of the zone of flexure. The angle of tilt of the fault blocks is shown at the bottom. The flow lines of point A, A' and B are shown in Fig. 15.

sphere, and on the rate of horizontal variation of vertical shear due to viscous flow beneath the ridge crest (Lachenbruch, 1976).

The average inferred height of the innermost fault scarps near the Kurchatov Fracture Zone is not significantly different from the average scarp height; this suggests that fault scarps grow to their maximum height in a time much less than 200,000 years, and this is compatible with measured faulting rates (Francis, 1974; Faure; 1975). Sea-floor spreading must be noncontinuous on a time-scale related to intrusive events - about 5 to 250 years for individual dykes-0.1 to 5 m wide (Coleman, 1977); or 10,000 years for the initiation of new extrusive volcanoes which must themselves be fed by intrusive dykes (Ballard and van Andel, 1977). The intervals between faulting episodes are, therefore, an order of magnitude greater than between volcanic episodes and hence, to a first approximation, sea-floor spreading is continuous between the faulting episodes.

Thus our data suggest that major faulting occurs at a small, but finite, distance from the spreading axis, episodically on a relatively uniformly moving lithospheric plate. As new crust moves past the faulting position it is faulted by forces related to the distance from the axis. As it moves away the faults become locked into the crust and subsequently do not change their throw significantly.

In order to determine the flow line of a point on the new crust it is necessary to model the effect of repeated faulting. Let us assume, as a first simplification, that the lithosphere retains a constant thickness after creation and that associated with the faulting is a zone of flexure either side of the fault (Fig. 13). (Some such assumption is needed since the whole lithosphere cannot be uplifted at each fault step). The next fault dislocates new crust, uplifting the now older frozen fault if it still lies in the zone of flexure, and increasing the flexure on the younger block. An equilibrium profile can be constructed by successive superpositions of fault and flexure until one point. has moved right through the flexure zone (Fig. 14). One direct consequence of such a simplified geometrical construction is the persistence of a relative depression at the faulting position. (The corresponding relative elevation resulting from the first faulting is carried off with the plate). Throughout the

Outward tilting of fault blocks of an average 2° at the inner wall and between 3° an 8° at the outer walls in the FAMOUS area have been observed by Macdonald and Luyendyk (1977). On the Reykjanes Ridge, our medium range side-scan sonar has shown outward tilting as high as 20° to 30°, although more commonly about 10°.

Fig. 16. Faulting and flexure in a more realistic lithospheric profile near the ridge axis assuming faulting with a periodicity of T. Stipple indicates the new lithosphere accreted at each stage.

30 LAUGHTON

The flow line of a typical point is dependent on whether it is in the centre of a block or immediately adjacent to a fault. Selected flow lines are shown in Fig. 15, derived from the labelled points in Fig. 14: a point (A) lying at a potential fault site will be depressed until faulting splits it into two points (A and A') on the down and up-faulted sides of the fault respectively. A point in the centre of a block (B), however, will be depressed, then elevated but never rise above the mean level. These flow lines take no account, however, of adjustments in height that may arise from non-equilibrium forces from below.

If lithospheric cooling and shrinking is superposed (Sclater and Francheteau, 1970) on the synthetic topographic profile in Fig. 14, the ridged profile far from the axis will gradually increase in depth.

This model says nothing about the origin of the stress that creates the fault and is clearly oversimplified by the assumption of uniform lithospheric thickness. A more likely model is one in which a relatively thin rigid lithosphere (i.e. the inner floor of the median valley) overlies the axial region above the mantle conduit or magma chamber, beyond which the lithosphere increases in thickness as material near the conduit or magma chamber walls cools and adds to the plate. At a time immediately following the relief of stress by the generation of an inner wall fault, the lithospheric cross-section may approximate to (a) in Fig. 16. The stresses on the mantle conduit walls, arising from gravity and viscous forces exerted by the rising material (Lachenbruch, 1976) will uplift both the lithcspheric wedge and, due to the finite shear strength of the younger lithosphere, the inner floor region (Fig. 16b, c). The latter will be out of equilibrium with the hydrostatic pressure head, reduced by viscous drag, in the rising mantle column, and will eventually collapse giving rise to a normal fault (Fig. 16d). The flexure associated with the uplift will, however, be preserved by the continual underpinning of the lithospheric wedge by mantle accretion on its walls.

Conclusions

The paper has set out to present new evidence on the faulting associated with slow spreading mid-ocean ridges and to provide constraints and perhaps new insights into modelling the tectonic processes at and near the accretion axis. The following conclusions have been reached:-(1) There is a pattern of normal faults aligned parallel to the median valley or ridge axis, but not necessarily normal to the spreading direction.

(2) The majority of these faults are facing inwards towards the axis.

(3) There is no significant change in fault throw beyond the crestal mountains, implying that

reverse faulting along pre-existing faults does not take place.

(4) The spacing between faults does not decrease with distance from the axis, implying that no new faults are generated outside the median valley.
(5) Typical fault spacing is 2 to 2.5 km, equivalent to initiation of a new fault, or cluster of faults, about every 200,000 years.
(6) Faults are generated at a more or less constant distance (2-4 km) from the ridge axis as the lithosphere moves past this position.
(7) Fault lengths vary from 5 to 50 km giving rise to long, thin fault blocks, sometimes continuous between fracture zones. This implies that the stress field is extremely uniform in the direction parallel to the axis.

From these data it is concluded that the profile of median valley, valley wall complex, crestal mountains, and ridge flank can be explained qualitatively in terms of a lithosphere continuously generated at the axis being transported laterally, through a region where the shear stresses associated with the edge of the asthenosphere conduit generate normal faults and associated flexure. As repeated flexure is added to the already faulted lithosphere, the fault blacks are progressively tilted to an angle of between 5° and 10° until they reach the crestal mountains. This region (from inner wall to crestal mountains) denotes the horizontal extent of the flexure rore, whose width may be related to the rate of increase of lithospheric thickness away from the axis, and the rate of change of vertical stress. Beyond the crestal mountains the thermal shrinking of the lithosphere accounts for the increasing depth of the sea floor along the ridge flaks.

CONSTRAINTS FROM THE FAMOUS AREA CONCERNING THE STRUCTURE OF THE OCEANIC SECTION

Tanya Atwater

Department of Earth and Planetary Sciences, Massachusetts Institute of Technology Cambridge, Massachusetts 02139

Abstract. Structural data from the Famous Area, near 37°N on the Mid Atlantic ridge, are examined for possible constraints they may place upon the interpretation of materials collected in deep basement drill holes in the Atlantic. Volcanic, petrologic, mantic and crude age data all suggest that the zone of emplacement of new lavas is 5 to 10 km wide, with possible occasional new additions as much as 15 km from the center. Implications for dike-flow relationships in the section are discussed. The most likely model appears to be one with a narrow, centered focus of volcanism which is then covered with a thinner covering layer by off-axis, late stage volcanism. The dimensions of volcanoes in the Famous Area, combined with magnetic layer thickness studies suggest a volcanic layer about three to six volcanoes thick. Each volcano consists of a pile of about 25 flows of highly variable thickness which erupt over a relatively short time span compared to the 5,000 to 10,000 years between major eruptions.

Ice

dor

αē

023,

Rubble in the section is likely to be generated in two ways: (1) as horizontal breccia sheets which broke off of steep flow fronts and then were overrum as the fronts advanced and (2) as fault zone breccias. The spacing and geometry of faults suggest that there is a 30% probability that a random 500m drill hole will encounter at least one major fault zone.

Two possible origins for large tectonic tilts are considered. Individual volcanic units may be rotated during burial, then larger coherent blocks may suffer additional tectonic rotations as they pass the rift mountain tops. The latter tilts probably affect less than 10% of the crust.

In the transform faulted region of the Famous area (age 5 m.y. and younger), about 3/4 of the crust appears to be "typical" oceanic material vs that which is highly tectonized by transform faults or which was originally emplaced there.

Introduction

In this paper I shall attempt to outline what we can tell about the structure of Atlantic Ocean crust from the point of view of its original formation. I shall draw most heavily upon data collected at the Mid Atlantic ridge near 36-37°N during the FAMOUS Project, adding a few preliminary remarks based upon a return expedition to that area, AMAR78, reported by Atwater et al. (1978), Macdonald and Atwater (1978), Atwater and Macdonald (1978), Crane and Ballard (1978) and Ballard et al. (1978). Comparisons to other parts of the ridge will also be made. Structurally, at least, the Famous section of the ridge crest appears to be quite typical, having a central rift valley with typical relative depth and width, fault block topography, mountainous flank relief, and rough but just discernable Vine-Matthews Anomalies. I shall summarize some of the volcanic and structural results from this area and discuss their implications for materials which might be encountered in a deep sea drilling basement hole. This is not an easy task, since most of the Famous data concern the horizontal upper surface of the ocean floor while the basement holes examine the vertical section to depth. Still, the former do include some implications for the vertical section. In particular, they put constraints upon the internal composition of the volcanic layer, the origin of rubble within the section, and the tilting of rocks during and after their emplacement. In addition, they allow one to estimate the amount of sea floor area which is "typical" oceanic crust versus that which was generated or was seriously deformed in fracture zones.

Structure and History of the Volcanic Layer

Width of the Zone of Extrusion. Before the FA-MOUS project, the most common type of model for the internal structure of the yolc. 'c layer was that illustrated in Figure la. It as mes that the zone of addition of new layas is narrow and well centered. Thus, each new volcano splits the previous one in two, building a new edifice overlapping the older ones in a quite orderly fashion.

Split volcano models such as the one in Figure la imply that only one major volcanic vent,

the central one, should be present on the sea floor. All older volcanoes would be represented on the surface only by their tilted flow toes. This is not what was found in the Famous area. Rather, the rift valley floor consisted of a number of hills flanking the central one and all the hills which were studied seemed to be intact volcanoes. Their flow directions were still oriented downhill and their summits were decorated with cones and "haystacks" (Ballard and van Andel, 1977). From this observation Ballard and van Andel postulated a somewhat different family of models for volcanic emplacement, illustrated in Figure 1b. They suggested that each new volcanic episode begins at the foot of an older edifice so that in general, whole volcanoes are carried away to one side or the other. Unfortunately, dating techniques for such young oceanic rocks are very poor so that it is not possible to distinguish the sequence of emplacement of the hills. Ballard and van Andel develop a model in which active volcanic centers are only slightly off center, each new one originating at one foot or the other of the previously active volcano, but they note that the data are equally compatible with a model in which activity occurs anywhere over some broader area and in a more random manner. The nearly centered model was motivated by the fact that the most recent volcanoes in the American submersible area are centered. On the other hand, one very recent volcano to the north, Mt. Mercury, is actually perched upon the first step of the western wall (Arcyana, 1975; Macdonald and Luyendyk, 1977) suggesting a more random emplacement of volcanoes.

Crustal emplacement models constructed to match magnetic effects also favor a wider zone of volcanic additions. In particular, Schouten (this volume) constructed a simplified model assuming that new discrete volcanoes are distributed about the center in a Gaussian way. When he tried to model various observed magnetic characteristics (polarity transition widths, magnetic anomaly variability and the presence of mixed polarities in deep crustal holes) he found that they required a standard deviation of about 2.5 km or a little less. In other words, most new volcanoes are added over a zone about 10 km wide and about 70% of them are spread over the central 5 km (in or near the rift valley floor).

Another study of the emplacement width was made by Maddonald (1977) when he estimated the bulk magnetic intensity of individual ocean floor peaks and scarps. Magnetic intensity decays very rapidly with age, from 20-30 A.m⁻ for features less than a₁ few hundred thousand years old to about 7 A.m⁻ at 1 million years. Thus, off-axis late stage volcances should have higher magnetic intensities than their surroundings. While most of Macdonald's intensities cluster about a smooth decay curve, a small number were clearly too intense for their distances from the center (figure 2). A possible explanation for these features is that they were late additions upon the older

Fig. 2. Bulk magnetic intensity of individual topographic features as a function of expected age, after Macdonald (1977). Triangles show average values and bars are 4 standard errors in length. Circle shows features with intensity greater than that typical for their expected ages, perhaps indicating that they were formed by younger, late stage vclcanism.

crust away from the center. In the region where this effect is easily detectable (.5 - 2 m.y. expected age), about 10% of the surface features seem to be .5 to 1.3 m.y. younger than their surroundings, i.e., they were emplaced 5 to 15 km outside the center of emplacement. This conclusion should be approached with caution, however, since the AMAR expedition found very little young volcanism associated with Mt. Saturn which had a high intensity deep tow magnetic anomaly (Atwater, et al, 1978). The source of that anomaly is presently being investigated.

Petrologic, geochemical and aging data from the rocks collected in the Famous Area also suggest a wider zone of emplacement, though not so wide as just discussed. Bryan and Moore (1977) found a strong zonation in rock type, from primitive in the center to differentiated at the edges of the valley floor. This they interpreted to be the result of an evolving, continually leaking magma chamber, so that all the surface lavas overlying the chamber are quite young. Crude age dating measures (manganese thickness and palagonitization (Bryan and Moore, 1977) and rock magnetic intensity (Johnson and Atwater, 1977) likewise suggest that the surface rocks all the way to the edge of the valley floor are younger than would be expected from a narrow, centered emplacement. Bryan and Moore supposed that the late stage volcanism is confined to the rift valley floor (a region 3-5 km wide). It is often supposed that the bounding faults mark the edge of the underlying magma chamber. However, very little is known about the ages of the rocks on the walls and beyond, so that this is not a compelling constraint at this time.

In conclusion, most data from the Famous rift valley suggest that the zone of extrusion is at least as wide as the valley floor, with pos-

ATWATER 35

sible occasional volcanic additions as much as 15 km from the center. This implies that the difference in age between the bottom and top flows in a given section will commonly be 200,000 years and occasionally will be 1 million years or more. The implications of such a wide region for volcano emplacement are very strong for models of the structure of the deeper volcanic section. Namely, the relationship between flows and feeder dikes and the ratio of one to the other at given depths would be entirely different from those in the countered split volcano model. Any whole volcano model requires that a significant number of dikes should be present high up in the volcanic section, and their number should increase rapidly with depth. Compare figures la with lc, for instance. Any increase in the width of the emplacement zone increases this intermingling of dikes and flows. Occasional clear crossings of dikes have been reported in the deep crustal holes (eg. Bryan et al., 1977), and Flower ct al., 1977) and others could easily go undetected as such. On the other hand, ophiolite sequences seem to show relatively little intermixing of dikes and flows (Cann, personal communication).

Volcanoes in the Vertical Section. Ballard and van Andel considered only the surface section in their emplacement models. The three deep crustal holes which have penetrated beyond 500 m in the basement were still encountering extrusives when they stopped drilling (Melson et al., 1974; Rabinowitz et al., 1976 and Flower et al., 1977). Thus, it seems clear that the oceanic layer 2A is generally more than one volcano thick. One simple extension of the intact volcano model is to assume that the volcanic layer consists of buried whole volcanoes. Figure 1c shows such a possibility. Given this assumption, we can use the dimensions of various volcances studied in the Famous Area to estimate the number of whole volcanoes which might be encountered in a given crustal hole.

Individual volcanoes in the Famous Area are about 500 to 700 m wide and 2 km long. The height of the edifice built during a given volcanic episode is not known, but if it is assumed that the present central volcanoes, Mts. Venus and Pluto, grew to fill intervolcano depressions such as the one which presently lies between them, then they are 200-300 m thick at their centers. This, however, may be an underestimate, since faulting surrounding them suggests that they sink into the crust after and probably during their construction (Ballard and van Andel, 1977).

The thickness of the volcanic layer is not known. Macdonald (1977) found an equivalent thickness of about 700 m by assuming that the entire layer has the same magnetization as near surface features. This is probably an underestimate since more and more instrusives and altered sections would be included with increasing depth

36 ATWATER

and these would have lower magnetic intensities than the young lavas. Also, as noted above, direct samples from the bottoms of deep crustal holes included pillow basalts to nearly 600 m depth into the basement. For the sake of discussion, then, we might suppose that the layer which includes significant amounts of quenched lavas extends to one km depth. If such a layer is built of whole volcances similar to Mts. Venus and Pluto, as described above, it would be three to six volcances thick.

In any given surface crossing of the valley floor, parallel to the spreading direction, the volcanoes identified by Ballard and van Andel (1977) occur at spacings of about 600 m. At the spreading rate here, this is equivalent in time to a spacing of 30,000 years. If, indeed, the volcanic layer contains two to five buried volcanoes for every one at the surface, then the average time between new volcanic starts would be 5,000 to 10,000 years.

It is not known how long a given volcanic episode lasts: whether there is a more or less regular outpouring of lava so that a given volcano takes 5,000 years to be formed, or whether the volcanoes are built very quickly, with long quiet periods in between. A number of lines of evidence suggest the latter hypothesis. The divers reported that all the lavas explored on each of the two youngest volcanoes, Venus and Pluto, seemed to be of similar age, in contrast to the older rocks surrounding them. The presence of thick units in the deep crustal holes within which geochemical, petrologic and magnetic properties are nearly constant, also argues for a very rapid building of thick piles.

Another promising model for the structure of the volcanic layer deserves consideration. It is essentially a hybrid, with a centered, split volcano structure for the lower portion of the construction plus an addition of superficial volcanoes from smaller amounts of late stage, off-axis volcanism. This is illustrated in figure 1d. This model satisfies the observations of a wide extrusion zone and intact volcanoes at the surface while minimizing and localizing the number of dikes in the volcanic section at depth. It constructs a section which is similar to that reported from Troodos, figure 3, and is similar to the model proposed by Bryan and Moore to explain their geochemical gradients in the Famo's Area. It also shares many features with the structure found on the fast spreading East Pacific Lise at 3.5°S (Lonsdale, 1977), although the various components are somewhat different and are differently developed. On the East Pacific Rise the central volcano is by far the dominant volcanic feature. It is linear, continuous and quite uniform, quite different from the alternating central highs and lows of the Famous Area. Off center volcanism at the East Pacific Rise appears to be represented only by small knobs scattered sparsely upon the terrain of the dominant central volcano. Thus, at Famous we must postulate an

Fig. 3. Diagrammatic sketch showing the relationships in cross-section between dikes, flows and diabase in Troodos, Cyprus, after Wilson (1959) as published in Coleman (1977), Figure 68. Dike/flow relationships suggest that the Lower Pillow Lava group may have been formed by a centered split volcano emplacement while the Upper Pillow Lava group represents off-axis, late stage volcanism, as illustrated in Figure 1d.

intermittant central edifice and a much more active late phase, one which conveniently hides most of the evidence for the earlier stage.

Flow Structure within Volcanoes. The Famous data may also be of use in understanding the lava structure encountered within a given volcano. Many flow fronts were examined during the Famous dives. Figure 4 shows a cross-sectional sketch of an advancing flow front as surmised by Ballard and Moore (1978) from these observations. The flow can be viewed as a sloping lake, budding on top and advancing by overflowing its dam and building new foresets of elongate pillows down the front and then moving over them. Van Andel and Bryan (personal communications) estimate that these volcanic fronts are typically 10 to 20 m high, although a great variability was seen. If we take this as a rough estimate for the thickness of flows and assume that a given volcano is 300 m thick, then a given section through the edifice might consist of about 25 flow units. Given the many uncertainties in such an estimate, however, it must be considered only a very rough working number. A given vertical section downward through such a flow would consist of top bulbous pillows (sometimes hollow and collapsed), a more massive core, lower elongate foreset pillows, and then a rubble sheet put down by materials spalling off of the advancing front and subsequently being run over.

Sheet Flows in the Section. An additional complication in the volcanic section will be the presence of sheet flows. These have been described in the Galapagos spreading center (Lonsdale, 1977, and Ballard et al., in press) but were not previously reported in the Atlantic. During the AMAR78 expedition we encountered these thin platey lavas forming lakes in many of the lows (Atwater, 1978, Ballard et al., 1978). In the various fault scarps examined we estimate that sheet flows constituted 10 to 15% of the vertical sections. This percentage probably increases with depth, since the sheets occur in the lowest spots and would be preferentially buried.

Rubble and Talus Within the Section

Volcanic rubble is one of the most common rock types found in deep crustal holes. What is the origin of this rubble?

Surface Debris. One of the more dramatic aspects of the ocean floor is the great amount of talus found there. However, it is probably a mistake to suppose that equal amounts have been buried. Most of the large, impressive talus piles are found at the bases of the major fault scarps and it appears that much of the large offset faulting occurs as the crust is uplifted away from the valley floor, after the completion of volcanism in a given section. Thus, the really large talus ramps are only surface phenomena and will not, in general, be found buried within the volcanic section.

The central valley floor, i.e., the part most likely to be buried by lavas in the future, is relatively barren of talus. Small amounts of rubble are seen where hollow pillows and tubes have collapsed and at the feet of small scarps and flow fronts. Still, the total area covered by talus reported by Ballard and van Andel in their detailed dive track descriptions, their figure 2, averages only 9% while deep tow photo

ATWATER 37

Fig. 4. Structure of an advancing pillow flow front as deduced by Ballard and Moore (1977) figure 21, from Famous Area observations. Dotted pattern indicates molten lava.

analysis indicates only 15-20% (Luyendyk and Macdonald, 1977).

Another probable source of buried rubble is implied by the observations of flow fronts by Ballard and Moore (1978). As a front advances. the steep elongate foreset pillows tend to break away, forming a rubble heap at the foot of the front. Thus every flow should rest upon a sheet of its own rubble which broke off of the oversteepened flow front as it advanced. The rubble formed by this process is different from that found in the fault scarp talus ramps in that it consists of whole or half pillow fragments while the latter generally consists of wedge shaped fragments (Atwater et al., 1978). It is not clear that such a whole pillow talus would be distinguishable in a drill core from the surrounding intact pillow flows. Some magnetic oddities such as discrepancies between magnetic and segregation vesicle orientations (Gruver, 1978) could arise from this ambiguity.

Fault Shearing and Gouge. Another way in which to form broken rock is by faulting. It appears that every section of crust formed in the Famous rift undergoes three episodes of deformation before it is finally welded on to the passive oceanic plate. First, it is pervasively fissured and faulted in the valley floor, then it is block faulted to form the rift valley walls. Finally

38 ATWATER

it is tilted or faulted yet again to form the undulating rift mountains.

One of the most impressive features of the rift valley floor is its pervasive parallel system of small faults and fissures. These features are remarkably linear and parallel to the valley trend and have nearly vertical dips. The fissures presumably o erlie dikes emplaced at depth which did not reach a surface. Their upper, empty parts become a psitories for sediments and rubble. The ubiquit, of these fine scale fractures can be seen in the table presented by Ballard and van Andel (1977) which lists tectonic features observed from the submersible Alvin. These data cover 7.5 (projected) km of east-west tracks within the valley floor during which they observed nearly 100 fractures or fracture groups, with an average spacing of about 80 m and offsets of 0.2 to 25 m. It is likely that many additional fractures of this type have been subsequently buried by lavas so that their frequency probably increases rapidly with depth in the section.

When oceanic crust moves outward to the edge of the valley floor it reaches a point where it begins to ascend the valley walls. This is accomplished by faulting the crust into long, narrow blocks and uplifting the separate blocks to form a staircase of sorts. These faults tend to have much greater throw (100 m average) and wider spacing (1.5 km average) than the valley floor fractures and are quite consistently inward dipping. Many of these "master faults" when examined in detail are represented at the surface by fault zones 100 m to 1 km wide consisting of a number of faults and slivers (e.g. see Figures 4 and 5 of Ballard and van Andel, 1977).

The actual values of the dips of these faults are difficult to ascertain. Macdonald and Luyendyk (1977) measured the slopes of the upper, talus free parts of 115 fault scarps crossed by deep tow and found an average slope of 50°. This is probably an underestimate of the actual fault dips since both erosion and the presence of undetected fault slivers and gouge would tend to produce a scarp slope which is less than the fault dip. The largest, clearest, best studied scarp, the inner west wall, has dips exceeding 75°. It is possible that this gives a better estimate for all fault dips and that other faults, with Letter resolution data, would be as steep. On the other hand, the inner west wall is clearly anomalous in its large throw and may be in dip as well.

The depth to which these faults penetrate as brittle features can only be surmised. As a rule of thumb, materials lose their ability to store stress at about one half of their melting temperatures (in degrees K), i.e., at 700-800°C for basalt. In thermal models, this temperature is reached at about 1-1.5 km depth On the other hand, these master faults may well become conduits of easy access for cold water penetration, cooling a halo around them and allowing the cracks to propagate deeper, cool deeper, propagate, cool, etc. (Lister, 1974). This could in fact be the mechanism for solidification of the underlying magma chambers at this point in space, as is often assumed to occur (e.g., Bryan and Moore, 1977).

It is interesting to consider what the chances are of encountering a fault or fault zone in a randomly placed drill hole. Given the above parameters the probability of hitting at least one large offset normal fault in a 500 m vertical hole is quite large, about 30%.

The nature of the third, mountain top deformation episode was investigated during the AMAR78 expedition and is presently being studied. Large scale flexures seem to characterize this zone (Atwater et al., 1978, Macdonald and Atwater, 1978). Their manifestation at depth is problematical.

Tectonic Tilt

Basalts recovered from deep sea drilling holes often have magnetic inclincations which are radically different from those predicted (e.g., see Hall and Ryall, 1977, or Low.ie, this volume). Furthermore, these "anomalous" inclinations can be constant over thick portions of the section. These variations are larger than would be reasonably predicted from secular variations of the field. The most popular explanation for them is that some sort o. tectonic tilt occurred after they were emplaced. Large tilts of 30 degrees or more are often required.

During the AMAR78 Expedition, we collected evidence near the rift mountain tops which suggests tectonic rotations of substantial blocks of crust by as much as 30° outward (Atwater et al., 1978, Macdonald and Atwater, 1978). This is in opposition to previous interpretations of morphologic data which appeared to preclude post formational tilts of more than a few degrees (Macdonald and Luyendyk, 1977, Macdonald and Atwater, 1978). In the ridge flank profiles presented in figure 10 of Macdonald and Luyendyk (1977), about 10% of the surface has a substantial outward slope. Some of these slopes are surely fault scarps. We may conclude that less than 10% of the area of the crust has been involved in these large mountain top flexures.

The tilts just described were observed at the surface and thus represent only post formational events. Tilts may also be acquired during formation. Indeed the models in Figures 1a and 1d require quite large consistent and predictable tilts. In the whole volcano model of 1c, large tilts are also quite possible for the buried volcanoes, since we have very little idea of how they sink out of sight. In deep holes, the observation that inclination changes often occur at lithologic breaks may also support a model in which each volcano in the vertical section experiences a somewhat different tilting history during burial. These ideas are more fully developed by Hall (this volume).

Fig. 5. Aerial patterns of fracture zone regime crust: (a) when all crust is formed at the ridge crest and then some is deformed during transform faulting (dotted area) and (b) when some addit² ral area is added within the transform fault itself (dashed area). Double lines show centers of spreading. Arrows show direction of motions of plates. Assuming east-west spreading, the pattern in the Famous Area is like that in (b) with three quarters of the fracture zone area appearing to be formed by ordinary spreading processes and thereafter deformed.

Typical Crust Versus Fracture Zone Crust

When we speak about a "typical" oceanic section we usually think of crust which was formed at a spreading center, faulted, and then carried away, pretty much undisturbed. In fact, a certain, not insignificant portion of the sea floor is either formed in fracture zones or highly deformed by them. It would be interesting to know what percentage of the ocean floor surface belongs to each category, and thus to know the chances of hitting fracture zone terrain when drilling in terrain which is less than perfectly mapped.

Simple topographic maps suggest that a very large part of the Atlantic sea floor belongs to the fracture zone domain. While the rift mountains are generally envisioned as linear features, in fact they appear as nearly circular features on the charts both in the Famous area and in many other well mapped, rifted sections of the Mid Atlantic ridge (e.g., Tag, Reykjanes). How-

ATWATER 39

ever, more detailed studies show that bathymetry is a very poor tool for delimiting the ridge and "typfracture zone domains. As discussed above. ical" oceanic crust has a very strong, consistent lineation in both the small and large scale tectonic features. In deep tow and multibeam data, individual step faults in the valley walls can be traced from one fracture zone to the next. However, these features, and indeed the valley floor itself, are not level but rather are bowed, being lower at their ends and higher at the center as shown by Macdonald and Luyendyk (1977) in their figure 16. This bowing causes the circular bathymetric appearance of the rift mountains on charts.

A Shit

Thus it seems that the best indicator of "typical" crust is probably its lineated character. We might define "typical" oceanic crust as that which shows a clear tectonic grain parallel to the ridge crest. The Gloria side scan information is a very good detector of this type of fabric. The lineation map produced by Whitmarsh and Laughton (1976, their figure 6) was taken and sections where the ridge crest grain is disrupted or non existent were shaded. The shaded area accounts for about 25% of the area less than 5 m. y. old. (The transform faults in this region are believed to have been formed during a spreading direction change starting about 5 m. y. ago, Atwater and Macdonald, 1977.)

The multibeam bathymetric maps published of the area by Phillips and Fleming (1978) allow a fine scale interpretation to be made of the fracture zone - ridge crest junctions. In their maps of the AB Rift Valley - Fracture Zone B intersection, the interaction of the rift and fracture zone tectonics are especially clearly shown. On the passive, eastern side of the rift floor, the linear rift valley scarps are continuous, undisrupted southward well into the fracture zone depression. On the western side, the side which faces the active transform fault, these same linear features are present at the edge of the valley floor but are broken up by east-west faults farther up the wall. Some square pieces of ocean floor, bordered by these two fault sets can be detected here. Farther to the west, these features disappear. Presumably they have been disrupted beyond bathymetric recognition as transform tectonism continues. These observations suggest that we must consider two types of material in the fracture zone domain: that which was formed as ordinary ocean crust and later tectonized, and that which was formed in the fault itself. If all material in the fracture zone were of the former type, fracture zone domains might be distributed as shown in figure 5a. In fact, the Gloria and multibeam maps show a pattern of disruption like that in figure 5b, in which a region in the center of the transform fault may never have been part of the "ordinary" crust. Assuming an east-west spreading direction in the Famous Area, this type of area appears to constitute about one quarter of the total

fracture zone domain in the Famous Area.

In conclusion, we find that using the structural and volcanic observations from the TAMOUS Project and other mid ocean ridge work we can make some comments concerning what is being encountered in deep basement drill holes in the Atlantic.

Concerning the structure of the volcanic section, morphelogic, magnetic, and petrologic data suggest that the zone of volcanic additions is probably as wide as the rift valley floor with possible occasional additions as much as 15 km from the center. This suggests that individual vertical sections should commonly include lavas with ages spanning a few hundred thousand years and may occasionally include as much as a million years or more. The evidence for a wide extrusion zone also leads one to models in which the number of dikes included in the volcanic section increases rapidly with depth. This is in opposition to the situation reported from ophiolites. If we wish to reconcile these two approaches, we can call upon a quite special model, one in which the bulk of the volcanic layer is emplaced by a very localized, centered process, but then a small amount of lava is extruded randomly on top, covering the surface with late stage, whole volcanoes. On the other hand, it may be a mistake to try to reconcile ophiolite and mid Atlantic models. There is a large variation among spreading centers, especially with respect to spreading rate. The ophiolite structure seems much more compatible with fast spreading ridges, where a continuous, centered site of extrusions is present and flank volcanism is relative's minor.

Famous Area observations suggest that a given section might commonly include three to six major volcanic episodes, that each episode might consist of about °^c flows and that flows might average 10 to 20m thick, though all these parameters show large variations. Flows may commonly be separated by layers of flow front rubble, consisting of whole or half pillow pieces. A vertical section downward through a pillow flow is expected to consist of bulbous pillows, a massive layer, elongate pillows, flow front rubble, and then (perhaps) some sediments. Sections of thin sheet flows are also expected. They might comprise 10 to 15% of the section near the top and greater amounts at depth.

Three sources of broken rock in the section are clear. Flows should be separated by flow front talus, described above; fault scarps may create large talus ramps, mostly on or near the top of the section; and faults may create zones of sheared rock at depth. Given the parameters associated with large normal faults in the Famous Area, 30% of deep crustal holes might expect to encounter fault zones at depth. These three sources generate quite different types of broken

40 ATWATER

rock which should be distinguishable in drill cores. The first sheds whole or large pieces of pillows; the second gives wedge shaped pieces, small sections of pillows; and the third generates lath shaped, sheared pieces.

If the transform faulted area of the Famous Area is typical, a randomly placed Atlantic drill site has a 75% chance of hitting material which was created at a mid ocean ridge and accreted to the crust without major disruption. The rest of the area was either formed within the transform fault itself (less than 10%) or was created at the ridge and then severely disrupted thereafter.

Acknowledgements

Tj. H. van Andel and W.B. Bryan were very generous with their time and ideas during the preparation of this summary. Discussions during the Ewing Symposium sessions were helpful; the comments and suggestions of R. Cann and W.B. Bryan being especially useful. Tj. H. van Andel and C.G.A. Harrison kindly reviewed the manuscript. This work was done under the partial support of the National Science Foundation.

Abstract. Over 120 drillholes deeper than 1000 meters have been drilled in Iceland, the maximum depth being 3085 m. Most of the holes are in geothermal areas where crustal temperatures are controlled by hydrothermal convection. Drillhole data are presented from type localities in structurally different areas such as active rift zones and central volcances as well as in dissected flood basalt and central volcanic sequences. The drillholes penetrate strata ranging in age from about 16-0 m.y.

)23, podos 34 pp.

> The chlorine content of waters issued from the deep wells is highly variable (<20-19000 ppm) which is largely due to different proportions of meteoric water and sea-water in the rock. The relative mobility of all the other major elements in these deep waters seems to be governed solely by various temperature dependent mineral/solute equilibria.

Rock alteration ranges from the zeolite to the greenschist metamorphic facies. Four alteration zones have been correlated with distinct rock temperature intervals. Fossil alteration zones and retrograde alteration of secondary minerals frequently demonstrate previous thermal conditions.

Magnetic susceptibility of drill chips has been measured in 15 holes and shows no systematic decrease with depth.

A regional survey of heat flow, based mostly on shallow drillholes located outside known hydrothermal areas, is summarized. The heat flow pattern is closely related to the history and development of the active zones of rifting and volcanism.

Introduction

A fairly large number of holes have been drilled into the leading crust, mainly in the last 20 years, for the purpose of producing geothermal water and steam for house heating, electric power production, and various industrial uses. The holes are of varying depth, mostly from about 500 m to 2000 m. The deepest one at present is 3085 m. Most of the holes are located in geothermal areas within the axial rift zone (high-temperature areas) or in the flood basalt areas flanking the axial rift zone (lowtemperature areas).

The purpose of this paper is to review drilling carried out in Iceland, with particular regard to results that may be of significance for understanding the oceanic crust, its structure and the processes at work within it. Among the topics discussed are: geological structure, stratigraphic logs, proportion of intrusives, resistivity logs, temperature profiles, hydrothermal convection, water chemistry, rock alteration, magneti- properties, regional heat flow, and crustal stresses. Typical drillhole data are precented from both high-temperature and low-temperature areas, followed by a general discussion based on all available data.

Rotary drilling rigs have mostly been used for the desper holes. Continuous cores are not taken, but cuttings are regularly sampled at 2 m intervals from the circulating fluid, which is usually water. The uncertainty in sampling depth appears to be of the order of 5-10 m, depending on depth and penetration rate.

Location of drillholes with regard to geology

The geological history of the land area of Iceland goes back about 15-16 My (Moorbath et al., 1968). Conventionally, three stratigraphic units are identified (Fig. 1.) on the basis of

PALMASON 43

the geomagnetic time scale and poleoclimatic evidence. They are (1) Tertiary rocks formed up to 3.1 My. ago, composed mainly of subaerial lava and only minor sediment and tufi. (2) Plio-Pleistocene rocks, formed between 3.1 and 0.7 My. ago, containing a substantial amount of sediment and subglacial volcanic rocks intercalated between subaerial lava flows, (3) Late Quaternary rocks of the active volcanic zones, formed during the Brunhes epoch, ize. since 0.7 My. ago. The zones of recent volcanism comprise the axial rift zones, which erupt tholeiitic rocks, and are the present locus of active plate growth, and the flank zones or lateral rift zones (Jakobsson, 1972; Saemundsson, 1978), which are characterized by alkaline or transitional rocks. The axial rift zones have in some places shifted position during the evolution of Iceland. In northwestern Iceland there is evidence of an extinct axial zone, marked by anomalous heat

Fig. 1. Location of drillholes over 500 m. The drilling areas are numbered for reference in the text. Coarsely dotted areas: Late Pleistcene to Holocene volcanics (yrunger than 0.7 m.y.). Finely dotted area: Plio-P⁻ istocene volcanics (0.7 - 3.1 m.y.). Unshaded areas: Miocene - Pliocene volcanics (older than 3.1 m.y.)

flow (cf.Fig. 17) and a synclinal structure of the basalts.

Deep holes have been drilled in all three stratigraphic units. The location of the drilling areas is shown in Fig. 1. In some of the areas there is only a single hole, while in others there are up to several tens of holes. The holes are in different structural environments, and penetrice rocks of the entire age spectrum of the volcanic succession. In the axial rift zones all the holes except one, Kaldårsel (loc. 19 in Fig. 1), have been drilled in high-temperature geothermal areas, which are often but not elways associated with central volcances.

It should be noticed that the depth of the holes does not always correspond to the depth from the original surface of the crust. This is especially true in the coastal areas and in valleys of the Tertiary flood basalts in eastern, northern and monthwestern Iceland, where glacial erosion has removed in places as much as 1500 m or more from the original surface. For example, the second deepest hole in Iceland at present (2820 m) is located in a valley in northern Iceland (Laugaland, loc. 40), where about 1500 m have been removed by erosion. The hole, together with the exposures alongside the valley, reaches about 4300 m into the crust as originally formed. In the axial rift zone on the other hand, drilling starts from a present-day surface that has not yet suffered erosion.

In the next section four examples will be given of data collected from drillholes in four different areas, two from high-temperature areas in the axial rift zone, and two from low-temperature areas in Tertiary and Plio-Pleistocene flood basalts outside the axial zone.

4. PÁLMASON

Fig. 2. Selected data from drillhole No. 8, Reykjanes (loc. 15) showing: a simplified geological section1), location of the main aquifers, temperature measurements1), percent intrusives, distribution of the main alteration minerals and the magnetic susceptibility of drill cuttings. The aquifers are located from recordings during drilling of loss or gain of circulation water and 'rom temperature measurements. The numbers refer to 1/s of lost or gained drilling fluid. The cemperature measurements are selected in such a way that they represent nearly undisturbed conditions. The percentage of intrusives is calculated for every 100 m of penetration. As the samples are cuttings some finegrained dykes may not have been identified. As dykes are cut under small angles the thickness will be highly exaggerated in the profile. Of the alteration minerals the most significant were selected and others omitted. The magnetic susceptibility represents smoothed values of measurements on samples from every ten meters of penetration.

1) Revised from Tomasson and Kristmannsdottir, 1972.

Examples of drillhole data

Reykjanes high-temperature area (loc. 15)

This thermal area is located at the tip of the Reykjanes peninsula, where the axis of the Reykjanes Ridge comes ashore. Fig. 2 gives data on stratigraphy, aquifers, temperature, alteration and magnetic susceptibility of the rocks penetrated in drilhole No. 8 which is the deepest hole in the area, 1754 m. The hole is close to sea level elevation, and located right at the axis as defined by earthquake epicenters (Klein et al., 1973) and recent volcanism. Some results of exploration and drilling in the Reykjanes area have been given by Björnsson et al., (1970, 1972).

The upper part of the stratigraphic section to a depth of about 900 m consists of mainly hyaloclastite and about one third of lava. In the lower part of the section basalt lavas predominate and are about 80% of the section. No dykes have been positively identified in this hole. The transition from the upper part to the lower

PALMASON 47

Fig. 3. Selected data from drillhole No. 10, Krafla (loc. 45). Legend as in Fig. 2.

part appears to coincide with a change in seismic P-wave velocity from 3 km/s to about 4 km/s, as inferred from seismic refraction profiles (Pålmason, 1971).

The lavas and the character of the sediments in the stratigraphic section indicate accumulation on dry land and in shallow water (Björnsson et al., 1972). This observation has a bearing on the mechanism of crustal accretion in the axial rift zone, and shows that crustal subsidence accompanies the deposition of volcanics at the surface. This process was already suggested by Walker (1960) to explain the regional structure of the lava pile in eastern Iceland.

The hydrochermal areas on the Reykjanes peninsula are somewhat unique among the Icelandic high-temperature areas in that the convecting fluid is largely sea-water, in which the chemical composition has been modified by interaction with the crustal rocks (Björnsson et al., 1972). The water is enriched in K, Ca and SiO₂ but depleted in Mg and SO₄ relative to sea-water.

The main aquifers in this hole are found in the lower part, where the basalt layas predomi-

48 PÁLMASON

nate. The alteration pattern reflects the relatively low temperature in the uppermost 2-300 meters. Chlorite and continuous occurrence of epidote are first obtained below about 1100 m.

Krafla high-temperature area.

The Krafla area is located in the axial rift zone of northeastern Iceland (loc. 45). Twelve holes have been drilled there in the last 4 years for a 60 MW geothermal power station which is under construction. The thermal area is located within a caldera structure, which is traversed by a volcanic fissure system, which has been tectonically and volcanically active for the past 3 years (Björnsson et al., 1972).

Fig. 3 shows sample data from one of the holes, KG-10. The uppermost 800 meters are mostly hyaloclastite, split into two parts by a 250 m thick suite of basalt lavas. Basalt lavas are predominant below 800 m depth, and hyaloclastites are rare. Dykes are common below 400 m, and from 1700 m the rocks are entirely intrusive and mostly fresh to the bottom of the hole at 2080 m. Thi

Fig

Fig. 4. Selected data from drillhole No. 16, Reykir (loc. 23). Legend as in Fig. 2.

The temperature values measured in the Krafla drillholes include the highest yet found in Iceland, about 340°C. The alteration pattern shows a fairly regular zoning, with some indication of a retrograde transformation of the sheet-silicates at depths less than 1200 m, where some cooling appears to have taken place (Kristmannsdöttir, 1977a). The magnetic susceptibility tends to increase with depth in this hole. One might perhaps be tempted to correlate this with the increase in the intrusives fraction with depth.

Reykir low-temperature area

This low-temperature area (Tomasson et al., 1975) is located close to a Plio-Pleistocene central volcano (Fridleifsson, 1973) on the western flank of the axial zone in southwestern Iceland (loc. 23). It is one of the main sources of hot-water for the Reykjavik district heating system, which serves about 120.000 inhabitants. Between 30 and 40 holes about 2000 m deep have been drilled in the area.

Fig. 4 shows data from one of the holes, MG-16, which is typical for the area. Hydloclastitles are dominant to about 1000 m depth. Below, there are mostly lavas, but hyaloclastite horizons are found to the bottom of the hole. Dykes are rare in the uppermost 1000 m, but their number tends to increase with depth. The temperatura profile shows a maximum at a depth of 300-600 m. The bottom hole temperature is very low compared to the expected temperature based on thermal conduction models; this illustrates the strong disturbance of the crustal temperature field by water convection in this highly permeable part of the crust. The hydrothermal system is characterized by horizontal aquifers. The best producing aquifers are found at the contacts of hyaloclastites and lavas. Fig. 5 shows a thermal cross section through a part of the Reykir thermal area, based on data from a number of holes. It shows two main tongues of ascending thermal waters, but otherwise the section is characterized by a relatively constant temperature, as one commonly finds in hydrothermal convective systems.

The alteration pattern in the Reykir area is very complex. Low-temperature alteration is superimposed on former high-temperature alteration associated with the extinct central volcano (Tômasson and Kristmannsdöttir, 1974).

and the second second second

Fig. 5. A thermal cross section through a part of the Reykir low-temperature area. The area of original hot spring activity is also shown.

A retrograde transformation of chlorites has been demonstrated.

Laugaland low-temperature area

Fig. 6 shows data from the Laugaland low-temperature area, located in the Tertiary flood basalt pile of northern Iceland (loc. 40). This is the second deepest hole yet drilled in Iceland, 2820 m. Basalt lavas with than intercalated sediments are the dominant rock type. Quartz-tholeiitic basalt is most common, but olivine-tholeiitics make up approximately 20 percent of the pile. Dykes are very common, especially in the deeper parts below about 800 m (Kristmannsdottir and Gudmundsson, in prep).

The temperature profile shows a fairly constant temperature of about 100°C. At the bottom of the hole this is very low compared to the expected temperature based on regional thermal gradients in central northern Iceland (cf. soction on heat flow). A strong hydrothermal convective cooling of the crust at 2-3 km depth is thus inferred. The aquifers are mainly connected with dykes, in particular where they cut scoriaceous and sedimentary interlayers between lava flows.

The alteration is mostly a fossil one, and effects of the present geothermal system appear to be minimal. This may be due to the relati-

50 PALMASON

vely poor permeability in the old lavas, and the rather narrow aquifers in this type of geothermal system. The magnetic susceptibility is fairly constant, and shows no trend of variation with depth.

As mentioned previously, this drillhole is located in a valley where approximately 1500 m have been eroded from the original top of the lava pile, as indicated by the zeolite zones. The hole thus reaches to well over 4 km into the original crust of northern Iceland.

Geophysical logging

Besides temperature measurements, which are made routinely both during and after the drilling, other geophysical methods are being adopted on an increasing scale. Resistivity (E-log) and diameter logging (caliper log) have been used in many holes for the last 3 years, and equipment has recently been obtained for making neutronneutron and gamma-gamma logs, although no results from these last methods are available yet for presentation.

The resistivity and caliper logs have proved to be useful as complementary methods to studies of drill cuttings in the basaltic crust of Icelund. Due to mixing in the nole, rock contacts obtained from the cuttings are not precise. Frequent changes in rock types without significant changes in the penetration rate are especially easy to overlook. A combined interpretation using the resistivity and caliper logs as well as the drill cuttings and the penetration rate, gives a much more detailed picture. Location of contacts is more exact, allowing thin layers and strata of contrasting porosity in the same rock unit to be distinguished.

In the following, an example will be given to illustrate the usefulness of the resistivity and caliper logs.

Fig. 7 shows a stratigraphic section, resistivity and caliper logs from a section of the drillhole LJ-8 at Laugaland in northern Iceland (loc. 40). The drillhole passes through a dolerite dyke in the section shown. It is not possible to locate exactly the boundaries of the dyke from the cuttings because of mixing with altered basalt lava cuttings above and below the dyke. This is indicated by two rock types shown in parallel in the stratigraphic section. The dolerite is predominant in the cuttings from about 1770 to 1940 m depth, and the penetration rate is also somewhat lower than in the surrounding lavas.

th

The caliper log has a rugged character at the upper margin, then shows a smooth surface to about 1940 m, below which the walls of the hole are very rugged, the diameter expanding to more than 30 cm in several places. This log locates the boundaries of the dyke at approximately 1780 and 1940 m, assuming the smooth part of the log to be associated with the dyke.

Fig. 6. Selected data from drillhole No. 8, Laugaland (loc. 40). Legend as in Fig. 2.

The E-log shows a conspicuous high resistivity associated with the dyke. The upper margin is not clearly indicated on this log, and the hole may well be following the dyke margin for some length before entering the dyke. At the lower margin the cuttings were a mixture of dolerite and lava fragments from 1940 to 2000 m depth. The E-logs in this depth range on the other hand are typical for a sequence of lava layers, with low resistivity porous boundaries between the less porous inner part of the lavas. The E-logs indicate a relatively sharp transition from the dyke to the underlying lava section. The caliper log is in good agreement with this interpretation.

The porosity is the main parameter affecting the resistivity measurements. On the basis of the cuttings and the caliper log the upper boundary of the dyke is located at about 1770 m. The resistivity logs then show that considerable variations in porosity exist within the dyke. The upper part in the section is highly porous, perhaps due to fractures, while the lower part has a very low porosity.

Water Chemistry

Chlorine variations.

The content of dissolved solids in waters from the deep wells is highly variable (150-29000 ppm). The waters in young formations near the coast tend tend to be highest in dissolved solids (Fig. 8); the increased salt content observed has probably

been derived from sea-water. Two different mechapisms can explain the transfer of salt from sea-water into the geothermal systems. They are: (1) leaching of salts from sediments deposited in marine environments (Tômasson, 1967), (2) percolation of sea-water into the geothermal systems and mixing with waters of meteoric origin either during the present sea level or during a higher sea level at the end of the Pleistocene when large parts of the lowlands were submerged (see Arnôrsson, 1978a). It is thought that process (1) is of little significance in affecting the salt content of the geothermal waters in Iceland. Thermal waters, which do not seem to have been affected by sea-water mixing, tend to be low in dissolved solids as reflected in their low chlorine content, which lies within about 5-50 ppm It is thought that this low chlorine content is due to the low chlorine content of the Icelandic basalts (see Sigvaldason and Öskarsson, 1976).

Mineral/solute equilibria.

In the following discussion the calculated activities of the various dissolved chemical species are always fitted to equilibrium cons-

52 PÁLMASON

Fig. 8. The chlorine content (in ppm) of thermal waters from deep drillholes in Iceland.

tants for mineral solubilities or ionic exchange reaction. The method of calculation has been described by Arnorsson et al. (1978).

The thermal waters tend to be saturated with chalcedony when the water temperatures are below about 180°C but at higher temperatures equilibrium with quartz is attained (Fig. 9A). It is generally found that other dissolved components fit better mineral equilibria at the chalcedony and quartz equilibrium temperatures than at the measured temperatures. This indicates that mineral/solute equilibria do not respond faster to cooling than quartz/chalcedony and dissolved silica do. The major exception is re-equilibration with calcite.

In general the waters are just saturated with calcite at the chalcedony/quartz equilibrium temperature (Fig. 9B). Only 5 samples show significant supersaturation. Three of these (1, 2, and 25) are significantly chalcedony supersaturated as can be inferred from Fig. 9A and Table 1.

Calculations show, however, that they are just saturated at the measured water temperature. It is thus concluded that these waters have reequilibrated with calcite upon cooling allough this has not been so for chalcedony.

Samples 11 and 15 are from vit-steam wells. Their supersaturation with respect to calcite is explained by flashing in the feeding aquifers and some loss of stor, and gas at the same time. This steam loss produces a gas deficient and calcite supersrouted well discharge (Arnorsson, 1978b).

Anhydr_ce is common in altered rocks associated wⁱ _n saline geothermal waters. Calculations shc, anhydrite saturation for the <code>hore</code> calcium .1ch saline waters and the hottest water (e.g. loc. 45), but other waters are undersaturated with respect to this mineral (Fig. 9C). There is an overall tendency for undersaturation to increase with decreasing salinity. It may be that sulphate in the more dilute waters is controlled by the following redox equilibrium:

 $H_{2}S + 4H_{2}O = SO_{4}^{-2} + 10H^{+} + 8e^{-1}$

where H_2S and the redox potential would in turn be governed by pyrite/pyrrhotite saturation and water pH.

Except for a few of the cooler drillholes all the waters are distinctly fluorite undersaturated (Fig. 9D). Waters from drillholes which are located in the vicinity of outcrops of acid rock tend to be higher in fluorine (25, 26, and 34) than waters that only have been in contact with basaltic rocks. It seems likely that thermal waters flowing through acid rocks may equilibrate with fluorite due to sufficient supply of fluorine from these rocks as has indeed been observed in the western U.S.A. (Nordscrom and Jenne, 1977). In basaltic rocks an ionic exchange equilibrium between flupridg and hydroxide ions is thought to govern the concentration of fluoride in solution (Fig. 11A). It is not known what OH-bearing silicates may be involved in this reaction but the plot in Fig. 11A suggests that probably two different minerals are involved. One of these minerals would be stable above about 100°C (1000/? less than 2.7) given a log F /OH ratio for the associated water of a little more than 0 and no variation with temperature. The other mineral is stable below about 100°C, giving log F /OH ratios between some -0.5 and -1.5. Variations with temperature are not c'ear. Samples 11, 45, and 46 plot at a low log F/OHT. This is considered to be the result of high pH calculated for these waters, glving a high figure for OHT as discussed below.

From Fig. 10 it can be concluded that the relative activities of the major cations (Na, K, Cu, and Ng) and protons are such that knowledge of the activity of one cation and the water temperature allows estimation of the activities of the other cations.

Samples 11, 45, and 46, plotted in Fig. 10, are from wet-steam wells and yield high metal/ proton ratios for all the cations. Flashing occurs in the aquifers feeding these wells. Some steam, and gas) loss accompanies this flashing giving a gas deficient well discharge. This results in a high calculated pH value relative to the unflashed reservoir water, which in this case is estimated to amount to about 1 pH unit.

The same samples tend on the whole to show the largest discrepancy from the best fit lines for individual metal/proton ratios, suggesting that the deviation may be mostly due to erroneous pH.

The distribution of Na⁺, K⁺ and H⁺ fits with equilibrium with alkali feldspar and K-mica over the whole temperature range (Figs. 11B, and 11C). The low-temperature waters seem to be wollastonite saturated (Fig. 11D). Equilibrium with

PÁLMASON 53

wollastonite and chalcedony (or quartz) would fix the ratio $\sqrt{Ca^{+2}}/H^+$ in the thermal waters. The more saline waters and waters above 100°C tend to be wollastonite undersaturated. It is not known what minerals control the $\sqrt{Ca^{+2}/H}$ ratio in these waters. The Ca⁻²/Mg ratio fits with equilibrium with montmorillonite as deduced

54 PÅLMASON

from thermodynamic duta of Helgeson (1969).

Analytical data for iron are not available for the waters from the deep wells. Preliminary studies of some other geothermal waters suggest, however, pyrite/pyrrhotite saturation for dilute water and pyrite saturation for geothermal sea water (Mottl, 1976; Gunnlaugsson, 1977) and a

Rock alteration

During growth and burial of the volcanic pile in the active zones of volcanism the rocks become altered to a varying degree. The degree of alteration increases with depth. High-temperature geothermal areas will locally create cupolas of high temperature alteration reaching to shallow levels.

of mineral zones was first demonstrated by Walker (1960) and has since been found to apply fairly well to other flood basalt areas studied in Iceland. The boundaries between secondary mineral zones represent fossil isotherm surfaces. Aureoles of a higher degree of alteration are exposed in the eroded roots of central volcances. Those are the depth equivalents of former high-temperature geothermal areas.

Two cross sections are presented here which show the extrapolation of secondary mineral zones from drillholes. One of the sections (Fig. 12) lies along the west side of Eyjafjordur in central northern Iceland, where erosion at sea level amounts to : 1200-1500 m. No central volcanoes occi alo.. the section, so that the results are probably representative of conditions in the Tertiary flood basalt pile in general. The dyke intensity varies along the section. It is between 5 and 102 in the northernmost part and in the extreme south. In between it is sligh-

downwards based on the examination of cuttings

56 PÁLMASON

Fig. 12. A cross section along the western coast of Eyjafjördur, northern Iceland, showing the subsurface extension of the alteration zones. The original surface of the lava pile is indicated in the figure.

tly less. The regional dip of the flood basalts cuts across the more or less horizontal mineral zoning.

The drillhole results show that the laumontite zone is extensively developed at depths generally between about 500 and 2200 m below sea level. The top of this secondary mineral zone is in other parts of Iceland visible only at the deepest level of exposure where dykes and intrusions exceed 10%. The laumontite zone is underlain by a zone with abundant epidote. This alteration zone is only exposed in the most extensively altered core of central volcanoes where intrusions form a significant proportion of the rock.

The second cross section (Fig. 13) lies across the axial rift zone in southwestern Iceland and the adjacent Plio-Pleistocene and Tertiary rocks. The regional lava dips are synclinal about the axis. The section passes through or near several central volcanoes with a high proportion of intrusions (Saemundsson, 1967; Fridleifsson, 1973, 1977). The secondary mineral zoning is disturbed around the intrusive complexes where hydrothermal convective systems have produced a zone of propylitic alteration with extensive development of chlorite, calcite, pyrite and epidote.

Correlation of rock alteration with temperature in active geothermal systems

Drilling in an active geothermal area gives an opportunity to observe metamorphism in progress. Most parameters affecting the process can be measured or calculated. The factors controlling the alteration pattern include temperature, pressure, texture, structure (incluaing porosity and permeability) and composition of rocks and also the original fluid composition.

At depths of 0-2 km the effect of pressure on the alteration pattern can be considered rather small. In rocks of similar composition, with geothermal fluids of similar origin, the main factors controlling the alteration pattern are temperature and permeability. The rocks in Icelandic geothermal areas investigated by deep drilling are largely basaltic in composition. The geothermal fluid is mostly meteoric water (see Arnason, 1976). There are differences in the lithology of the rocks, which affect more the kinetics than the products of the alteration process. The same main groups of alteration minerals are found to be formed in the holocrystalline basalts as in the basaltic hyaloclastites.

In the active high-temperature geothermal areas one comes closest to an equilibrium situation between mineral assemblages and rock temperature. In the low-temperature areas on the other hand one must be cautious of the relics from former alteration processes under different temperature conditions than those prevailing today. The appearance or disappearance of certain groups of alteration minerals and transformation of one clay mineral group to another has been used to define successive alteration

PALMASON 57

zones (Kristman.nsdóttir; 1975, 1977b, 1978) in the basaltic rocks of the Icelandic geothermal areas (Fig. 14). The zones can be correlated with certain metamorphic facies. Rock temperature is estimated from temperature measurements in the drillholes. Distribution of alteration minerals from all investigated areas is compared, and results from areas showing signs of relict alteration and disequilibrium are discarded. From such compilation and critical study of the data the temperature interval for

the formation of a certain mineral assemblage is fixed. The estimated transformation temperatures for the clay minerals are assumed to be quite reliable. The range of stability for laumontite is assumed fairly reliable and this is also valid for wairakite and epidote. The stability ranges for other zeolites is considered more uncertain and the same is true for actinolite. For the calcium silicates, prehnite and a few other alteration minerals in the Icelandic crust no stability temperature interval

Correlation of alteration zones with rock temperature in high-temperature geothermal fields

Fig. 14. Successive alteration zones observed with increasing depth and temperature in active high-temperature areas in Iceland. A correlation is made with rock temperature and regional metamorphic facies. Also shown are the index minerals and mineralogical changes characterizing each of the zones.

has been determined due to too few and in some cases contradictory data.

Fig. 14 is based mainly on data from high-temperature geothermal areas. The "low-temperature zeolites" are grouped together since a distinction can not be made between individual zeolite zones in the high-temperature geothermal areas due to their steep thermal gradient. A zeolite zonation comparable to that observed in the Tertiary basalt pile is observed in some low-temperature areas on the flanks of the axial zone (Kristmannsdóttir and Tómasson, 1976).

Due to the complex thermal history of the lowtemperature geothermal areas it is more difficult to relate the low-temperature zeolites to certain temperature intervals than is the case for the high-temperature alteration minerals.

Magnetic properties

Remanence

From various paleomagnetic surveys we infer that the polarity of primary magnetic remanence in deep drillholes outside the volcanic zones of Iceland is likely to change sign on average some eight times per km of depth, including short events. However, in the almost complete absence of core material from Icelandic deep holes, it has not yet been possible to utilize the remanence polarity for mapping or stratigraphic correlation in these. Little is also known about remanence intensities in subsurface formations (Kristjånsson and Watkins, 1977). Logging devices for downhole magnetic fields are difficult to construct because of the severe environment met with, and interpretation is subject to interference from lateral inhomogeneities, secondary and induced magnetization components, and variations in hole dimensions.

A proton magnetometer, developed by T. Sigurgeirsson and E. Jónsson, has been successfully tested to 470 m depth in Reykjavik (Jónsson, 1976). In basalts it shows: rapid and irregular field intensity variations, commonly \pm 10 ky (10 µT) in a few meters, while in thick tuff beds the field variations are of order of \pm 0.1 ky.

PÅLMASON 59

Fig. 15. Histograms of magnetic susceptibility values in samples of drill cuttings at 10 m intervals in Reykjanes hole No. 8 (shaded) and Krafla hole No. 4, grouped by rock type. Data from thin units are excluded.

Magnetic minerals

A TENE CONTRACTOR

The magnetic properties of basalts from deep drillholes in Iceland appear to be mostly due to cation-deficient magnetite. Strong field thermomagnetic curves obtained on 25 samples of drill cuttings from 14 deep holes (Kristjånsson and Watkins, 1977, and subsequent work) generally yield a single high Curie point in the range 540°-610°C. The major exception is two samples from below 1400 m in Heimaev island, both having a main Curie point near 350°C.

The magnetite probably exsolves from tranomagnetites on oxidation, in some cases during initial cooling of the igneous bodies, in others by the action of hot ground water during later burial. Incompletely exsolved titanomagnetites or magnemites are likely to occur at depth only in rapidly cooled rock units in areas where the thermal gradient has been low, as in Heimaey.

Susceptibility

Ē

Room temperature magnetic susceptibility χ of drill curtings has been measured at 10 m intervals for holes reaching to about 1000 m or more i. the fc''owi '4 localities (2, 11, 14, 15, 17, -9, 21, 23, ..., 30, 40, 45, 46, 47).

Manually smoothed graphs of χ for some of these holes are included in Fig. 2, 3, 4 and 6, and for a few others in Kristjansson and Watkins (1977).

The susceptibility in high Curie point samples

CO PÁLMASON

is a good indicator of the amount of magnetite present, that is broadly speaking the original magnetite content of the rock less what has been converted to non-magnetic minerals by secondary processes. The frequency distribution of observed χ values depends on the rock type. As an example we have 'lotted histograms of χ values from two high temperature drillholes (Fig. 15) where two main rock types occur. In contrast to hyaloclastite, susceptibility values of lava are high and tightly clustered. This shows that in basalt units the conversion of magnetite is a slow process, even at above 250°C, if they are massive enough to limit water circulation.

In the volcanic zone, the χ values from each drillhole, after smoothing, reflect to some extent the lithology (Fig. 2,3,4 and 6). A remarkable feature is the occurrence of relatively fresh and highly magnetic basalts at 300-500 m and below 1000 m in Krafla (45) (Fig. 3), at 1600-1700 m at Nåmafjall (46), and below 1500 m in Reykjanes (15) (Fig. 2). Some of these basalts may be quite recent intrusions, cf. section on Krafla above. In some holes in the volcanic zone

the susceptibility is uniformly low (Heimaey (2), Kaldårsel (19)), which may reflect the petrochemistry of the rock, or even almost zero due to alteration (Nåmafjall (46)). However, on the whole a trend towards low χ values with increasing depth is not observed so far.

Outside the volcanic zone the susceptibility lies mostly between 0.5 and 2 times 10^{-3} emu/g. It is very rare to find χ values lower than 0.5 10^{-3} units occurring consistently over a depth range of more than one hundred m (Fig. 4 and 6). No general trend towards low susceptibilities with increasing depth in a drillhole is observed, but there is a distinct increase in hole-average χ with increasing age of the area drilled. It has not been attempted to correlate these results with local magnetic anomalies in detail, but Kristjansson and Watkins (1977) have discussed the general implication of such observations to the "magnetic layer" problem in oceanic areas.

Heat flow

Heat is transported to the surface in Iceland by the three processes of heat conduction, water convection and volcanism. The following discussion will be confined mainly to the conductive heat flow. The convective part, i.e. the heat output of the geothermal areas, is in most cases poorly known. It has been roughly estimated to be 10^9 cal/s or about 4000 MW (Bod-varsson, 1961), of which the major part is from the high-temperature geothermal areas within the axial zone. The heat output of extrusive volcanism may be derived approximately from the rate of production of volcanics which is on the average about 0.045 km³/y. (see Jakobsson, 1972), giving a heat output of about 6000 MW (Pálmason, 1973).

Determining the conductive heat flow from shallow drillholes is complicated by the disturbing effects of convective hydrothermal systems, primarily in the neighbourhood of surface geothermal manifestations. Within the youngest axial zone, where the surface rocks are highly permeable, the movement of cold ground water by the effect of gravity also severely disturbs the shallow crustal temperature field. A few examples of temperature profiles disturbed by the effect of water convection are shown in Fig. 16. PALMASON 61

Fig. 18. The relation of the measured thermal gradients in the Icelan. ic crust to the distance from a reference spreading axis (Fig. 17). The error bars denote the sample standard deviations for grouped values within each 25 km distance interval. Theoretical curves for the thermal gradient versus distance from the spreading axis are shown for reference.

The location of the drillholes is shown in Fig. 1.

An attempt has been made to map the conductive heat flow pattern, by a careful selection of data to avoid the thermal effects of convecting water as much as possible. The main criteria in selecting drillholes for this purpose are that the temperature profiles be linear and that the holes be located outside known hydrothermal systems. There is of course always the possibility that hydrothermal systems may occur at depths below the bottom of the holes, but such systems would probably show as irregularities in the overall heat flow pattern of the area, if they existed.

The thermal conductivity of the rocks is not known for each individual hole, but since the lithology is similar in most of the holes, the gradient values will give a fairly good idea about the variation in heat flow values from one hole to another. Some 150 samples have been taken for conductivity measurements (unpublished measurements by B. Polyak, V.Kononov and A Jessop), and they indicate that a value of about 1.7 W/m°C is representative for a typical drillhole in the Icelandic crust. This value has been used to estimate the heat flow from the gradients.

Fig. 17 shows the thermal gradients from the holes selected. The holes are of varying depth, from about 100 meters to over 1500 meters. Data on some of the holes have been published by Pålmason (1973), others are more recent. A summary of the available data is given in Table 2.

62 PÁLMASON

We have tried to relate the gradient values to distances from an axis of spreading, using a reference axis as shown in Fig. 17. The reference axis follows the Reykjanes-Langjökull volcanic zone in southwestern Iceland and then shifts over to the eastern zone in northeastern Iceland. The heat flow values in central southern Iceland which are rather low near the eastern zone, support the assumption that the eastern zone in southern Iceland is relatively young, and that the Reykjanes-Langjökull zone has been the main zone of the rifting and volcarism during most of the geological history of Iceland (Saemundsson, 1974). In northern Iceland the ε tuation is loss clear. The first heat flow measurements from eastern Iceland indicated relatively low values suggesting that the main axial zone might have been a direct northward continuation of the Reykjanes-Langjökull zone (Palmason, 1973). When a larger number of new g: adient values were obtained in eastern Iceland, they were generally higher, suggesting that eastern Iceland crust might have been generated near the present axial zone in northeastern Iceland. This is in agreement with "ecent radiometric dating studies from eastern Iceland (Ross and Mussett, 1976; McDougall et al., 1976). We have therefore chosen here to locate the reference axis is northern Iceland along the present y active zone there.

The gradient values are plotted in Fig. 18 versus distance from the reference axis. The direction of drift is assumed to be N75°W, corresponding to the pole of rotation deduced by Pitman and Talwani (1972), and Talwani and Eldholm (1977). For comparison theoretical curves are shown which are based on model calcu: tion of crustal accretion for the lcelandic segment of the Mid-Atlantic Ridge (Pålmason, unpublished). For distance greater than about 100 km the theoretical curve is ident:cal with the result of Parker and Oldenburg (1973), while near the axis different curves are obtained for different assumptions regarding the mechanism of crustal accretion.

The data from southwestern, southern and eastern Iceland agree reasonably well with the theoretical curves. On the other hand the northwestern Iceland gradients are noticeably high. A conspicuous gradient high occurs on the northern part of the Snaefellsnes peninsula extending out into Breidafjördur bay. These values are shown encircled in the diagram, termed the Breidafjördur high. Other values from western North-Iceland are also high as shown separately in the diagram. It seems likely that an explanation for these high values in northwestern Iceland is to be sought in an extinct axis, possibly located along the Breidafjördur high. This possibility is also supported by the synclinal structure of the Tertiary basalt pile on both sides of this high. The continuation of such an extinct axis to the northeast of the Breidafjördur high is not clear, however.
Stress measurements in drillholes

The first direct measurements of the state of stress at shallow levels in the Icelandic crust outside the axial rift zone were made by N. Hast (Hast, 1969). His measurement., which were made by an overcoring technique, indicated compressive horizontal stress with average magnitudes greater than the overburden pressure at the depth of measurement. The depths at which Hast's measurements were made, were in most cases less than 30 meters.

The results of all the drillhole stress measurements made so far indicate that the maximum horizontal compressive stress at shallow levels on the flanks of the axial rift zone is oriented approximately perpendicular to the zone.

Earthquake focal mechanism solutions in the axial rift zone indicate on the other hand a minimum horizontal compression in a direction perpendicular to the main trend of the axial zone (Björnsson and Einarsson, 1974). Thus a significant change in the crustal stress appears to take place from the axial rift zone to the adjacent flanks. A possible explanation for this, which has been discussed in some detail by Haimson and Voight (1977), is that the cooling and thickening of the lithosphere as it moves away from the axial zone may cause horizontal compressive stresses, with the stress orientations changing with depth, as indicated by the Reykjavik hydrofracturing results. This possibility needs to be tested further by model calculation: , but it appears in a qualitative way capable of reconciling the earthquake focal mechanism results and the result of static stress measurements in drillholes by overcoring and hydrofracturing methods.

Conclusions

On the basis of data from drillholes into the Iceland crust several conclusions may be drawn regarding the structure of the crust and the processes at work within it. Some of the more significant points are enumerated below.

- Subaerial lavas are the main fock type to the bottom of all the holes, the deepest of which reaches to more than 4000 meters below the original uner ded surface of the crust.
- 2. In general, the fraction of intrusives increases with depth.

- 3. Aquifers occur in the drillholes to a depth of at least 2-3 km. Disturbance of the thermal state of the crust indicates that hydrothermal circulation reaches well below 3 km in some areas.
- 4. The magnetic susceptibility of the basaltic rocks generally shows no systematic variation with depth.
- 5. None of the holes yet drilled is deep enough to reach the high-'relocity (v_p≈6.5 km/s) lower crust indicated by seismic refraction surveys. Some shallower reismic boundaries have been penetrated by drillholes.
- 6. The chlorine content of the geothermal waters is mostly low, but high values are found near the coast, especially within the active volcanic zone, and are caused by mixing with sea-water.
- 7. Other chemical species in the geothermal waters appear to be governed by remperature dependent mineral/solute equilibria.
- 8. The alteration pattern observed in surface outcrops due to low grade burial metamorphism is also found in the drillholes. and there extended farther downwards. The deeper holes reach into the epidote zone, which in surface exposures is only found in the intensively altered cores of central volcanoes.
- 9. The rock alteration in active high-temperature hydrothermal systems has been correlated with rock temperature. Greenschist facies metamorphism occurs at temperatures above about 260°C.
- 10. The conductive heat flow pattern, based on data from 48 holes, shows certain regularities with respect to the active zone of rifting and volcanism, with decreasing heat flow values with distance from the zone. In certain areas, however, irregularities exist in the overall pattern.
- 11. Stress measurements by overcoring and hydrofracturing methods in relatively shallow holes show horizontal compressive stresses on the flanks of the active zone. The axis of maximum compression is approximately perpendicular to the strike of the zone of rifting and volcanism.

Preface

IT WARK

In early 1976 we embarked on a multiinstitutional field program to investigate the Mid-Cayman Rise Spreading Center, located along the North American-Caribbean plate boundary (Figure 1). Our study was designed to elucidate the tectonic behavior and petrologic processes associated with a short (110 km long) accreting plate boundary that is truncated by transform faults. This paper represents a general summary of our field program that spanned two field seasons and that involved traditional surface ship marine geophysical and geological techniques, a deep-towed camera system (ANGUS), a submersible (DSRV ALVI^M), a bathyscaph (DSRV TRIESTE II), and the United States Navy multi-narrow beam sonar mapping system (SEABEAM). These diverse, intensive and sophisticated tools provided investigators with a plethora of data that is still undergoing analysis. Consequently, our presentation is not meant to be a complete synthesis of the program but rather an opportunity to identify the types of data that we recovered, to summarize the results of our work to date and to outline the aims of our ongoing investigations. This general and integrated presentation is not meant to supplant the specific and in-depth papers, authored by a subset of the authors of this paper, that will tollow during the coming ear.

GEOLOGICAL AND GEOPHYSICAL INVESTIGATION OF THE MIDCAYMAN RISE SPREADING CENTER: INITIAL RESULTS AND OBSERVATIONS

*CAYTROUGH

Introduction

Regional Morpho-Tectonic Setting

The 1600 km long, east-west trending Cayman Trough (Figure 1) extends eastward from the Gulf of Honduras and terminates at the Windward Passage to the southeast of Cuba. The north side of the Trough, bounded by the Cayman Ridge, is characterized by precipitous escarpments. The Nicaraguan Plateau, rising roughly 5000 m above the floor of the Trough, flanks it to the south. Bathymetric and seismic reflection surveys made by Holcombe, et al. (1973) clearly indicate that the central portion of the Cayman Trough is comprised of rugged, north-south trending elongated ridges and troughs that have relief of 200 to

Fig. 1. Bathymetric map of the Cayman Trough showing location of the study area and two dive areae. The inset (after Jordan, 1975) shows the relation of the map area to the plate boundaries of the Caribbean. NOAM = North American Plate; COCO = Cocos Plate; SOAM = South American Plate; CARI = Caribbean Plate; MCR = Mid-Cayman Rise. 66 FOX 2000 m. Holcombe and coworkers found these lineated morpho-tectonic elements to be bilaterally symmetric about a central, deeply incised (to ~6000 m), north-south trending V-shaped valley. Seismic reflection data (Ewing, et al., 1960; Edgar, et al., 1971; Erickson, et al., 1972; Holcombe, et al., 1973) indicate that the sediment blanket thins toward the axis of this central valley. The observations of Holcombe, et al., that the basement morphology and the distribution of sediment within the Cayman Trough are virtually indistinguishable from the distinctive topographic fabric and sediment patterns associated with some slowly accreting plate boundaries, led them to suggest that the central valley is the axis of a slowly accreting plate boundary. They called this plate boundary the Mid-Cayman Rise and suggested that the Oriente Fracture Zone, which terminates the axial valley to the north, and the Swap Fracture Zone terminating the axial valley to the south, are transform faults. In support of their interpretation, Holcombe and coworkers

____: participated in field program.

noted that earthquake activity is confined to the axial valley and to the Oriente and Swan transforms; in addition, first motion studies along the Oriente and Swan transforms yield fault plane solutions consistent with left-lateral strikeslip motion parallel to them (Sykes and Ewing, 1965; Molnar and Sykes, 1969; Jordan, 1975).

Other marine geophysical and geological data are consistent with the interpretation of Holcombe and coworkers. Seismic refraction experiments (Ewing, et al., 1960) indicate that the crust of the Cayman Trough has a velocity structure which is similar to that of oceanic velocity sections, although the crustal velocity structure in the Cayman area appears to be much more variable than normal oceanic crust. Analysis of free air gravity anomaly patterns and Bouguer anomaly values suggests that, like the Mid-Atlantic Ridge, the Mid-Caynan Rise is compensated and that it is underlain by a low density root (Bowin, 1968). Erickson, et al. (1972) have shown that high heat flow values (2.0 HFU) are associated with the central portion of the Mid-Cayman Rise and the transform boundaries. The distinctive magnetic anomaly pattern recognized in ocean basins characterizes the Cayman Trough region and appears to be bilaterally symmetric about the central valley (Matthews, 1974; Macdonald and Holcombe, 15/8). In addition, Macdonald and Holcombe suggest that the Mid-Cayman Rise has been a symmetrically-spreading accreting plate boundary for at least the past 6 m.y., at a total opening rate ranging from 2.0 cm/yr (0 to 2.4 m.y.B.P.) to 4.0 cm/yr (2.4 to 6.0 m.y. B.P.). Eggler, et al. (1973) and Perfit and Heezen (1978) report the recovery of rocks identical to those recovered from other ocean basins; Perfit (1977) and Perfit and Heezen (1978) present chemical data demonstrating that the basaltic rocks recovered from the Mid-Cayman Rise are similar to abyssal tholeiitic basalts recovered from many parts of the mid-oceanic ridge system.

The geological and geophysical properties of the Cayman Trough are consistent with the suggestion that the Trough is underlain by oceanic crust and that presently oceanic crust is being accreted along a short (110 km long), north-south trending spreading center. To the north and south the Mid-Cayman Rise is truncated by two left-lateral transform faults. The bilateral symmetry of topography and sediment distribution about the Rise axis, the gentle decay of sea floor topography away from the flanking rift valley mountains, and the correlatable and bilaterally symmetric magnetic anomaly pattern all lend support to the suggestion that the locus of sea floor spreading has been positioned beneath the central valley of the Mid-Cayman Rise for at least 6 m.y.

The accreting plate boundaries of the Earth are continuously evolving as the geometry of the plate mosaic adjusts and the dynamics of the driving mechanism change. Accreting plate boundaries exhibit a wide range in morpho-tectonic character: rates of crustal accretion range from a few cm/yr to as high as 18 cm/yr; some accreting plate

boundaries are characterized by frequent ridgetransform-ridge intersections, others are unbroken for hundreds of kilometers. If we are to understand fully the salient geologic processes operative during plate accretion and how these processes vary in time and space, then we must study representative segments of the accretionary continuum. The Mid-Cayman Rise spreading conter epresents an end-member example of this continuum in that its rate of spreading is a' the low end of crustal accretion rates ($\approx 2 \text{ cm/yr}$), and it is an isolated short accreting plate boundary truncated by two long transform faults that juxtapose cold, thick lithosphere against the spreading center. Our intention during the Caynan Trough project was to document the structural and petrologic character of this accreting segment and ask the question "how do these geologic properties compare with the rest of the plate accretion continuum?"

The Cayman Trough Project

The Cayman Trough Project took place between January 1976 and July 1977. During this period four separate field programs were conducted. The first effort in January and February 1976 involved the use of the submersible ALVIN and the deep-towed ANGUS photographic system, with the ALVIN conducting a detailed sampling and observational program on the steep fault scarps that border the rift valley of the Mid-Cayman Rise spreading center and the ANGUS conducting a comprehensive photography program in the rift valley itself. ALVIN, aided by its advanced acoustical transponder navigation system (ALVIN), carried out a series of 15 dives at two sites on either side of the rift valley (Figure 2). While these dive traverses were being conducted, scientists aboard the R/V KNORR used a similar tracking system (ACNAV) to conduct 46 dredge stations (Figure 2) and 21 camera lowerings (Figure 3) in various portions of the rift valley and flanking terraces. The ANGUS system used in our investigation consists of a 35 mm color-camera system mounted in a heavy-duty steel frame.

The initial field program was followed in April 1976 by a detailed bathymetric survey of the region using the USNS BOWDITCH. This U.S. Naval Oceanographic Office ship is outfitted with an advanced multi-narrow beam sonar mapping system capable of surveying large areas of the sea floor very rapidly (Glenn, 1970). The multi-narrow beam sonar system (SEABEAM) aboard the USNS BOW-DITCH consists of a hull-mounted sonar array and a sophisticated inertial navigation system. The hull-mounted sonar is a T-shaped unit having two separate arrays. The fore and aft array generates a narrow signal which sweeps out an arc perpendicular to the direction the ship is traveling. The reflected acoustical signals are received by the thwart ship array, which divides them electrically into a large number of narrow beams. This acoustical information is combined with satellite and inertial navigational data to produce a swath of bathymetric information printed

in

duced from tris survey was at a scale of 1:136,000 (sigure 4) and a contour interval of 50 fathoms (uncorrected). These topographic data, which are recorded in a digital format, can subsequently be displayed at smaller scales.

Based upon an analysis of the data collected on the first two field programs, a return visit by the submersible ALVIN and the research vessel OCEANUS was conducted in March of 1977. This field program had tw primary putposes; the first was to use ALVIN to make a series of eight addicional dive traverses up the stee, faulted terrain on the eastern side of the rift valley, where outcrops of Layer 3 were found the previous year. The purpose of the OCEANUS program, on the other hand, was to conduct another dredging program throughout the rift valley and flanking terrace regions to delineate further the central zone of volcanic activity, as well as to obtain samples of ultramafic material exposed in the nearby fault scarps that are below ALVIN's diving limit of 3600 meters.

The final phase of the Cayman Trough Project was carried out in July of 1977 using the U.S. Navy's bathyscaph TRIESTE II. The KNORR and CCEANUS programs using ANGUS and precisely navigated dredge stations had succeeded in delineating the recent zone of volcanic activity. Using this information and the detailed multi-narrow beam topographic maps, a series of three dive traverses will e made by the TRIESTE II in the northern, critral and southern portions of the rift valley (Figure 2) during which observations, bottom phocographs and basalt samples were collected.

General Topography of the Mid-Cayman Rise Spreading Center

The Inner Floor

The bathymetric map compiled from the SEABEAM data clearly defines the first-order morphotectonic character of the 110 km long axial valley. The inner floor is outlined by the 2500 fm (4575 m) contour and has a general north-south trend as defined by the strike of the flanking rift valley walls. The volcanic ' ctonic grain of the rift valley floor is more complicated, however, than the reconnaissance surface-shipbathymetric surveys (Holcombe, et al., 1973) had originally indicated. The SEABEAM results (Figure 4) show that the inner floor is not continuous along its 110 km length, but appears to be disrupted and offset in a right lateral sense by a short, several kilometer long, northeastsouthwest trending discordant zone (nascent transform fault?) positioned at a point midway between the truncating Oriente and Swan transform faults.

The rift valley segment north of the discordant zone is characterized by a closed-contour, 3500fm (6402 m) deep depression at $18^{\circ}45$ W where it intersects the Oriente transform (Figure 4). The inner floor proximal to the transform intersection is 15 km wide, and the volcanic/tectonic terrain comprising the floor is linear, strikes northsouth. and has relief on the order of a few hundred meters. Away from the intersection towards the south, the floor of the rift valley progressively shallows to 2800 fm (5120 m) and continuously narrows to a width of a few kilometers; in addition, the aris of the inner floor is offset to the east by several kilometers (to its most easterly point at $18^{\circ}20'W$), and the lineated elements of the inner floor are progressively rotated from a trend of 180° at the northern end to 160° in the south at the intersection of the floor with the discordant zone $(18^{\circ}20'W)$. This intersection is characterized by a welldefined, conical volcanic hillock. As in the north, the intersection of the

southern inner floor with the Swan transform at 15°43'W is characterized by a closed-contour, 3600 fm (6585 fm) depression. The inner floor is approximately 15 km wide at the rift valleytransform intersection, but over a distance of 20 km the floor narrows to a width of several kilometers and shoals to a depth of 2700 fm (4940 m). Northwards from this narrow gate, approaching the intersection with the discordant zone, the inner floor becomes progressively wider (reaching a maximum of -18 km) and deeper (characterized by a 3000 fm (5487 m) deep closed-contour depression). The linear volcanic/tectonic grain of the southern inner floor strikes approximately 180° near the terminus of the inner floor with the Swan transform, but towards the north, adjacent to the discordant zone, the elongated closed-contour depressions and an intervening 500 fm (915 m) high ridge strike 160°.

The inner valley floor of the Mid-Cayman Rise spreading center exhibits many of the morphotectonic characteristics that have been shown to be typical of slowly accreting plate boundaries. The deep, closed-contour depressions defined at the northern and southern terminus of the inner floor are a characteristic feature of slowly accreting ridge/transform fault intersections (Fox, et al., 1969; Sleep and Biehler, 1970). Like the rift valley segments of the FAMCUS region (Ballard and van Andel, 1977; Macdonald and Luyendyk, 1977) the width of the inner floor is variable, ranging along strike from a few kilometers to many kilometers, and the morphologic elements of the inner floor are characterized by a series of linear ridges and troughs striking roughly parallel to the overall strike of the rift valley and with relief on the order of several tens of meters.

The ANGUS photographic data and TRIESTE observations indicate that the ridges are characterized by linear volcanic edifices comprised of elongated pillow flows stacked in a chaotic manner (Figure 5a, d). The flanks of the constructional piles are dominated by steeply dipping flow fronts draped by elongated pillow forms pointing downslope. In general, the troughs between the parallel volcanic ridges are constructional depressions formed by interlocking pillow fronts emanating from the flanking ridges. In the northern valley segment, however, the zone of most recent volcanism is also characterized by an

Fig. 5. (a) Photograph taken by ANGUS camera system of typical pillow lava terrain. Pillow form in lower right-hand corner has been broken, exposing its hollow interior. (b) ANGUS photograph of a sheet flow.

(c) ANGUS photograph of open fissures cutting across the older volcanic terrain which flank the central zone of volcanism. (d) Picture taken by the bathyscaph, TRIESTE II, near the summit of a young central pillow volcano in the northern rift valley segment. The vertical face shown in the picture is a small fault scarp exposing the truncated cross-section of pillow forms.

extensive sheet flow (Figure 5b) which has filled a linear depression adjacent to a contral offlowed ridge. Mannive wheet flows have been observed along the axis of accreting plate boundaries exhibiting a wide range in spreading velocities (Ballard, et al., in press), and they appear to represent an important phano in the volcanic cycle that creates the extrusive carapace of the oceanic crust. In general, where constrained by ANGUS and TRIESTE data, the zone of most recent volcanism within the inner floor is 2 to 3 km wide and is characterized by sediment-free, elongated volcanic constructional piles similar to those observed in the FAMOUS region (Ballard and van Andel, 1977; Ballard and Moore, 1977). The one exception to this observation is obtained by the TRIESTE and ANGUS traverses across the elongated depressions and ridge located at the northern terminus of the southern inner valley floor, revealing that this area has not experienced recent volcanic activity, since the terrain is blanketed by a thin veneer of sediments and only rarely is the pillowed oceanic basement exposed. ANGUS and TRIESTE results indicate that the areas flanking the zone of most recent volcanic activity are characterized by older sedimented volcanic terrain that is undergoing distension, as exhibited by open fissures (Figure 5c) and small fault scarps flanked by talus ramps.

The Rift Valley Walls

The morpho-tectonic boundary between the inner floor of the rift valley and the bounding inwardfacing walls is abrupt and defined by north-south striking escarpments which rise in a series of steps several hundred to over a thousand meters above the inner floor (Figure 4). These nearvertical elements, undoubtably comprised of a family of small-throw faults, are linked to one another by broad terraces that dip gently toward the inner floor. This morphologic fabric, known to be characteristic of the topography developed along the rift valley walls of slowly accreting plate boundaries, integrates to create over 2000 fm (3658 m) of relief from the inner floor to the crest of the bounding mountain tops. The welldefined north-south tectonic grain of the rift valley walls is interrupted in places by a second order east-west grain that, when combined with the north-south grain, outlines a number of blocks that flank the inner floor. Two of these blocks were chosen to be investigated during the Cayman Trough Project by the submersible ALVIN. The first area of investigation, referred to as Dive Area 1, was visited in 1976 (Dives 611-616) and 1977 (Dives 737-742), and is located on the eastern wall of the rift valley near the southern terminus of the Mid-Cayman Rise spreading center (Figure 2). Dive Area 2 was visited in 1976 (Dives 620-625) and is located on the western wall of the rift valley on a block that is midway between the Oriente transform to the north and the Swan transform to the south (Figure 2).

the 18 diven made by ALVIN in the two dive areas provide a perspective of the norphulogic elements of the new floor that can be attained. only by this type of in elty observation. Even at the relatively small scale (50 to 100 meter contour intervals) depicted on the base maps for each dive area (Figures 6 and 7), observed variability in topography cannot be accurately represented. As can be seen on the dive crosssections (Figures 8 and 9), the regional slope of the rift valley walls is actually created by a series of N-S striking, steep (slopes range from 60° to vertical), inward-facing rock scarps with relief on the order of a few meters to soveral tens of meters. These near-vertical elements are linked by inward-facing carbonate/ talus ramps characterized by widths ranging from a few meters to several hundred meters and by slopes ranging from 10° to 45°. The steeper carbonate slopes contain numerous talus fragments and rock bolsters that protrude through and are incorporated in the sediment blanket. ALVIN survey data indicate that the character of a given topographic element can change markedly along strike. Over a distance of a few tens to a few hundred meters a carbonate/talus ramp may vary considerably in slope and/or width, or a welldefined escarpment may lose definition and disappear.

Superimposed upon the N-S striking inwardfacing escarpments and carbonate/talus ramps is a family of generally E-W striking valleys and promontories which modify the dominant N-S grain and produce a saw-tooth morphology. The vertical extent of these E-W features varies from a few tens to several tens of meters, and reconnaissance mapping on the bottom indicates that the E-W trending valleys and promontories are discontinuous over distances of several tens to a few hundred meters. In general, the valleys are characterized by moderately dipping carbonate slopes $(10^{\circ}-30^{\circ})$ covered by talus and bolsters, but occasionally rock escarpments are observed with relief of a for tens to several tens of meters suggesting that these E-W trending elements are fault controlled.

The faces of individual scarps are cut by a family of intersecting joint sets (N-S and E-W, and a third set which appears to be roughly horizontal) and by anastamozing cracks which interrupt the structural continuity of the massive, joint-bounded blocks. The intensity of jointing and cracking varies from relatively unfractured faces which are continuous over several tens of meters (Figure 10a) to outcrops at which the rodos are fragmented into cobble-sized blocks. The faces of a few escarpments that are not badly disrupted by jointing and fracturing exhibit the polished and grooved surfaces typical of slickonsides (Figure 10b). We suggest that all of the steep rock escarpments represent relief elements created by faulting, but that gravitational collapse of joint-bounded blocks has resulted in removal of the original faulted surface.

Rocks From the Mid-Cayman Rise Spreading Center

Our bottom sampling program during the Cayman Trough project had two thrusts. The first of these was an extensive dredging program carried out during two cruises: R/V KNORR, 1976 and R/V OCEANI3, 1977. Numerous dredge stations (Figure 2, Tables 1 and 2) were positioned along the length of the rift valley inner floor, and these results confirmed that a central lineared zone along the inner floor is characterized by recent volcanism as evidencea by glass-encrusted pillow lavas. Fewer dredge stations were located along the flanks of the rift valley (Figure 2, Tables 1 and 2); these dredges recovered weathered basalts, metabasalts, gabbroids and ultramafic rocks. Our sampling program on the rift valley walls focused on two blocks that flank the inner floor and was carried out by the submersible ALVIN (Figure 2).

- 4

During ALVIN's 18 traverses across the bottom an effort was made to sample the outcrops as frequently as possible. Sampling was limited by time and by the difficulty of recovering rocks from massive outcrops with a mechanical arm. Of necessity some samples were recovered from the flanks of bolsters or rarely from isolated talus blocks. Most frequently samples were obtained directly from rock escarpments or from loose fragments lying on an escarpment or at its base.

Ninety-four sampling stations were occupied during our dive program, at which 142 samples were collected. A diverse range of rock types, all typical of those recovered from other areas of the ocean floor, are represented in our collection. Gabbroic rocks are the most abundant. In situ sampling along some outcrop faces and closely spaced sampling up an escarpment indicates that the predominantly gabbro terrain is occasionally cut both by foliated amphibolites (Figure 10c), and by ultramafic screens that alter the country rock, often resulting in the production of rodingitized .abbro. At other localities, intensely fractured zones of altered and deformed gabbro lie adjacent to gabbro that is fresh and undeformed. No basalts were collected in situ during our investigation of Dive Area 1, and no outcrops were observed there which exhibited macroscopic features suggestive of extrusive basalt. During one dive (742, station 5 at 2800 m depth), gabbros were collected to within 250 meters of the crest of the rift valley wall, and on this same traverse, 13 meters above station 5, cross-cutting structures suggestive of dikes sere observed (Figure 10d). In Dive Area 2 basalt samples were collected in situ from pillow lava terrain during two dives (624 and 625).

All of the exposed rock surfaces are covered by a veneer of manganese, and therefore only the macroscopic texture of the rock outcrop can be unequivocally characterized. The outcrops sampled during the submersible program exhibited four distinct textural expressions. Most frequently we observed massive blocks characterized by a rough surface. If an outcrop of this nature was cut by only widely spaced intersecting joint sets, then the rock type recovered was relatively unaltered troctolite or gabbro (Figure 10a). In some instances at there outcrops we observed a subtle subhorizontal foliation suggestive of layering. When the continuity of the rock, although still coarsely textured, was disrupted by anastamozing fractures, we recovered altered and deformed gabbro. The second outcrop type exhibits a moderately well-defined foliation and has a rubbly appearance (Figure 10f). Samples recovered

from there outcrops are foliated amphibolites. The third outcrop type is heterogeneous and chaotic in character. In some cases the outcrop has the appearance of a fruitcake with large ovoid fragments of rock randomly set in a finer rubbly matrix (Figure 10e) Rocks recovered from exposures with this texture are serpentinized ultramafics. The fourth outerop type was observed only in Dive Area 2 and is characterized by very gently dipping clopes covered by pillow lava.

Petrology of Basalts from the Inner Floor

There is some difference in the external character of the basalts recovered from different areas within the spreading center. Basalts collected from the volcanic constructional highs which define the axis of the rift valley floor are fresh and glassy with little or no mangamese surface coating; these samples exhibit no evidence of low temperature alteration. Basalts that were sampled from the sides of the rift valley floor and from the crest of the flanking rift valley mountains are encrusted by a thin veneer of manganese and do exhibit the effects of low temperature alteration.

The majority of the basalts recovered by dredging are aphyric or sparsely porphyritic. When phenocrysts arc present they occur as olivine and plagioclase; in a few samples olivine is the sole phenocryst phase. Clinopyroxene phenocrysts have not been observed. Microphenocrysts of spinel are rarely present, and large corroded xenocrysts of olivine and plagioclase are present in a small number of samples. The range in phenocryst abundance is 0 to 5% of the total volume. Most samples are microscopically

TABLE 2. Successful Dredge Results from R/V OCEANUS Cruise 23.

vesicular, containing 0.10% to 1.5% of vesicles by volume.

To date our petrologic studies of basaltic rocks have concentrated on the fresh glassy pillows recovered from the axis of recent volcanism centered along the rift valley floor. Major element chemistry of 33 glass specimens from pillow lavas were analyzed by electron microprobe at the Department of Mineral Sciences, Smithsonian Institution. Carefully separated glass fragments were hand picked from the same samples and cleaned of alteration products or phenocrysts and analyzed for their trace element content. B, Ba, Co, Cr, Cu, Li, Ni, Sr, V, Y and Zr were determined by direct-reading emission spectrometry.

The 33 major and trace element analyses indicate (Tabl^s 3 and 4) that when compared with typical mid-ocean ridge basalts (MORB), the Cayman basalts are higher in TiO₂, Na₂O, K₂O, P₂O₅, Zr, Y, Sr and Ba contents and generally lower in CaO content for a given FeO/MgO ratio. Transition metals and large ion lithophile (LIL) element covariances are similar, but not identical to MORB. Overall, the Cayman glasses seem transitional between MORB and 'plume' or 'hot spot' related oceanic basalts, but the Cayman samples clearly have some unique features of their own (e.g. high TiO₂, Na₂O, Zr, Sr and Y contents).

The range in composition and tight correlation between LIL-elements (Figs. 11 and 12) suggest that the liquids producing our suite of samples are derived from a common source, and that the variable composition of these liquids is controlled by fractional crystallization. Preliminary modelling of the observed compositional variations is compatible with a sequence of crystallization involving plagioclase, olivine and clinopyroxene. The lack of clinopyroxene phenocrysts in the basalts indicates that clinopyroxene is not an equilibrium phase in the low pressure environment of a magma chamber at shallow depth. Aluminum-chrome diopside is present in the plutonic samples collected by ALVIN from the rift valley walls and may represent an early fractionating (high pressure) phase. Observed

variations in the Cayman basalt chemistry can be explained by a two-stage fractionation model: selective removal of an aluminum-chrome diopside having the chemistry of those observed in the plutonic rocks, followed by shallow-level fractionation of plagioclase and olivine. If, as our results suggest, the gabbros and basalts are genetically related, then there is long-term consistency of the magnatic processes that produce both the basalts dredged from the rift valley floor and the gabbros sampled from the flanking rift valley walls.

Petrology of Gabbros from the Rift Valley Walls

The principal rock types sampled from the flanking walls of the rift valley (in both dive areas 1 and 2) include "normal" gabbro, olivine gabbro, orthopyroxene gabbro, troctolite, norite, serpentinized ultramafic, amphibolite, diabase (one sample) and crystalline basalt. The samples

Fig. 11. TiO2 versus Na20 contents of Cayman glasses. 82 FOX

were recovered from the faces of individual scarps, were sampled as loose fragments associated with a given rock outcrop, or (rarely) were recovered from talus piles in otherwise heavily sedimented terrain. Almost all specimens were encrusted with a thin veneer of manganese. The samples exhibit a wide range in degree of alteration and deformation.

Our freshest samples vary from medium to extremely coarse-grained, with individual minerals ranging in size from 0.2 to 4 cm, and are equigranular to slightly porphyritic. Primary phases include plagioclase, clinopyroxene, olivine and orthopyroxene, and a minor amount of hornblende and primary opaque minerals. The principal accessory phases are apatite, zircon and sphene. Ophitic to subophitic intergrowths of plagioclase

and clinopyroxene and poikilitic intergrowths of olivine and plagioclase or olivine and clinopyroxene are sometimes present. Although mineral layering or banding is not observed in our collection, other textural evidence (such as an apparent volumetric excess of plagioclase) suggests a cumulate origin for some samples.

Primary plagioclases are subhedral to euhedral and many show simple twinning, but only very rarely are optically zoned. Polysynthetic twins are common but in most cases are clearly deformation-related. Clinopyroxene exhibits a variety of exsolution textures, and minerals present as exsolution lamellae are brown hornbiende, opaques and orthopyroxene. The lamellae may be wide and stubby, very thin and closely spaced, or, in rare instances, worny, similar to myrmekitic texture. Olivines within our suite of samples are anhedral to subhedral and within even the freshest rocks are cross-cut by fractures filled by alteration phases. Orthopyroxene is not a common phase.

Brown hornblende is a primary phase in many of the fresh or only slightly altered gabbroic rocks. Chestnut-brown pleochroic hornblende commonly occurs in rims around mafic minerals in pyroxene-rich rocks and very rarely in troctolites. Brown strongly pleochroic hornblende appears in small, irregular and isolated patches in a few samples. Two styles of alteration characterize the Cayman Trough gabbros. The first style is a relatively high temperature recrystallization of primary igneous phases (typically plagioclase, clinopyroxene and hornblende) involving changes in phases, grain size and composition. The second type of alteration which is associated with brittle fracturing of the samples and which is characterized by static replacement of a pre-existing phase by a new phase or phases, produces reaction rims, pseudomorphs and veins of secondary minerals. Most of the gabbroic samples exhibit some evidence of the low temperature, static alteration. Incipient alteration is characterized by the filling of brittle fractures with secondary minerals (e.g. chlorite, actinolite, etc.). More extensive alteration is characterized by the replacement of mafic phases by a host of secondary minerals; pervasive alteration is indicated by the complete replacement of mafic phases and the alteration of plagioclase.

At least two phases of deformation also appear to have affected the plutonic rocks collected from the rift valley walls of the Mid-Cayman Rise spreading center. An early ductile phase is indicated by bending, twinning, kinking, subgrain formation and recrystallization of primary phases. A later brittle phase is indicated by penetrating fractures and broken grains. The degree of intensity of these features varies considerably within the suite. Some specimens preserve original ig-

neous textures whereas others have been almost entirely recrystallized and/or are greatly fractured. Even on the thin-section s ile, narrow zones of intense shearing and recrystallization cut through domains much less affected by the deformation.

Whole-rock major element chemistry of selected representatives of the principal rock types sampled from the wal's of the Mid-Cayman Rise spreading center is presented in Table 6. One hundred and thirteen plutonic rocks and eight crystalline basalts were analyzed on the electron microprobe after preparation of glass beads by rapid fusion at 1700° C in a molybdenum strip furnace under argon atmosphere. Detailed major element data on these samples and trace element data on a subset of sixty samples will be presented elsewhere.

Unlike the chemistry of the basalts dredged from the Cayman area, the bulk chemistry of the gabbro samples appears to be identical to that reported for other oceanic gabbros and abyssal tholeiitic basalts. All but one of the entire suite are olivine-normative and all but twenty are hypersthene-normative. The percentage of K.0 is uniformly low, ranging from 0 to 0.43% and averaging 0.18%; this is comparable to the range defined by previous determinations on fresh abyssal tholeiitic basalts collected from several oceanic regions, which have uniformly low potash contents varying from 0.03 to 0.40% (Shibata and Fox, 1975), and slightly lower than the range defined by Shibata and Fox for fresh abyssal tholeiitic basalts from the Oceanographer Fracture Zone, North Atlantic (0.16 to 0.75%). The range of K₂0 for Cayman gabbros is slightly larger than the range of values for gabbros collected from the Indian and Atlantic Jceans (0 to 0.30%; Fox and Stroup, in prep.). SiO2 for individual analyses

of the Cayman rocks varies between 35 and 55 percent and averages roughly 49 percent. Al203 content is moderately high, averaging 18%, which is only 1-2 percent higher than the average $A1_20_3$ given by other workers (i.e., Miyashiro, et al., 1970, for ocearic gabbros and Shibata and Fox, 1975 for abyssal tholeiitic basalts). The range in FeO*/MgO ratio (FeO* is total iron calculated as FeO) in the Cayman gabbro samples is 0.27 to 3.24, as compared with a range of 0.32 to 2.84 presented by Miyashire, et al. (1970) for other oceanic gabbros. It is interesting to note that the variability in chemistry observed within the gabbroic samples from this single, geographically well-constrained area of the ocean floor is as large as that observed in gabbroic samples collected from all of the world's oceans.

The effects of two distinct processes, primary igneous crystallization differentiation and secondary alteration must be evaluated in a preliminary analysis of major element variations. Our results might appear to suggest that alterat on has not significantly modified the primary igneous chemistry of the Cayman gabbroic samples (reflected in the composition of the least altered aphyric basalt 624 7-1. Table 6). When the population of Cayman plutonic rocks is plotted relative to gabbros from elsewhere in the world's occans, as shown in Figure 13, the Cayman samples follow the tholeiitic differentiation trend defined by Miyashiro, et al. (1970) for gabbros dredged from the Mid-Atlantic Ridge. In addition, many of our samples are rel tively less fractionated than other oceanic gabores and appear to be the relatively unfractionsted extension of (or cumulate compositions complementary to) the basalt glasses dredged from the axial valley of the Mid-Cayman Rise spreading center.

Fig. 13. FMA ternary diagram showing fields of Cayman basalts and gabbros (sampled by ALVIN) and basalt glasses (dredged by the R/V KNOKR), and plotted compositions of gabbros dredged from other oceanic regions (analysis made by Miyashiro, et al., $^{3}70$; Melson and Thompson, 1970; Bonatti, et al., 1971; Thompson, 1973; Engel and Fisher, 1975).

Positive correlation of FeO*/MgO with TiO₂, as shown in Figure 14, would appear to confirm that variations in total iron and magnesium abundances in the Cayman plutonic rocks are a function of differentiation processes, since TiO_2 has been suggested to be stable under a wide range of hydrothermal alteration conditions (Pearce and Cann, 1973). However, more recent evidence suggests that seawater leaching of late-stage magmatic fluids enriched in alkalis, Fe, Ti and the light rare earth elements from some parts of the oceanic crust could result in the enrichment of these elements in other parts of the crust (Stakes 1978). These leaching reactions would produc .nemical variations mimicing those produced by fractional crystallization. The suite of gabbros collected from the Mid-Cayman Rise provides an opportunity to examine in detail the effects of and hopefully to determine the contribution to chemical variations made by these two processes; this examination is currently in progress.

An initial attempt to model fractionation of the major phases to produce the range of chemistries of the plutonic rocks recovered from the Mid-Cayman Rise spreading center is shown in Figure 15. Variability of $A1_2C_3$ versus FeO*/MgO in some of the samples appears to reflect accumulation or removal of plagioclase from an initial liquid having the composition of basalt 624 7-1.

Fig. 14. Diagram showing the variation of TiO₂ relative to FeO*/MgO ratio in the ALVIN-sampled plutonic rocks and dredged basalt glasses. The highest TiO₂ value is 8.97.

Fig. 15. Diagram of Al₂O₃ versus FeO*/MgO ratio, showing fractionation curves for different proportions of the crystallizing phases plagioclase and oliving and the percent crystallization that has occurred for any given proportion.

1.

The extreme degree of crystallization, however, necessary to produce other gabbros and the KNORR basalt glasses with fractionation involving only plagioclase and olivine suggests either that (1) derivation of these gabbro and basalt compositions may also involve fractionation of clinopyroxene, or (2) crystallization differentiation is not the sole mechanism producing the observed chemical variations. The former suggestion is compatible with the basalt glass data indicating that highpressure removal of an aluminum-chrome diopside present in the Cayman gabbros could produce a derivative liquid having the chemistry of the KNORR basalts (see discussion on basalt chemistry above). Further work is essential, however, before either of these two suggestions for producing the range observed in gabbro chemistry can be validated.

233.M

Thirty-eight representative samples were selected from the gabbroic suite for detailed microprobe analysis of the primary minerals plagioclase, olivine, clinopyroxene, orthopyroxene and amphibole. Secondary plagioclase, clinopyroxene and amphibole phases can often be disti guished by granoblastic texture, irregular grain shape, multi-crystal aggregates, reduced grain size and irregular optical zoning. In some cases the chemical analyses clearly support the secondary origin of particular grains.

The total compositional range of olivine in twelve samples is Fo_{70-88} , but within individual samples variation is limited to 3 mole percent Fo or less. The olivines show no primary zoning; alteration along cracks and grain boundaries has apparently not affected the chemistry of the relict olivine. Figure 16 plots these data against Fe/Fe + Mg (molar) of each host bulk-rock composi-

Fe/(Fe+Mg) Bulk rock

tion. Most data points are impatible with a distribution coefficient $(K_D = (MgO/FeO)_{1iquid}/(MgO/FeO)_{0livine}$ somewhat higher than the value of 0.30 determined by Roeder and Emslie (1970). This may reflect the less fractionated nature of these rocks if they represent liquid compositions; alternatively, if the rocks are cumulates, the curve for $K_D = 0.30$ could be used to estimate Fe/Fe+Mg in the original liquids from which these olivines crystallized. Values of Fe/Fe+Mg of the liquid that are determined in this way are not substantially different from the range of values actually observed in the gabbros.

The majority of all analyzed pyroxene grains are clinopyroxenes that plot in a tight cluster near the diopside corner of the quadrilateral (coincident with the three largest enclosed areas in the upper left of Figure 17). The overall range of Mg/Mg + Fe (~ 0.9 to 0.5) is relatively large in the whole suite, however, and is notably greater in pyroxenes than olivines. Coexisting clino- and orthopyroxene compositions are shown in Figure 17 and are broadly similar to trends found in DSDP Site 334 samples by Hodges and rapike (1976), although we have not yet explored the exsolution effects that they discuss.

Plagioclase compositions range from An_6 to An_{84} . Primary plagioclases (about An_{50} or more calcic) show no significant optical or chemical zoning. Secondary plagioclases may be considerably less calcic (up to 30% An) than immediately adjoining relict primary plagioclase; this is reflected in the somewhat greater range of An contents in the more altered gabbros as compared with the range observed in relatively fresh gabbros. Compositional differences within a single specimen are greatest where the extent of deformation, recrystallization and/or alteration is most variable; intra-sample differences are least in unaltered samples (which have presumably been "homogenized" by these later processes).

The amphiboles show a large range in Mg/Mg + Fe, but have a relatively constant proportion of Ca (Figure 18). Brown Ti-rich hornblendes rim and are intergrown with pyroxenes and occur as

Fig. 17. Pyroxenes plotted in Ca-Mg-Fe. Tielines connect clinopyroxene compositions (upper) and coexisting orthopyroxene compositions (lower).

CAYMAN TROUGH AMPHIBOLES

Fig. 18. Amphiboles plotted in the Ca-Mg-Fe quadrilateral.

isolated crystals, suggesting a primary or deuteric origin; these brown titaniferous hornblendes are also found in recrystallized zones with plagioclase and opaque minerals and without pyroxene. Actinolitic amphiboles are primarily Mg-rich and commonly form as alteration products after olivine and orthopyrox-ene rather than clinopyroxene.

Petrol y of Ultramafic Rocks from the Rift Valley Walls

Partially serpentinized peridotites were recovered during six Alvin dives: three in Dive Area #1 and three in Dive Area #2. Peridotites in varying degrees of serpentinization were also recovered from six dredge sites along the eastern and western rift valley walls. At the dive sites where outcrop was sampled directly, the peridotites come from relatively narrow zones which cut gabbro and metagabbro country rocks. These peridotites are often highly deformed, and we suggest that the heavily serpentinized peridotites were emplaced along major zones of weakness from deeper sections of the oceanic crust and upper mantle. On the other hand, two dredges (Oceanus Dredge 13, 14) taken from the upper and lower face of a promontory on the eastern wall of the rift valley at 18°10'N and 81°35'W both contained over 90% relatively unaltered, though heavily weathered, peridotite suggesting that the promontory may be a relatively large (15-20 km²) fault block of peridotite.

A variety of lithologies are included in the peridotite suite from the escarpments of the Mid-Cayman Rise spreading center (see Tables 1, 2 and 5). The three principal lithologies are spinel hurzburgite, plagioclase-spinel harzburgite, and spinel troctolite or plagioclase-spinel dunite. In addition, dunite, olivine websterite and gabbro are all found in small patches or layers within the harzburgite samples.

The spinel harzburgites are tectonites with well-developed pseudoporphyritic textures in which round and abraded, or stretched and greatly elongated, enstatites are enclosed in a matrix of recrystallized olivine. Clinopyroxene, present in amounts varying between one and seven percent, is characteristically finer grained than coe.: sting enstatite. Spinel is present as a ubiquitous accessory phase in amounts up to one percent. The spinel typically is anhedral, occurring in irregular patches, often intergrown with pyroxene. Olivine has a composition ranging from Fog0.0 to Fog1.1 (5 analyses). . statite contains 3.7 to 5.3 weight percent Al203, 0.30 to 0.61 weight percent Cr_2O_3 , and has $Hg/(M_5+Fe)$ ratios from 0.904 to 0.909 (5 analyses). One diopside analysis gives an Mg/(Mg+Fe) 1atio of 0.909 and 6.24 weight percent Al₂03 and 0.94 weight percent Cr₂0₃. Chromian spinel is generally aluminous with Cr/(Cr+Al) ratios between 0.17 to 0.48 and Mg/(Mg+Fe²⁺) ratios from 0.72 to 0.79.

The plagioclase-spinel harzburgites (70-85% olivine, 10-20% orthopyrozene, 1-5% diopside, 1-5% plagioclase, < 1% spinel) are less tectonized than the spinel harzburgites, noticeably lacking the strongly deformed eastatites of the latter. Undulatory extinction and kinking of enstatite are present in many thin sections, but not common. Spinel occurs as relatively rare subedral and subhedral grains and in highly irregular patches and stringers intergroun with olivine and pyroxene. Plagioclase is generally altered to nearly isotropic fine-grained calc-silicates. It occurs as angular lenses that are clearly interstitial to olivine and pyrorene. Similar textures have been attributed to the crystallization of trapped melt within peridotite at the Lanzo Massif by boudier and Nicolas (1977). There appears to be no reaction-relation between spinel and plagioclase and the two appear to be in equilibrium. Olivine from one sample has a composition of Fo_{90 1}. Enstatile from the same sample has 2.6 weight percent Al_{20} , 0.31 weight percent Cr203 and Mg/(Mg+Fe) of 0.895. Dicpside from one sample has 4.19 weight percent Al₂O₂, 1.04 Cr203 and Mg/(Mg+Fe) of 0.918. Chromian spinel from one sample has a restricted composition "ith an intermediate chrome content (Cr/(Cr+ A1) = 0.452 - 0.473).

Plagioclase-spinel dunites and troctolites were recovered during ALVIN dive 620 (Dive Area 2) and in one dredge haul (Oceanus 23-14). Olivine in these rocks is weathered and serpentinized, while plagioclase is completely replaced by white calc-silicates. Spinel is generally fresh though in some sections it is pseudomorphed by ferrichromite. Plagioclase and diopside clearly crystallized late and form angular lenses along olivine grain boundaries and triple junctions. Where these rocks are least deformed the olivine grains appear to have been equant to elongated anhedral or subhedral crystals. Spinel grains in the relatively undeformed dunites are euhedral and may be occluded within olivine grains.or,

more frequently, lie in the plagioclase-filled interstices between them. Layering can be seen in one sample, defined largely by variations in the olivine to plagioclase ratio.

Dunite, olivine websterite and gabbro all are found as minor segregations in the different major lithologies. Dunite occurs as a small patch in one spinel harzburgite and as a layer in a feldspathic dunite. Olivine websterites, similar to those described by Dick (1977), are found as 1-2 cm thick layers in the spinel harzburgites. Gabbroic segregations found in the plagioclase peridotites are similar to those in peridotites of the Lanzo massif described by Boudier and Nicolas (1977). These authors suggest that such segregations represent basaltic liquid generated in the peridotite during anatexis.

21707775

The spinel and plagioclase-spinel harzburgites have all undergone some degree of hydrothermal metamorphism, lower temperature serventinization and weathering. Much of the deformation of these rocks appears to have occurred prior to serpentinization. The degree of hydrothermal alteration is highly variable and its affects are often slight, expressed chiefly by the replacement of some primary olivine and pyroxene by talc, amphibole and secondary diopside. A significant, often large, variation of spinel composition was seen in many thin sections with increases in Cr203 and FeO contents attributed to hydrothermal alteration of primary spinel. In many rocks serpentine has completely replaced the olivine and most of the pyroxene. The serpentinization appears to have occurred late and, at least in part, post-deformation. In addition, many of the peridotites are criss-crossed by late aragonite veins.

It is clear from the textural data alone that the feldspathic dunites are olivinc-spinel cumulates. The spinel harzburgite has all the features typical of presumed mantle harzburgites from aipine peridotites: a tectonite fabric, a similar restricted range in silicate compositions. The plagioclase-spinel peridotites, however, have features that seem to make them intermediate between the feldspathic dunites and the spinel harzburgites. Plagioclase-spinel harzburgites and feldspathic dunites occur together at locations where they were collected.

The intrusive, cross cutting relationships of the partially serpentinized peridotites collected during ALVIN traverses indicate that, at least locally, partially serpentinized peridotite derived from upper mantle sources can intrude the plutonic foundation of the oceanic crust along fractures which cut deeply into the crust. The peridotites recovered in two carefully navigated dredges located on the same tectonic block but at different levels suggests that at least in this locality upper mantle rocks are exposed. The deepest dredge (Oceanus 13; 4400 m) recovered predominantly tectonized spinel harzburgite whereas the shallower dredge (Oceanus 14; 3280 m) recovered plagioclase bearing peridotites and troctolite. This apparent stratigraphic order as defined by two dredges is similar to that described from the transition zone in many ophiolite suites (e.g. England and Davies, 1973; Menzies and Allen, 1974) and is thought to represent the transition across the "petrologic moho" from mantle tectonite to cumulate peridotites at the base of the lower crust. To our knowledge, this represents the first time that this sequence has been described in oceanic rocks collected essentially in situ.

Magnetic Properties of Gabbros from the Rift Valley Valls

The large number of plutonic samples collected during the Cayman Trough Project has permitted the characterization of the magnetic properties of the plutonic foundation of the oceanic crust in the Cayman area. We have measured 1) the intensity of the natural remnant magnetization (NRM); 2) the stability of this intensity (mean destructive field and NRM_{time 1}/NRM_{time 2}); 3) the susceptibility of these rocks to the earth's field; 4) the relative importance of the NRM and susceptibility (the Konigsberger ratio, Q); and 5) the directional stability of the NRM (maximum angular change after exposure to a 250 oersted alternating field). Curie temperatures were measured for a variety of lithologies to determine the dominant magnetic mineralogy. A total of 58 plutonic rock samples was cored for magnetic measurements. These were cut into one inch lengths, producing 138 specimens.

The NRM of the Cayman Trough plutonic suite (all rocks excluding basalts) ranges from 10^{-7} to 10^{-2} Gauss (G), and has an arithmetic mean of 6.5×10^{-4} G. (Although the NRM and susceptibility values are approximately log normally distributed, total magnetization is the sum of all the magnetic vectors and therefore the arithmetic mean is considered a better indicator of total magnetization than the geometric mean (Lowrie, 1977).) The susceptibility of the entire plutonic suite ranges from 10^{-5} to 10^{-2} G/emu. The susceptibility of the gabbros alone has an arithmetic mean of 6.5 x 10^{-4} G/emu. The NRM and susceptibility of all specimens measured are plotted in Figure 19.

The relative importance of the remnant magnetization and the susceptibility is expressed as the Konigsberger ratio, Q = NRM/(susceptibility xgeomagnetic field intensity at sample site). Thus, for samples with Q > 1, the remnant paleomagnetization dominates and a remnant paleomagnetic vector direction might be retained. A line representing Q = 1 is drawn in Figure 19. Twothirds of all the specimens measured in this study lie above this line. Clearly, in order to contribute to the magnetic anomalies observed from the ocean's surface, a major portion of the

Fig. 19. Natural remnant magnetization and susceptibility of Cayman plutonic rocks (plotted log/log). Solid dots represent gabbroic rocks; a = moderately to severly deformed amphibolite; u = serpentinized ultramafic.

plutonic complex must have a Q > 1. The rocks sampled from the Mid-Cayman Rise spreading center meet this requirement.

Eighty-five specimens representing 54 samples were subjected to alternating field stepwise demagnetization to ascertain the stability of the magnetic vector in these rocks. NRM measurements were repeated immediately before demagnetization a 3 to 6 month period had lapsed since because the original NRM measurements had been made. The ratio of these two measurements is an indicator of the short-term stability of the rocks. Of the 45 gabbro samples subjected to this storage test only seven include specimens which show an NRM variation greater than 10%; all of these had Konigsberger ratios less than one. This storage test also provided a measure of the directional stability of a rock magnetic vector. The angular distance between the initially determined NRM direction and that determined just prior to demagnetization has been measured for 42 gabbro specimens for which Q > 1. Ninety percent of

these showed a directional change of 5° or less. The results of alternating field demagnetization of our gabbro samples are depicted graphically in Figures 20 and 21. Sixty-seven percent of these rocks have median destructive fields of 200 oe or more. By comparison, only 36% of the DSDF basalts have MDF of 200 oe or more (Lowrie, 1977. The resistance of the NRM vector direction to an applied field was also observed during stepwise alternating field demagnetization. In this study a parameter called the "250 oersted diameter" is used to describe the results. The 250 oersted diameter is the apical angle of a cone which circumscribes the vector directions obtained during stepwise demagnetization up to 250 oersteds. In most cases, this data set is comprised of 6 measurements made at 50 oersted intervals. A histogram of 250 oersted

250 OERSTED DIAMETER

Fig. 21. NRM vector direction stability during alternating field demagnetization for Cayman Trough gabbros and troctolites. 250 oersted diameter is defined as the apical angle of a cone which circumscribes the NRM vector directions obtained during stepwise demagnetization up to 250 oersteds.

diameters for 70 specimens of gabbro is presented in Figure 21.

Curie temperatures obtained for 9 samples chosen to be representative of the entire collection in terms of both mineralogy and magnetic character are tabulated in Table 7. The values range from 535° C to 580° C. These are interpreted as evidence that magnetite (Curie temperature 570°) with low Ti content is the dominant magnetic mineral in all rock types.

From their study of ocean floor gabbros from the Atlantic, Kent and others, (1978), concluded that the intensity and stability of the magnetization in such rocks is a result of deuteric alteration or originally homogeneous titanomagnetite. During this process, ilmenite lamellae are exsolved, isolating large numbers of single domain magnetites and armoring them against further oxidation. The high Curie temperatures reported here and their association with a wide variety of Ti concentration (see Table 7) supports this idea.

The magnetic properties of ocean floor plutonics dredged in the Atlantic Ocean have been determined by Opdyke and Hekinian (1967), Fox and Opdyke (1973) and most recently by Kent and others (1978). The magnetic properties of the plutonic rocks cored at DSDP site 334 are reported in Aumento and others (1977). Data from these studies compare favorably with ours for the Cayman plutonics. The arithmetic mean NRM of the Atlantic dredge samples is 8.8 x 10⁻⁴G (Kent and others, 1978). For the Cayman gabbros this value is about a factor of two lower, 4.8 x 10^{-4} G.

The Konigsberger ratio averages slightly higher for the Atlantic plutonics and the fraction of samples that have Q > 1 is high in both data sets: .75 in the Atlantic and .66 in the Cayman. The stability of these rocks to alternacing field demagnetization is also comparable. For samples with Q > 1, 70% of the Cayman and 81% of the Atlantic samples have mean destructive fields of 200 oersteds or more.

Detailed magnetic studies of basalt from DSDP cores have cast some doubt on the assumption that the magnetic character of 0.5 km of

Sample	Rock Type	Curie Temperature 1)	Whole Rock Ti Concentration

extrusive basalt and shallow intrusive basalt which comprises seismic layer 2a is sufficient to explain the amplitude of magnetic anomalies observed in the oceans (e.g. Ryall, et al., 1977; Lowrie, 1977). These authors have found that the basalt layer is far more magnetically heterogeneous than is accounted for in models of magnetic anomalies, and the primary result of this inhomoeneity is to decrease the total bulk magnetization.

ted

are

Layer 3 is an increasingly appealing additional source for magnetic anomalies. The NRM of the plutonics is surprisingly stable, apparently due to the deuteric isolation of single domain magnetites. The remnant magnetization is more important than susceptibility in the large majority of plutonic samples. Perhaps most importantly, the great thickness (3-5 km) of layer 3 compensates for the low average NRM (about 1/10 the average for ocean floor basalts). Kent, et al., (1978) have calculated that for block widths greater than about 20 km, a deep, 5 km thick layer of NFM 8 x 10^{-4} G will actually contribute more intensity to the observed anomaly than a shallow 0.5 km thick layer of NRM 40 x 10^{-4} G. Although the relative importance of its contribution to the marine magnetic anomalies is difficult to evaluate, the plutonic foundation of the oceanic crust must make a contribution and should not be neglected when considering the source region for magnetic anomalies.

Summary and Conclusions

The intensive survey of the Mid-Cayman Rise spreading center made possible by the use of sophisticated marine geological and geophysical tools has provided a wealth of data enabling us to define the tectonic and petrologic character of a short (~2 cm/yr full rate) plate boundary that is truncated at either end by two long transform faults.

Our high resolution bathymetric data set, deep-towed photographic results, bathyscaphe observations and bottom sampling all confirm the original proposition by Holcombe, et al. (1973) that the north-south trending axial valley of the Mid-Cayman Rise is the locus of recent basalt volcanism and represents a zone of plate accretion. Like other rift valley segments, the inner floor is characterized by a narrow zone (2-3 km) of recent basaltic volcanism arranged in elongated ridges composed of a chaotic assemblage of pillow lavas. Although this type of volcanism appears presently to dominate the extrusive mode operating along the inner floor, at one locality near the northern end of the inner floor a massive sheet flow was observed filling a trough between two constructional ridges. The major and trace element chemistry of basalt glasses recovered from the recent volcanic lineaments show that the extrusive rocks have first order chemical properties similar to ocean floor tholeiites, although they exhibit some differences in chemistry from typical mid-ocean ridge basalts. That portion of the inner floor which flanks the narrow zone of recent volcanism is characterized by a blanket \uparrow f sediment that thickens away from the volcanic axis, and is experiencing tectonic modification as evidenced by the formation of fissures. The inner floor is bounded by steep inward facing fault scarps and terraces which parallel the inner floor and which create morphologic elements typical of rift valley terrain.

When one considers the tectonic and petrologic details associated with the Mid-Cayman Rise, however, it is clear that this short accreting plate boundary is distinctive. The rift valley floor resides at depths from 2000 to 3000 m deeper than the floors of other rift valleys. The width of the inner floor varies along strike from a few kilometers to 18 kilometers and the trend of the volcanic/tectonic lineaments changes down the length of the inner floor. Furthermore, the continuity of the rift valley floor is interrupted and offset by a short, several kilometer long NE-SW trending discordant zone positioned midway along the Mid-Cayman Rise. Large tectonic blocks comprise segments of the bounding rift valley walls and seem to be the product of both N-S and E-W tectonic lineaments. We suggest that these tectonic subtleties, played against the processes operative and typical of slowly accreting plate boundaries, are the consequences of the North American-Caribbean plate geometry in this region. The Mid-Cayman Rise represents a short accreting plate boundary truncated by two, long (> 1000 km) transform faults. We propose that although the strike slip tectonics associated with the trans-

> Iomains of the Oriente and Swan transform are concentrated along narrow zones to

....y created lithosphere along the Rise axis is not completely independent of the effects of strike slip motion of the two transforms. Although the Mid-Cayman Rise is principally an extensional regime, a left lateral shear-couple, a function of the juxtaposition of two long left lateral transform faults against a short accretionary plate boundary, perturbs and disrupts the morpho-tectonic grain of this slowly accreting ridge segment.

The in situ sampling by the submersible ALVIN and our dredging results document another peculiar characteristic of the Mid-Cayman Rise spreading center. The well navigated, intensive in situ sampling by ALVIN of escarpments in two areas representative of the rift valley walls indicates that gabbroic rocks outcrop in abundance. In fact, the sampling results argue persuasively that the volcanic carapace (extrusive basalt and shallow intrusives) must be as thin as 250 m. The plutonic component of the oceanic crust may be thin as well (~1000 m), because dredge results suggest that ultramafic rocks, which exhibit structural and petrologic characteristics considered to be representative of the petrologic Moho, are exposed in the escarpments at the base

of the rift valley wail. The apparent thin nature of the oceanic crustal components along the Mid-Cayman Rise can be explained in several ways. Firstly, they could be tectonically thinned by faulting out portions of the crustal column. In order to thin the oceanic crust to the extremes recognized in the Cayman Trough, normal or reverse faults with throws of several hundreds of meters would have to be envoked. Our detailed bathymetric studies and bottom observations provide no evidence which documents the existence of faults with these offset magnitudes. .' second explanation is that the processes which control the production of basaltic magmas beneath rift valley floor are perturbed and less magma is produced thereby creating a thinner oceanic crust. It has been suggested that the Mid-Cayman Rise may be relatively cold because of the proximal, cold truncating transform boundaries and this environment results in the production of less basaltic melt in the rising asthenospheric wedge bencath the rift valley axis (Fox, 1978, and in prep.). A third possibility is that the gabbroic and ultramafic rocks represent intrusive bodies which have melted their way up into overlying occanic crust of normal thickness. Perhaps these intrusive bodies follow penetrative zones of weakness caused by the tectonic setting characteristic of the Mid-Cayman Rise spreading center.

Our work on the CAYTROUGH data set is ongoing and in time the ideas briefly outlined above will be developed more rigorously. The preliminary results, however, indicate clearly that although new oceanic lithosphere is being accreted along the Mid-Cayman Rise spreading center in a way that develops a morpho-tectonic fabric typical of slowly accreting plate boundaries, important structural and petrologic differences are developed which must reflect this particular plate tectonic setting. Indeed, although the Mid-Cayman Rise spreading center represents an extreme example of an accreting plate margin dominated by transform tectonics, we suggest that processes operative along this plate boundary may be operative, albeit more subtly developed, along other ridge-transform-ridge boundaries. For example, the Mid-Atlantic Ridge south of the Azores-Gibralter triple junction is characterized by frequent ridge-transform-ridge plate boundarjes with transform faults of varying offset lengths, occurring every 50 to 100 km. If our initial results from the Cayman Trough Project stand the test of continued investigation, then a major conclusion will be that the crust formed proximal to and sandwiched between transform boundaries may be structurally and petrologically much more complex than previously suspected.

Acknowledgments. We would like to thank the Captains, officers and crews of the USNS BOWDITCH, R/V KNORR and R/V OCEANUS and the pilots, engineers and technicians who work with the submersible ALVIN and bathyscaphe TRIESTE for their dedicated support throughout the field program. The mineral chemical data reported in this paper was done while one of us (F.L.M.) was a Visiting Scientist at the Lunar and Planetary Institute which is operated by the Universities Space Research Association under contract no. NSR-09-051-001 with the National Aeronautics and Space Administration. The Field programs and the other laboratory investigations were supported by the Submarine Geology Branch, National Science Foundation through grants OCE-75-18533 (UKOI) and OCE-76-21882 (SUNYA and Wesleyan), and <u>Office of</u> <u>Naval Research grant N09014-74-C-0262 (R.B.).</u> Woods Hole Oceanographic Institution Contribution No. 4278 ult

Contribution of the Earth Physics Branch 751

Abstract. A detailed study of physical properties was made on core samples from 1 km deep boreholes into islands of Bermuda and the Azores. The properties measured are seismic velocity, density, electrical resistivity, porosity and thermal conductivity. The properties of subaqueous lava flow samples from Bermuda and the Azores are very similar to those for deep ocean tholeiites. Subaerial flows and pyroclastics from the Azores have quite different properties, reflecting their higher porosity. Lamprophyric intrusive sheets from Bermuda also have significantly different and unusual properties, notably lower velocity and higher density than the flows. It is concluded that aseismic ridges, islands and seamounts may have significantly different physical properties from normal upper oceanic crust if they contain subaerially erupted material as on Sao Miguel, Azores or are produced by intrusion of lamprophyric sheets or dykes into older oceanic crust as inferred for Bermuda.

Introduction

Laboratory data on the physical properties of rocks are an essential element in the interpretation of surface geophysical measurements; and for structural and petrological models. Much work has been done on oceanic crustal samples, particularly those from the Deep Sea Drilling Project. that gives a reasonably clear picture of the upper part of the normal oceanic crust (e.g. Christensen and Salisbury, 1975; Hyndman and Drury, 1976.) However, there are some anomalous oceanic areas of particular significance. These are the assistic ridges and oceanic islands, which reflect higher than normal vulcanism and are referred to as hot spots or hot spot

HYNDMAN

traces. They may arise as the surface expression of deep mantle plumes (Wilson, 1965; Morgan, 1971) or from propagating lithospheric fractures (e.g. Shaw and Jackson, 1973). In either case, compared to normal oceanic crust they are characterized by greater crustal thickness and by different composition.

This article reports seismic velocities, densities, electrical resistivities, porosities, and thermal conductivities for basaltic samples from approximately 1 km deep boreholes into the islands of Bermuda and São Miguel, Azores (Fig. 1 and 2) and discusses the geophysical significance of these measurements.

An 802 m deep borehole was drilled into the islands of Bermuda at 32°22'N, 64°42'W (Fig. 1) at an elevation of 10 m during the summer of 1972 for Dalhousie University and Lamont-Doherty Geological Observatory. The hole was cored with almost complete recovery for geological and geophysical studies. The islands of Bermuda lie approximately 1100 km east of the North American coast, about one third of the distance to the mid-Atlantic ridge. They have a maximum elevation of 30 m and occupy the southern 7% of the 116 km² platform that makes up the top of the Bermuda pedestal. Only limestones are exposed, the volcanic platform lies at an average of about 80 m below sealevel (Gees and Medioli, 1970). Bermuda is the northernmost and largest of three seamounts of the Bermuda Rise. From potassium-argon dating, the Bermuda seamount appears to have been formed 33 m.y. ago by the intrusion of numerous lamprophyric sheets into oceanic crust that was then about 80 m.y. old (Reynolds and Aumento, 1974; Gees, 1969). The surrounding seafloor is now about 110 m.y. old (Larson and Pitman, 1972). This age of the seamount is substantiated by the age of the oldest limestones overlying the volcanics (see

Wilson, 1963) and by the low heat flow and the subsidence history of the platform (Hyndman et al., 1974a). Temperatures in the drilled section are low, reaching only about 38°C at the hole bottom (Fig. 3). In addition to radioactive dating, heat flow and heat production studies, extensive rock magnetic studies have been performed on the core (Ade-Hall et al., 1973) as well as detailed petrology (Aumento and Ade-Hall, 1973) and geochemistry (Aumento et al., 1976; and F. Aumento and B. Gunn, personal communication). A preliminary report of laboratory velocity measurements was presented by Barrett et al. (1973).

The borehole first penetrated 36 m of limestone, then 772 m of volcanic rocks made up of over 1000 igneous units. The whole core snows evidence of hydrothermal alteration both in petrology and in high Curie temperatures. Of the igneous units, 64% vere altered subaqueously extruded tholelike lavas and 36% were thin lamprophyric sheets of unusual composition, e.g. low silica, high Ti, K etc. It appears that any subaerial volcanics that were present have been eroded by a subsequent uplift before final subsidence. Such uplift could have been produced by the intrusion of the sheets.

During the summer of 1973, a 981 m deep borehole was drilled into the island of São Miguel, Azores at 25°31'%, 37°48.9'N (Fig. 2) at a surface elevation of 72 m for Dalhousie University and Lamont-Doherty Geological Observatory. Core recovery was almost complete except in the upper 148 m. The Azores are a group of 9 islands aligned in a NW-SE chain which crosses the mid-Atlantic ridge near 39°N. The region is marked by a change in trend of, and by a broadening of the ridge into a large platform (Krause and Watkins, 1970) and a positive regional gravity anomaly (e.g. Kaula, 1972). The Terceira rift, along which the main islands are located, trends from the ridge toward Gibraltar, probably defining a plate boundary that originated about 45 m.y. ago (Krause and Watkins, 1970). Sao Miguel is the largest island and lies 400 km east of the mid-Atlantic ridge crest. The drill site was located on the lower southern flank of the volcano Agua de Pau, which has erupted 5 times in the past 4,600 years, the last in 1563. Numerous hot springs and sporadic seismic activity indicate the volcano to be only domant at present.

Extrusive lavas make up 72% of the Azeres core in 140 flows averaging 5 m in thickness (Muecke et al., 1974). The main rock types are alkali basalts, hawaiites and mugearites. Three trachyte flows make up 6% of the total. The upper 763 m consists of 3 distinct subaerial volcanic eruptive sequences. This section is underlain by a 107 m transition sequence of basaltic sandstones and basaltic breccias, then by pillows and massive basaltic flows of subaqueous origin.

Temperatures were reasured in the hole at intervals during drilling until the hole was terminated by the eruption of steam. Only bottor hole measurements appeared to represent in-sit: temperatures, (Fig. 3) giving gradients up to 250°C/km. Temperatures in the hole nearer the surface were dominated by in-hole convection (see Muecke et al., 1974). The geothermal gradient is dominated by probably near-horizontal water flow so a meaningful geothermal heat flux cannot be ascertained. The temperature at the bottom of the hole was 200°C. Two K-Ar dates of 117,000 + 24,000 vr at 57 m and 280,000 + 140,000 yr at 950 m (Muecke et al., 1974) and that all of the core was normally magnetized presumably in the Brunhes polarity epoch that extends to 690,000 yr ago, indicate the youth and rapid formation of this volcanic edifice. It appears that the island has subsided over 900 m in less than 0.5 m.y. probably in isostati response to the increasing volcanic load. A

Fig. 3. Temperature-depth profiles in the Bermuda and Azores boreholes.

detailed description of the petrology of the core has been made by McGraw (1976) and extensive rock magnetic studies have been made (J.M. Hall, N.D. Opdyke and W. Lowrie, personal communication).

Density

.....

The bulk densities of water saturated samples (stored in water from time of drilling) were determined by weighing the cores in air and obtaining the volume either by measuring the weight loss with the samples suspended in distilled water or by measurements of sample dimensions (Tables 1 and 2). The estimated accuracy is ± 0.01 g cm⁻². The grain or mineral densities for samples for which porosities are reported were determined simply by subtracting the mass and the volume of the pore fluid and recomputing the densities. Since the porosities tend to be underestimated because of incomplete drying (i.e. effective porosity), the grain density also will be too low. The estimated error limits are ± 0.02 to -0.01 g cm⁻³.

The mean bulk density of 43 samples from Bermuda is 2.83 ± 0.02 g cm⁻³ with no systematic variation with depth (Fig. 4). However, the intrusive lamprophyric sheets have a significantly higher mean of 2.90 ± 0.03 g cm⁻³ (16 samples) and larger variation compared to the flows, with a mean of 2.79 ± 0.01 g cm⁻³ (27 samples), the higher mean perhaps reflecting the high density of the pyroxene in the former since the porosities are similar. Taking the mean sheet and flow densities and their relative proportions of 36% and 64% respectively in the drilled section gives a section mean of 2.83 g cm⁻³, identical to the sample mean indicating that there was a representative sampling of sheets and flows. The mean grain density of 17 Bermuda samples is $2.35 \pm$ 0.02 g cm⁻³; the mean for 17 samples of the flows is 2.81 ± 0.01 and for 8 samples of the sheets is 2.92 ± 0.05 g cm⁻³.

TABLE 2. Physical Properties of Samples from the Azores

The mean bulk density of 56 samples from the Azores borehole is 2.64 ± 0.03 g cm⁻³. There is some systematic increase in density with depth (Fig. 4). The mean is much lower and the scatter of values is more than double that for the Bermuda samples reflecting the wide variation and generally high porosity of the Azores rock types, particularly the pyroclastics in the subaerial section. The mean for the subaerial section is 2.60 ± 0.04 g cm⁻³ (41 samples). The mean for the igneous-sedimentary transition sequence is $2.71 \pm 0.09 \text{ g cm}^{-3}$ (4 samples), and the mean for the subaqueous sequence is 2.79 ± 0.04 g cm⁻³ (11 samples). As expected, the mean density of the subaqueous Azores rocks is the same as the mean of 2.79 for the flows from Bermuda, and for deep ocean tholeiiti · basalts (e.g. Hyndman and Drury, 1976). The mean grain density of 23 Azores cores is 2.87 ± 0.02 g cm⁻³, not greatly different from the Bermuda value, indicating that most of the bulk density differences arise from variations in porosity or water content. Bulk density is plotted as a function of porosity in Fig. 5 for both Bermuda and Azores samples. The intercept of about 2.85 gm cm is in agreement with the above grain density estimates. This lower grain density and lower porosity, compared to the mean respective values for fresh deep ocean basalts (2.95 g cm 3 and 7.8%) suggests that initially free pore water in the Bermuda and Azores rocks is now bound in hydrous minerals, there being little change in total water in the alteration process.

(c) S. M. C. RANKANAN, C. A. L. L. L. L. L. M. D. M. M. M. M. L. L.

For both the Bermuda and Azores core there is some sampling bias, low density fracture zones and rubble not being recovered, so the insitu density is lower than the means from the core. We believe that the effect is significant only for the upper several hundred meters of the Azores hole where core recovery was poor.

The densities of subaerial volcanic flow samples have been reported for the island of Hawaii, which is in a similar setting to São Miguel, by Manghnani and Woollard (1968) and Kinoshita (1965). They found that most surface and borehole samples had a density of in close agreement with the one 2.3 * . sample from the Azores borehole near but con. _erably lower than the mean of 2.60 g c. $^{-2}$ for the subaerial section. They 2.60 g c. found a number of dykes and plugs with much higher densities of 3.0 to 3.2 g cm 3 . Woollard (1951) estimated the mean density of the Hawaii island of Oahu to be 2.3 g cm 3 from that required to minimize the effect of topography on island gravity values. However, taking a larger area, including marine gravity and a more sophisticated model, Walcott (1970) and Watts and Cochran (1974) estimated a mean density of 2.80 g cm 3 for the Hawaiian Islands, close to our Bermuda mean and Azores subaqueous samples suggesting only the near surface rocks have low density (see also Worzel and Harrison, 1963). A similar density has been estimated from gravity measurements for the Great Meteor seamount (Watts et al., 1575). Lower values of about 2.5 g cm 3 , however, were estimated for the Caryn seamount by Worzel and Talwani (1959) and of 2.3 g cm⁻³ for the Jasper seamount off California by Harrison and Brisbin (1959). A possible explanation for this low density is that they may have carbonate caps. In a detailed gravity study of the Cook Islands, Robertson (1967) estimated that the island platforms had an average density of 2.32 g cm⁻³ with large central plugs of 2.88 g cm⁻³ (see also data in Malahoff, 1969). From Bermuda gravity measurements Woollard (1954) computes a

HYNDMAN 97

Fig. 4. Density as a function of depth in the Bermuda and Azores boreholes.

mean density of 2.80 for the seamount structure itself with lower density material, 2.50 g cm⁻³ of several km thickness on the adjacent sea floor.

On the basis of our sample densities from Bermuda and the Azores and the above gravity estimates for seamounts and islands we conclude: The mean density for the bulk of oceanic volcanic islands and seamounts is about 2.8 g cm⁻³, which is appropriate for subaqueous pillow lava flows with a few higher density dykes and sills. Density means as low as 2.3 g cm⁻³ and commonly 2.6 g cm⁻³ exist for the subaerially erupted volcanics which make up the upper part of active volcanic islands. As occurs in São Miguel, subaerially erupted volcanoes may extend to a kilometer or more below sea level in an active volcanic island because of loading subsidence (see Muecke et al., 1974). As in the case for Bermuda, most old seamounts will have the subaerial volcanics removed by erosion, so that only the higher density subaqueous volcanics remain (see discussion in Hyndman et al., 1974a). A thick low density coral cap. of course, exists on the tops of many shallow sea mounts. The fairly low density material apparently on the seafloor surrounding many islands and seamounts, probably consists of pyroclastics and volcanic sediments such as found in our Azores borehole transition sequence. The high density of the intrusive lamprophyri: sheets could be a

useful diagnostic parameter for seamounts or accessic ridges formed by later intrusions into older seafloor, compared to those made up primarily by subaqueous lava flows, but the contrast probably is not sufficient to be detected by gravity measurements. 3 - 2 2 3 3 11

Porosity

Porosities (% pore volume) were determined by weighing the 2.5 cm dia. 5 cm long minicores seawater saturated (preserved in water from time of drilling) and after crying at abut 70°C under vacuum for two weeks. There was significant weight loss for the first 7 days but little thereafter. This treatment should remove most of the pore water except in very low permeability samples and it should produce only minor dehydration of hydrous minerals. liowever, we note that there probably is a continuum between free pore water and strongly bound water in hydrous minerals, some water being loosely bound. A small correction was made for the rasidual salt in the porosity estimate, assuming an original salinity of 35 ppt and that all of the salt was left behind on drying. We estimate the accuracy to be \pm 10% to -5% of the value for porosity and water content.

The porosities of 20 samples from the Bermuda borehole range from 1.1 to 8.27 with a mean of 2.9 \pm 0.3%. The mean for the lava flows of

Fig. 5. Density as a function of porosity for Bermuda and Azores samples. (\bullet , Azores subaerial; (O Azores transition; (O) Azores subaqueous; (Δ) Bermuda flows; (D) Sermuda sheets.

 2.6 ± 0.47 is lower than the mean of 3.4 ± 0.47 for the sheets. These values are significantly lower than the means for fresh young seafloor basalts, (e.g. 7.8%, Hyndman and Drury, 1975), indicative of some pore space filling by secondary minerals during hydrothermal alteration in the Bermuda rocks.

The porosities of 19 samples from the Azores borehole range from 3.0 to 33.1% with a mean of $9.4 \pm 1.5\%$. The mean of the subaerial section is $10.6 \pm 1.7\%$, while that for 3 subaqueous samples is $4.4 \pm 1.2\%$, slightly higher than for Bermuda lavas and lower than young subaqueously extruded tholeiitic lavas. The porosity is presented as a function of depth for both borcholes in Fig. 6.

The permeabilities of 14 Bermuda samples by Boyle's Law gas expansion in a Hassler Holder were measured by Core Laboratories Ltd., Calgary. The all are less than 0.01 millidarcys the resolution limit of the method, except for one sample cut by a fracture with a value of 7.7. Low values are also suggested by the low drying rates. Of course water flow in the oceanic crust must be primarily in cracks and fractures. The permeability of the Azores subaerial rocks probably is much higher.

Seismic Velocities

Compressional and shear wave velocities were measured on 2.5 cm diameter, approximately 5 cm long water saturated samples to pressures of 6 kbars. The technique is essenlially as described by Birch (1960) and Christensen and Shaw (1970). The accuracy estimated is 0.5% for compressional and $\pm 1.0\%$ for shear wave velocities. The fluid pressure medium was excluded from the samples by a thin copper foil jacket and pore pressures were maintained at values much less than external pressure by placing 100 mesh screens between the samples and jackets.

The usefulness of laboratory measurements depends on how well the insitu conditions are simulated, notably the pressure, temperature, extent of water saturation and sample orientation if the rocks are anisotropic. It is also important to consider how representative the samples are of the section being investigated. In this study we wish to estimate the insitu velocities both in the sections penetrated by the boreholes and in other more general situations where the rocks may be similar such as in the upper few kilometers of an aseismic ridge. The velocities of most rocks increase significantly with increasing pressure, up to about 2.0 kbars (e.g. 7 km depth) primarily from the closing of microcracks and some pores. In addition to the effect of pressure insitu, the drilling process probably causes microcracks. These cracks should close at :-mall confining pressure. We take the 0.4 kbar velocities to be representative of insitu values in the sections penetrated by the boreholes and the 2.0 kbar values as representative of depths greater than a kilometer in the crust.

stress that laboratory pressure can be related only approximately to equivalent depth in the crust. In our laboratory samples we have attempted to maintain close to zero pore pressure (see Hyndman and Drury, (1976) for a discussion of the importance of pore pressure), so the effective confining pressure is close to the external fluid pressure. The mean effect of pressure on velocities of Bermuda and Azores samplet .3 given in Table 3 and Fig. 7.

Increasing temperature decreases the velocities of most rocks. Only a few measurements have been reported and over very limited temperature ranges. The effect on mafic rocks to 300°C ranges between -0.6 x 10⁻⁴ and -15 x 10⁻⁴ per °C (Birch, 1958; Hughes and Maurette, 1957; Nafe and Drake, 1968; Kroenke et al., 1976). Recent detailed measurements on basalts from the East Pacific Rise show -5×10^{-4} to be a representative value for oceanic basalts (Christensen, in preparation). Thus, the difference from a laboratory temperature of 25°C and the 200°C in the lower part of the Azores borehole (Fig. 3) requires a correction to the measured values of -0.1 km s^{-1} . The correction is negligible for the Bermuda borchole where the maximum is about 40°C (Hyndman et al., 1974a). The temperature in the crust under aseismic ridges and other old volcanic islands

will rarely exceed the 200°C found in the Azores borehole. The temperature may be significantly higher it depth under active volcanic islands, requiring a greater correction.

All of the measured samples have been water saturated before measurement to simulate insitu conditions (Christensen and Salisbury, 1975). Velocities were measured in the vertical direction only since previous measurements have shown negligible anisotropy in extrusive oceanic volcanic rocks (e.g. Christensen and Shaw, 1970; Christensen and Salisbury, 1972).

Relations Between Velocity and Other Parameters

The relations between compressional and shear velocities and bulk density are important because they permit the estimation of density from seismic refraction data. Birch (1961) showed that there is one nearly linear velocitydensity relation for all rocks with a particular mean atomic weight. The mean atomic weight of unaltered basaltic rocks varies only slightly so a single relation is expected. The relation might be different for altered rocks since the high water content associated with alteration will lower the mean atomic weight significantly perhaps without a corresponding decrease in bulk density. Christensen and Salisbury (1975) found a better fit with non-linear relations.

Fig. 7. Compressional and shear wave velocity as a function of pressure in the Bermuda and Azores samples. The inner bounds are the standard error estimate of the mean, the outer bounds are the standard deviation. The open circles are the Azores transition sample.

Fig. 8. Compressional and shear wave velocity as a function of bulk density for Bermuda and Azores samples. Symbols as in Fig. 5. The curves are from Christensen and Salisbury (1975).

The relation for the Bermuda and Azores samples is shown in Figure 8 along with the non-linear best fits for 77 sea floor basalts from the Deep Sea Drilling Project given by Christensen and Salisbury. An additional 79 samples from deep holes on the mid-Atlantic ridge fit their relations well although the shear velocities for the latter are slightly higher for a particular density (Hyndman and Drury, 1976). Only the Azores subaerial volcanics have a significant range of density but they define similar relations. The one transition and 3 subaqueous Azores samples also lie close to the lines. The lamprophyric sheet samples from Bermuda generally fit the relation although they scatter widely. In contrast, ad of the altered tholeiitic lavas show much less scatter and have both compressional and shear velocities averaging 0.3 km s^{-1} above the relation of Christensen and Salisbury (1975). This difference may reflect a lower mean atomic weight produced by the extensive hydrothermal alteration (see Aumento and Ade-Hall, 1973), and possibly the filling of vesicles with alteration products. The contrast between the Bermuda-lavas and fresh sea floor tholeiites is also evident, for

102 HYNDMAN

example, in the high thermal conductivity (see below). It is important to note that the Azores subaerial samples, which have low velocities primarily because of high porosity in flows and pyroclastics, have the same velocity-density relation as the deep ocean samples reported by Christensen and Salisbury (1975) in which low velocities arise primarily from low temperature weathering. Thus, the relation should be valid for the upper oceanic crust, of any age of either normal ridge origin, or an origin associated with a hot spot.

The relation between Poisson's ratio (a measure of the ratio of compressional to shear velocity) and compressional velocity for Bermuda and Azores samples is shown in Figure 9. Only the Azores subaerial samples have a sufficient range to define a trend. Poisson's ratio increases systematically with decreasing velocity below about 5.0 km s⁻¹, in agreement with the general trend found for many seafloor tholeiitic basalts obtained by dredging or shallow drilling (Christensen, unpublished data; Hyndman, 1979). But the trend is in contrast to that of increasing Poisson's ratio with increasing velocity found by Hyndman and Drury (1976) for young fresh basalts from Deep Sea Drilling Project, 0.5 km deep holes on the mid Atlantic ridge, in the velocity range 5.5 to 6.5 km s⁻¹. The opposite dependences probably reflect the different nature of the porosity structure associated with the velocity variation. The young fresh tholeiites from the mid Atlantic ridge deep holes have porosity primarily in nearly spherical vesicles that are poorly connected, while in the Azores subaerial samples the porosity is primarily along woll connected grain boundaries (see discussion in Hyndman, 1979).

On a plot such as Figure 10 (see below) the mid-Atlantic ridge rocks have a mean pore aspect ratio of 1/2 compared to about 1/10 for Azores subaerial volcanics. Two highly vesicular basalts from the Lau ridge with a 5.0 km s⁻¹ compressional velocity (Christensen and Salisbury, 1975) also have a low Poisson's ratio of 0.27. In contrast, the low velocity samples from dredging or shallow drilling have porosity primarily from low temperature weathering which occurs along grain boundaries giving well connected spaces. Similarly, the low velocity Azores subaerial volcanics have well interconnected porosity, particularly in the pyroclastic sections and well fractured flows. We thus emphasize that variations in Poisson's ratio of unaltered basaltic rocks with velocity probably arise mainly from the porosity structure rather than from differences in mineralogy. Alteration products such as chlorite have high Poisson's ratios so Poisson's ratios of basalts may increase with very extensive hydrothermal alteration that also decreases the compressional velocity.

Fig. 9. Poisson's ratio as a function of compressional velocity for Bermuda and Azores samples at 0.4 kbar pressure. Symbols as in Fig. 5. The dashed line illustrates the general trend. The solid line is the relation of Hyndman and Drury (1976) for basalts from deep drilling on the mid-Atlantic ridge.

Figure 10 shows the relation between compressional velocity and porosity for the samples. A knowledge of the porosity and its form in the upper oceanic crust and in islands is important for an understanding of alteration processes, and for rough estimates of the permeability available for hydrothermal circulation processes (e.g. Francis, 1976; Whitmarsh, 1978). The relation may be useful for the estimation of upper crustal porosities from seismic refraction measurements, although much of the upper crustal pore space probably is in large fractures and voids so is not represented by small samples. The relation of Figure 9 is largely based on the data for the Azores subaerial rocks. A good correlation has been expected from the relation between velocity and density (Fig. 8) and the relation between density and porosity (Fig. 5). Figure 10 also shows the predicted velocityporosity relations for various pore aspect ratios (or elongations) from the non-interaction theory of Toksöz et al. (1976) as applied to the upper oceanic crust by Whitmarsh (1978). A mean aspect ratio of 1/10 gives the best fit in rough agreement with the large scale upper crustal values suggested by Whitmarsh.

Mean Elastic Parameters For Drilled Sections

Compressional and shear wave velocities for Bermuda samples as a function of depth are shown in Figure 11. There is no systematic variation. There are, however significant differences in both velocities and in Poisson's ratio between the lava flows and lamprophyric

Fig. 10. Compressional velocity at 0.4 kbar pressure as a function of porosity. Symbols as in Fig. 5. The curves are the predicted relations for different pore aspect ratios from Whitmarsh (1978).

HYNDMAN 103

104 HYNDMAN

sheets. The mean compressional velocities are 5.97 ± 0.08 and 5.89 ± 0.07, mean shear velocities 3.22 ± 0.06 and 3.07 ± 0.05 km s⁻¹ respectively. The mean Poisson's ratios are 0.295 ± 0.003 and 0.314 ± 0.006 (Table 1). The velocities for the flows are higher and Poisson's ratios lower than for the sheets even though the flow densities are lower (Fig. 4). Christensen and Salisbury (1975) show how appropriate differences in mineralogy can affect velocity and Poisson's ratio. The mean velocities for the lavas are higher than for most sea floor samples that have been measured, reflecting the low porosity of these hydrothermally altered rocks. The mean velocities and Poisson's ratio of the flows are almost identical to those for samples from deep drilling on the mid-Atlantic ridge (Hyndman and Drury, 1976). The mean compressional velocity of 5.94 km s⁻¹ for the drilled section is somewhat higher than the velocity of 5.1 km s⁻¹ estimated for under the Bermuda platform by Woollard (1954).

The compressional and shear wave velocities for the Azores samples as a function of depth are shown in Figure 11. There is no systematic variation with depth ir. the subaerial section which has a mean compressional velocity of 4.92, mean shear velocity of 2.49 km s⁻¹ and mean Poisson's ratio of 0.328. The scatter of all parameters is large. The high Poisson's ratios are associated with low velocity (Fig. 9). The velocities of the 3 subaqueous samples are significantly higher than those for the subaerial samples, the mean compressional velocity being 5.60, mean shear velocity 2.97 km s⁻¹ and Poisson's ratio 0.307. The latter is typical of the higher velocity subaerial samples, but is slightly higher than for either fresh sea floor basalts (e.g. "yrd_an and Drury, 1976) or the hydrothermally altered Bermuda subaqueous lava flows of 0.295. The mean velocities of the Azores subaqueous samples also is slightly lower than for the latter two rock types. One sample from the transition zone has similar values to the subaqueous rocks.

Electrical Resistivity

The electrical resistivity of the Bermuda and Azores minicores were measured by applying a 0.5V, 10 or 50 Hz signal to the ends which had been painted with electrically conducting epoxy resin (see Hyndman and Drury, 1976). The precision of the measurements is better than 17 but variations in surface water makes the values reproducible only to about ± 107 . All of the data reported are for samples saturated with seawater except for one Bermuda sample measured dry to high temperature. The rocks beneath Bermuda and the Azores are undoubtedly water saturated. Seawater salinity probably is a good approximation for beneath Bermuda and for the subaqueous section penetrated by the Azores borehole. The salinity of the insitu fluid in the Azores subaerial section might be lower than that of seawater so that our measured resistivities may be too low. In order to relate the measured resistivities to variable insitu conditions and to investigate conduction mechanisms, the variation of resistivity with porosity, pressure and temperature were measured on a number of samples. The resistivity change with different degrees of dehydration and with varying signal frequency for some Bermuda and Azores cores have been presented by Drury (1977).

Resistivity as a Fuction of Porosity

The resistivity of rocks for which conduction is primarily through fluid filled pore spaces, is found to correlate closely with the rock porosity. The empirical relation is (Archie, 1942):

$\rho = A \rho_f \phi^{-n}$

where ρ_f is the resistivity of the fluid, Ø is the porosity and A and n are constants depending primarily on the extent of interconnection between the pore spaces. A is usually close to 1. If the porosity consists of randomly spaced spherical pores n is about 2. (Brace et al., 1965; Brace and Orange, 1968; Sharkland and Waff, 1974). Values of n gr_ater than 2 are possible if the pores are less than randomly interconnected.

The resistivity (at atmospheric pressure and 22° C) of all Bermuda and Azores samples correlates well with porosity (Fig. 12) with an n value of 2.4, and a seawater resistivity of 0.2 ohm-m, in agreement with thin sections which indicate most of the porosity to be in roughly spherical pores perhaps w'.h less than random connection. Deep sea floor basalts also have shown high n values of 2.5 (Hyndman and Drury, 1976) suggesting less than random interconnection. The correlation clearly implies conduction primarily through pore fluid in the Bermuda and Azores rocks.

Resistivity as a Function of Pressure

The effect of pressure on resistivity provides important diagnostic information on rock conduction mechanisms. If pore fluid conduction dominates, resistivity should increase with increasing pressure as microcracks and pores are closed, reducing the available conduction paths. If conduction through mineral grains dominates, resistivity should decrease with increasing pressure, as the conducting grains are brought into more intimate contact (e.g. Brace and Orange, 1968). The effective pressure in either situation is the confining pressure, i.e. the external pressure minus the internal pore pressure.

HYNDMAN 105

The problem of relating laboratory sample confining pressure to depth in the crust is iscussed by Hyndman and Drury (1976).

The variation of resistivity of seawater saturated samples from Bermuda was measured to 2 kbars pressure at 20 to 22°C. The sample cylinders are placed between two stainless steel e¹ectrodes of the same diameter and the assembly encased in heat-shrink plastic tubing to exclude the hydraulic fluid pressure medium. The electrodes have perforations leading to small reservoirs, that hold the fluid squeezed from the sample with increasing pressure. Thus, the pore pressure is close to zerc and the confining pressure close to the external pressure.

The resistivity increases with increasing pressure for all of the samples measured indicating that pore fluid conduction is the dominant mechanism. The increase is by about 50% to a pressure of 0.5 kbar and 100% to 2.0 kbar (Fig. 13).

Fig. 13. Electrical resistivity as a function of pressure for Bermuda samples, at 23°C and seawater saturated.

through pore fluid the temperature dependence expected is of the form exhibited by the fluid itself. At moderate temperatures seawater resistivity decreases with increasing temperature (e.g. Horne, 1969). Its behaviour at higher temperatures probably is similar to NaCl solutions which have decreasing resistivity to about 300°C because of the increasing ionic mobility from decreasing viscosity. At still higher temperatures resistivity increases because of a decrease in ionic concentration due to density and association effects (e.g. Quist and Marshall, 1968). At very high temperatures or for dry rocks semiconduction through the mineral grains may dominate. The resistivity is then given by

$$\frac{1}{p} = \frac{1}{po} e^{-E/kT}$$

where ρ is the limiting resistivity at very high temperature, E is the activation energy (in electron volts) and K is Boltzmann's constant. Previous measurements of sea floor basalts have shown a more rapid decrease in resistivity with temperature than for sea water or saline solutions even though pore fluid conduction in the basalts was indicated by the dependence on porosity and on pressure. The effect might arise through c.aduction partially through clay minerals (Hyndman and Drury, <u>1976</u>).

The resistivity of seawater saturated basalts from Bermuda at a pressure of 0.3 kbar was measured up to 250°C (Fig. 14).- One sheet

Fig. 14. Electrical resistivity as a function of temperature for Bermuda samples at 0.3 Kbar pressure, seawater saturated. The sample measured by Olhoeft (1977) had 14% porosity and was saturated with 1.7 ohm-m NaCl solution.

and two flow samples show a more rapid decrease in resistivity with increasing temperature than seawater at low temperatures, becoming similar to seawater above about 150°C. We suggest clay mineral conduction may be important in these samples (see Drury, 1977). One lava flow sample exhibits a linear decrease of log resistivity with inverse of temperature which suggests a semiconduction primary mechanism. This is a low porosity, high resistivity sample.

Clay minerals may be important to conduction in some basaltic rocks, producing through ion exclusion and cation exchange mechanisms, the more rapid change in resistivity with temper : ... expected for pore fluid conduction. A more complex interaction appears to exist among pore fluid, clay, and mineral grain conduction to produce this behaviour (see the discussion in Drury, 1977). Clay mineral conduction probably occurs but is less pronounced for subaerial basalts than for subaqueous tholeiite pillows lavas. Olhoeft (1977) also found that some process in ddition to simple pore fluid conduction was ecessary to explain the effect of temperature n the resistivity of a Hawaiian tholeiitic usalt. (See Fig. 14).

One Bermuda sample was measured dry to 400°C Fig. 15). It exhibits a linear dependence idicating semiconduction in the mineral rains. All of the pore water should have been moved and the clays dehydrated between 100 d 200°C (e.g. Deer et al., 1966). The activation energy is 0.5 eV and $\rho = 10^{-2}$ ohm-m, close to the values of 0.34 to 0.99 eV and 10^{-1} to 10^{3} ohm-m found for deep ocean tholeiites by Schloessin and Dvorak (1976) to 1000°C. In the ocean crust mineral semiconduction probably dominates above about 300°C, if such temperatures occur. Pore fluid and clay mineral conduction dominate ε^{r} lower temperatures.

Mean Resistivities for Drilled Sections

The mean resistivity of 23 Bermuda samples at 22°C and atmospheric pressure is 780 ohm-m with no trend with depth (Fig. 16). The mean for 17 lava flows is 1320 ohm-m and for 6 sheets is 340 ohm-m. The mean resistivity for the sheets is slightly lower reflecting their higher mean porosity. The mean resistivity is significantly higher than for deep ocean tholeiites recovered by the Deep Sea Drilling Project which have a mean of about 250 ohm-m (Hyndman and Ade-Hall, 1974; Hyndman and Drury, 1976; Drury, 1977). The higher resistivity of the Bermuda rocks reflects their reduced porosity resulting from hydrothermal alteration. The insitu mean resistivity of the drilled Bermuda section to 800 m depth should be close to the 800 ohm-m measured since the slightly higher average insitu temperature of about 30°C (Hyndman et al., 1974a) 8°C above

Fig. 15. Electrical resistivity as a function of temperature for one fry Bermuda sample at atmospheric pressure.

HYNDMAN 107

the laboratory temperature, will be about offset by the higher insitu pressure. At greater depth the resistivity should be significantly lower, the effect of the increasing temperature, 22° C km⁻, being more important than the effect of increasing pressure. At a depth of 5 km similar rocks would have a resistivity of about 200 ohm-m.

The mean resistivity of 23 Azores samples at 22°C and atmosphere pressure is 110 ohm-m. There is a general increase with depth (Fig. 16). The mean for 19 samples of the subaerial sequences is 82 ohm-m, for one transition zone sample it is 4900 ohm-m, and for 3 subaqueous samples it is 230 ohm-m. The very low resistivities of the subaerial rocks simply reflects their very high porosity. The subaqueous pillow lavas have resistivities very close to the mean for deep sea samples. The mean insitu resistivity of the drilled subaerial section should be about 5 ohm-m, significantly lower than the laboratory mean because of the much higher mean insitu temperature of about 140°C (Muecke et al., 1974). The subaqueous rocks under insitu conditions will have a resistivity of about 50 ohm-m. The temperature probably increases only slowly at depths greater than that penetrated by the borehole, unless a recent intrusion is approached, so the resistivity will be only slightly less than the 50 ohm-m,

Fig. 16. Electrical resistivity as a function of depth in the Bermuda and Azores boreholes, for samples at 23°C and atmospheric pressure, seawater saturated. The dashed lines are the geometric means.

108 HYNDMAN

perhaps 10 ohm-m at 5 km, for similar pillow lavas.

Thermal Conductivity

- ----

The thermal conductivity of samples from the Bermuda and Azores boreholes was measured on 32 mm diameter, 10 mm thick disks with a divided bar instrument of the type described by Jessop (1970). The samples were water saturated, at a mean temperature of 25°C and subject to an axial pressure of 25 bars. Corrections were applied for disk-bar contact resistance, lateral heat loss and small variations in disk diameter. Calibration was with crystalline quartz and fused silica using the conductivity values of Ratcliffe (1959). Measurements on individual disks were reproducible to ± 27 and we estimate the accuracy to be better than ± 57 .

The mean thermal conductivity of 53 samples from the Bermuda core (Fig. 17), 32 flows and 21 sheets is 2.12 ± 0.03 W m⁻¹ K⁻¹ (5.07 ± 0.07 mcal cm⁻¹ s⁻¹ °C⁻¹). The mean of sheets of 2.19 ± 0.07 (5.23 ± 0.16) is significantly higher than the 2.08 ± 0.02 (4.96 ± 0.05) for the flows. The variation indicated by the standard deviation of 0.31 (0.74) also is much greater than that for the flows of 0.13 (0.31). The conductivity for the sheets appears to reflect primarily the content of pyroxene which has relatively high conductivity (e.g. Clark, 1966). The mean for the flows is also much higher than the 1.7 (4.0) representative of most previously measured fresh oceanic tholeiitic lavas (e.g. Hyndman and Drury, 1976). The higher conductivity in this case appears to be associated with the extensive hydrothermal alteration of the Bermuda lavas that probably occurred at the time of the intrusion of the lamprophyric sheets.

The mean thermal conductivity of 40 samples from the Azores borehole (Fig. 16) is from the azores borehole (rig. 10) is $1.75 \pm 0.04 \text{ W m}^{-1} \text{ K}^{-1}$ (4.19 ± 0.10 mcal cm⁻¹ s⁻¹ °C⁻¹). The mean of 31 subaerial samples is 1.75 ± 0.04 (4.18 ± 0.11) and of 5 subaqueous lavas is $1.73 \pm \overline{0.04}$ (4.13 \pm 0.10). The subaerial volcanics have a similar conductivity to that for similar rocks from Hawaii with porosity from 5 to 10% (Robertson and Peck, 1974). The large variation (s.d. = 0.25 (0.59)) reflects primarily large variations in porosity, although the composition also is highly variable, (Muecke et al., 1974). The subaqueous lavas have a much smaller scatter (s.d. = 0.09 (0.22)). The mean is slightly higher than for most fresh tholeiitic flows, reflecting the significant hydrothermal alteration which was actually still in progress at the time of drilling (see temperature profile, Fig. 3). We conclude from both the Bermuda and Azores cores that hydrothermal alteration increases the

Fig. 17. Thermal conductivity as a function of depth for the Bermuda and Azores boreholes. The dashed lines are the simple arithmetic means.

conductivity of submarine tholeiitic lavas. In contrast, low temperature weathering appears to decrease the conductivity, in one case to 1.55 (3.7) (Hyndman et al., 1974b; Hyndman and Drury, 1976).

The effect of pressure on the thermal conductivity of basalts is quite small and can be neglected at least for upper crustal pressure of 0.5 kbar. The effect of temperature is significant being a decrease of about 0.054 (0.13) per 100°C increase (see review of data in Hyndman and Drury (1976)) implying a mean insitu conductivity at the bottom of the Azores borehole where the temperature is 200°C, of 1.64 (3.92). Such high temperatures and thus low thermal conductivity will occur locally in the upper crust of many young areas. The temperature effect can be neglected in old areas such as Bermuda at least for the upper few kilometers of the crust. The insitu conductivity may also be slightly lower than the sample means because of fractured sections of low conductivity, not represented in the core. In our study, we think these zones are important only for the upper part of the Azores borehole.

Conclusions

The physical properties of basalt samples from boreholes into the islands of Bermida and the Azorés (Tables 1 and 2) are generally similar to those from the deep ocean floor. The most significant differences are for samples from the Azores upper subaerial section. They have high porosity and as a consequence lower density, lower seismic velocities, higher Poisson's ratio, lower electrical resistivity and lower thermal conductivity as compared to deep ocean tholeiitic basalts. Mineralogical differences affect the measured physical properties but much less than differences in porosity. The lamprophyric sheets in ' Bermuda section have higher density, lower seismic velocities, higher Poisson's ratio, and higher thermal conductivity than the lava flows from Bermuda or from the deep ocean floor. The hydrothermal alteration of the Bermuda lava flows appears to have reduced their density, particularly the grain density, reduced their porosity, increased their electrical resistivity and increased their thermal conductivity. This is assuming that their original properties before alteration were similar to samples from the deep ocean crust. The hydrothermal alteration apparently has not significantly affected the seismic velocities. The subaqueous Azores samples exhibit a similar but smaller difference compared to deep ocean lavas, probably from less pronounced hydrothermal alteration at the present 200°C insitu temperature.

The only physical properties of those measured, that are different for aseismic ridges and volcanic island seamount chains or 'hot spot traces' compared to normal oceanic

HYNDMAN 109

× j

crust, that might be detected by surface peophysical measurements are the slightly higher density an Higher Poisson's ratio compared to t + surrounding oceanic crust, suggested by the Bermada samples.

Acknowledgements. We wish to acknowledge the efforts of Dr. F. Aumento who was primarily responsible for the arilling effort in dermuda and Dr. 1.M. Hall who organized the drilling in the Azores. Dr. M.J. Keen supported and encouraged both projects. D.L. Barrett undertook some of the early velocity measurements on the Bermuda core and was of considerable assistance in the setting up of some of the measurement equipment. J. Hull assisted in the velocity measurements and analysis of the data. The Bermuda drilling was financed by Dalhousie University, the National Research Council of Canada and by the Lamont-Doherty Geological Observatory. Financial support for the Azores drilling came from the U.S. National Science Foundation (International Decade of Ocean Exploration), the Research Corporation, the National Research Council of Canada. Dalhousie University, and the Empressa Insular de Electricidade (Ponta Delgada) S.A.R.L. Financial support for the measurements was provided by the Office of Naval Research Contract N-00014-75-C-0502 and the National Research Council of Canada. The drilling and some of the measurements were undertaken while R.D. Hyndman and M.J. Drury were at Dalhousie University.

<u>Abstract</u>. The combined results of logging, physical properties studies and the oblique seismic experiment conducted during DSDP Legs 51-53 at Sites 417 and 418 in Cretaceous crust at the southern end of the Bermuda Rise allow the first detailed evaluation of the physical state of the upper levels of old oceanic crust.

From first arrival and synthetic seismogram analysis of the results of the oblique seismic experiment, the P-wave velocity increases linearly from 4.8 ± 0.2 km/sec at the top of layer 2 to 6.4 ± 0.2 km/sec at a sub-basement depth of 1.3 km. The P-wave velocity of layer 3 at approximately 1.5 km is 6.7 ± 0.2 km/sec. The S-wave velocity is 2.6 ± 0.1 km/sec at the top of layer 2 and 3.7 ± 0.1 km/sec at the top of layer 3.

The average value of V_p (4.8 km/sec) measured by logging in the uppermost basement in Hole 417D is in excellent agreement with the value obtained from the oblique seismic experiment, but is lower

¹⁾Now with the Department of Geology and Geophysics, Woods Hole Oceanographic Institution, Woods Hole, Massachusetts 02543

²⁾Now with the Graduate Program in Geophysics, University of Washington, Seattle, Washington 98195

than the formation velocity (5.3 to 5.6 km/sec) reconstructed for the site from laboratory measurements of velocity through recovered core material. This requires that the formation contain cracks on a scale finer than the resolution of the logging and oblique seismic experiments but greater than that of laboratory samples. From these results and petrologic constraints inposed by the core, the upper crust in Hole 417D consists of 90% basalt with an average grain boundary porosity of 8%, less than 1% interpillow limestone, 5% smectite consisting of about 50% water, and 5% open cracks filled with standing water. The formation porosity thus resides in two domains, grain boundaries and open cracks, and totals 13-147. This value is confirmed by electrical resistivity logs which indicate, in addition, that the cracks are interconnected, giving the formation an average permeability in the thousands of darcies, with lower values in the less fractured massive basalts.

: 法法法圣法保承法法法法 化光空压

A comparison of these results with logging data obtained in young crust in Hole 396B on the Mid-Atlantic Ridge indicates that although the porosity and permeability of the upper levels of the crust at Site 417 are much lower than at the ridge crest, the formation is still not entirely sealed. Although water circulation is thus still possible in old crust, it may be limited by the presence of massive basalts and the absence of shallow sources of heat.

SALISBURY 113

in the second
Introduction

During the past several decades, our perception of the structure of the oceanic crust (Table 1) has evolved from simple layered models derived from surface refraction data (e.g., Raitt, 1963), through multiple layered models based on OBS and sonobuoy data (e.g., Hussong, 1972; Peterson et al., 1974; Houtz and Ewing, 1976) to detailed velocity gradient models derived from velocity and amplitude analysis of reflection and refraction data (e.g., Helmberger and Morris, 1970; Orcutt et al., 1976; Spudich et al., 1978). Although the velocity structure of the crust can now be determined in considerable detail, the composition of the crust has remained largely conjectural beyond the limits of direct sampling because of the difficulties of interpreting velocities in terms of petrology in the absence of in situ data on the distribution of cracks and voids in the basement and their effects upon in situ pressure, water saturation and formation velocity.

During the past five years, several attempts have been made to drill deep into the oceanic basement in order to determine its petrology and geophysical behavior directly. Although the composition of the crust is known from such efforts to depths of more than 0.5 km at several sites in the Atlantic (Table 2), low core recovery has prevented reconstruction of its geophysical behavior.

Recently, two attempts have been made to measure the $\underline{in \ situ}$ physical properties of the crust by means of downhole geophysical experiments.

During the first such experiment (Kirkpatrick. in press), a 200 meter se ion of basement was logged in DSDP Hole 396B in 10 m.y. old crust at 23°N on the Mid-Atlantic Ridge. Although the operating conditions were not ideal, the experiment nonetheless clearly demonstrated that <u>in</u> <u>situ</u> compressional wave velocities in young crust are consistent with those of Layer 2A (Houtz and Ewing, 1976) and that the porosity and fluid permeability of the uppermost levels of the tasement are extremely high due to the presence of numerous water-filled cracks and voids.

A second such attempt, consisting of both downhole logging and the first successful application of the oblique seismic experiment (Stephen et al., in press), was recently completed in DSDP Hole 417D in conjunction with drilling conducted in 108 m.y. old crust at the southern end of the Bermuda Rise during DSDP Legs 51-53 (Figure 1). As can be seen in Figure 2 and Table 3, four holes were drilled during this program for a cumulative basement penetration of 1129 meters and a maximum penetration in one hole (418A) of 544 meters. The results of laboratory studies of the rocks obtained from these holes (Site 417 and 418 Reports in Bryan et al., in press; Christensen et al., in press; Hamano, in press; Johnson, in press \underline{a} , in press \underline{b}), together with those of the downhole logging and oblique seismic experiments in Hole 417D (Salisbury et al., in press; Stephen et al., in press), represent the most comprehensive body of geophysical data in existence on the in situ properties of the crust. The purpose of the present paper is to determine the physical

state of Layer 2 from a review of this data and a comparison of results determined at different scales of investigation in the same hole.

Basement Lithology and Physical Properties

The section drilled at Sites 417 and 418 consists of approximately 300 meters of unconsolidated to semiconsolidated pelagic clay, claystone and chalk of Recent to early Aptian age underlain by pillow basalt, breccia and massive basalt, the latter cut by dikes in the bottom of the deepest holes (417D and 418A). The basalts are plagioclass-phyric with subordinate phenocrysts of olivine ± clinopyroxene and tend to be fairly uniform in composition. Despite their age, they are quite fresh with the exception of those recovered from the upper levels of Hole 417A, which are among the most profoundly altered basalts ever recovered from the sea floor (Donnelly et al., in press). Since the basal Aptian to Cenomanian section is missing in Hole 417A (Figure 2) and the hole was drilled into a small basement high, it has been suggested that the basement section in the hole was exposed to sea water for millions of years before its eventual burial (Site 417 Report in Bryan et al., in press).

As can be seen in Table 3, the basement material recovered at Sites 417 and 418 consists of 71% pillow basalt, 22% massive basalt and 7% breccia. Of this material, approximately 6% consists of smectite and calcite fillings in cracks and between pillows. Although studies of the distribution of cracks in the core (Johnson, in press b) suggest that the basement is strongly fractured in situ, the basement recovery at Sites 417 and 418 was unusually high (70%) due to partial healing of the crust by such material. This suggests

that the figures cited in Table 3 are representative of the drilled section, and thus of the upper levels of layer 2 in old crust.

'n

la1

Detailed studies of the physical properties of the material recovered from these holes have been completed by several investigators and are reported elsewhere (Site 417 and 418 Reports in Bryan et al., in press; Christensen et al., in press; Hamano, in press; Johnson, in press <u>a</u>, in press b). These include measurements at room temperature and pressure of wet bulk density, porosity, compressional and shear the velocity, permeability, thermal conductivity, and electrical resistivity as well as measurements of compressional wave velocity as a function of hydrostatic confining pressure. The values of wet bulk density, porosity and compressional wave velocity obtained at room temperature and pressure from these studies, together with calculated values of grain density and acoustic impedance, are shown as a

¹⁾Site 417 and 418 Reports in Bryan et al., in press.

function of depth for Hole 417A, Hole 417D and Holes 418A and 418B in Figures 3, 4 and 5 respectively. Also shown for each hole are synthetic physical property profiles based on the values shown and section-by-section estimates of the relative abundance of basalt, smectite and calcite. The density profile was reconstructed from the relation,

$$\rho_{\rm s} = {}^{\rm x}_{\rm b} \rho_{\rm b} + {}^{\rm x}_{\rm sm} \rho_{\rm sm} + {}^{\rm x}_{\rm 1s} \rho_{\rm 1s} \tag{1}$$

where $\rho_{\rm s}$ is the mean density of the depth interval or Section under consideration, x_p, x_{sm} and x₁ are the respective volumetric fractions of basalt, smectite and limestone in the interval, $\rho_{\rm b}$ is the nearest measured density value in basalt, $\rho_{\rm sm}$ is the mean density of smectite in the hole (2.20, 2.40 and 2.45 g/cm³ in Holes 417A, 417D and both Holes 418A and B, respectively) and $\rho_{\rm 1s}$ is the density of limestone (2.7 g/cm³).

Similarly, the velocity, impedance and porosity profiles were determined as a function of depth from the relations.

z

$$V_{p_{s}} \approx \left[\frac{x_{b}}{\overline{v}_{p_{b}}} + \frac{x_{sm}}{\overline{v}_{p_{sm}}} + \frac{x_{1s}}{\overline{v}_{p_{1s}}}\right]^{-1}$$
(2)

$$s = (v_p) (\rho_g)$$
(3)

and

$$\phi_{s} = x_{b}\phi_{b} + x_{sm}\phi_{sm} + x_{1s}\phi_{1s} \qquad (4)$$

where V_{ps}, V_{pb}, V_{psm} and V_{pls} are respectively the compressional wave velocity of the section in question, the nearest measured velocity value in

118 SALISBURY

basalt, the mean smectite velocity in the hole (2.9, 3.8 and 4.0 km/sec in Holes 417A, 417D and both Holes 418A and B, respectively) and the velocity of limestone (5.9 km/sec); where Z is the acoustic impedance of the interval; and where $\phi_S, \, \phi_b, \, \phi_{Sm}$ and ϕ_{1S} are respectively the porosity of the section, the nearest measured porosity value in basalt, the mean porosity of smectite in the hole (54% in Holes 417A and D and 20% in Holes 418A and B), and the porosity of limestone (equaled to that of the nearest basalt). The profiles shown were calculated on a section-bysection basis, that is, in 1.5 m long increments roughly equivalent to the sensor spacing in downhole logging tools. Since for the purposes of calculation, the formation was considered to be crack-free, the synthetic velocities, densities and impedances shown will be maximum values and the porosities will be minimum values.

A comparison between these profiles and the laboratory measurements upon which they are based indicates that the density and velocity measurements do not represent formation properties but rather maximum density and velocity envelopes for each hole, while the porosity values represent minimum envelopes. The discrepancy is largely due to sampling bias: although care was taken to sample each component (basalt, smectite or limestone) according to its overall abundance in the core, this was often impractical within specific lithologic units, with the principal result that the physical properties of the smectites are often inadequately represented in the laboratory data. The resulting discrepancy between laboratory values and the synthetic profiles can be substantial, particularly in zones of strong alteration. For example, the synthetic velocities of lithologic Units 4, 9 and 13 in Hole 417A are considerably lower than the

Figure 3 Lithology, interstitial fillings and physical properties vs. depth in DSDP Hole 417A. Synthetic profiles based on laboratory measurements and estimates of the relative abundance of basalt, smeetitie and calcite in each section (see text).

laboratory velocities of the relatively unaltered samples which bracket these units above and below. Since the synthetic profiles are based on laboratory data but reduce the effects of sampling bias, they are considered to be a more realistic presentation of the data.

and

is

here sity

ir

ne

sed

It is clear in Figures 3, 4 and 5 that many (but not all) of the units distinguished on lithologic grounds can also be delineated on the basis of physical properties. For example, in Hole 417A, Units 1-2 can be clearly distinguished from Units 3-4, 5-8, 9-11, 12, 13, 14-18 and 19, while in Hole 417D, Units 1-2 can be distinguished from Units 3, 4, 5-9b, 9c, 9d-11 and 12-14 and in Holc 418A, Units 1-4 can be distinguished from Units 5-62 and 6b-16. Among these subdivisions, the breccias are notable for their high smectite content (locally greater than 50% by volume) and consequent high porosity, low density and low velocity, while the massive basalts display low porosities, high densities and high velocities beneath a strongly altered, low velocity cap formed by prolonged interaction with sea water at elevated temperatures. Not unexpectedly, the physical properties of the pillow basalts end to range irregularly between these two exremes. Although the units described above can be distinguished in terms of physical properties t is unlikely that many can be detected geophysially. The only likely exceptions are the brecias which may be detectable as sub-basement relectors because of their low-acoustic impedances. From the physical property ata summarized in

Table 4, it is clear that there is a pronounced difference between basalts recovered from holes drilled in topograph', depressions (Holes 417D and 418A) and basalts from topographic highs (417A). The compressional wave velocities and wet bulk densities of samples from Holes 417D and 418A, for example, average 5.5 km/sec and 2.8 g/cm³, respectively, while the porosities average 8.4%. These values are in marked distinction to those observed in Hole 417A, which average 5.0 km/sec, 2.7 g/cm³ and 13.7%, respectively. Since the age and lithology of the holes are virtually identical, the differences in physical properties are attributed to differences in alteration due to varying exposure to sea water, a suggestion consistent with the presence of sharp physical property gradients in the upper levels of Hole 417A. If this conclusion is correct, it is clear from the more subt: , but no less striking gra-dients in Hole 418A (Figure 5), that the effects of alteration are fult to considerable depths in the crust; a projection of the laboratory data, for example, suggests that the porosity approaches zero and that the wet bulk density approaches the grain density (i.e., the physical properties approach intrinsic values) at about 700 meters sub-basement.

Although of considerable interest, it must be born in mind that the physical properties discussed to this point were neasured on small samples which were free of large cracks. Since the velocities of fresh basalts measured in the laboratory tend to be considerably higher than the

Figure 4 Lithology, interstitial fillings and physical properties vs. depth in DSDP Hole 417D. Synthetic profiles based on laboratory measurements and estimates of the relative abundance of basalt, smectite and calcite in each section (see text).

velocities observed for the upper levels of layer 2, it is clear that at least the upper levels of the crust are strongly fractured. To understand the significance of such cracks, we must examine data obtained at a larger scale of investigation.

Downhole Logging in Hole 417D

As can be seen in Figure 2, an extensive program of downhole geophysical logging was conducted in Hole 417D in an effort to obtain <u>in situ</u> data on the physical properties of both the sediment column and the underlying basement. Although the uppermost levels of the sediments could not be logged directly (the hole was cased by drill pipe to a depth of 114 meters and later, to 144 meters,

120 SALISBURY

to prevent caving), the open hole below the pipe was logged in four stages to an obstruction in the basement at 445 meters sub-bottom using Schlumberger high resolution temperature, natural gamma ray, density, porosity, velocity, resistivity and caliper tools in various combinations (Table 5). In addition, the uppermost sediments were logged through the pipe using the natural gamma ray and temperature tools. The results of this experiment, together wich a discussion of the tools and their limitations are presented in detail elsewhere (Salisbury et al., in press). Only the results from the basement section logged between 343 and 445 meters sub-bottom will be discussed here. u Charlan in the state of a last a

Since many of the properties measured by logging are sensitive to temperature, pressure, the

Figure 5 Lithology, interstitial fillings and physical properties vs. depth in DSDP Holes 418A and 418B. Synthetic profiles based on laboratory measurements and estimates of the relative abundance of basalt, smectite and calcite in each section (see text).

hole diameter and the properties of the fluid in the hole, the data obtained was corrected to in itu conditions assuming a 10" hole filled with a water, an average hydrostatic confining presire of 0.6 kbar, a temperature at the mudline of .4°C (from the temperature log), a temperature radient of 5.4 x 10^{-2} C°/m in the sediments (also rom the temperature log) and thus, a gradient of .2 x 10^{-2} C°/m in the basalts and a temperature of bout 21°C at the top of layer 2 (as required by niform heat flow). The corrected logging data or the basement; together with the lithology of the drilled section and visual estimates of the relative abundance of smectite and calcite are presented in Figure 6.

Although the basalts in Hole 417D all have essentially the same composition, it is clear from Figure 6 that most of the units and subdivisions delineated on the basis of lithology can also be distinguished on the basis of logging. The massive basalts of Unit 3, for example, have distinctly higher and more uniform velocities than the pillow basalts of Units 1, 2 and 4 and individual flows within the pillow basalts can often be dis-

damage (the Laterolog 8 and ILD data coincide throughout most of the basement), this can be accomplished provided the logging data can be used quantitatively.

いい いいじょうがい たいえい たまやけ たい

Of the four active tools employed in Hole 417D, the resistivity and velocity tools functioned properly while the density and porosity tools malfunctioned intermittently due to a broken excentralizer. Thus the resistivity and velocity data are considered to be of high quality throughout the logged section of the hole, while the density and porosity data are considered marginal between 343 and 369 meters sub-bottom and useless below 369 meters with the possible exception of the low prosity values observed in Unit 3 between 425 and 433 meters sub-bottom when the tool swung intermittently against the side of the hole.

As can be seen in Figure 6, the electrical resistivity of the uppermost levels of the basement in Hole 417D ranges for the most part between 30 and 80 ohm-meters, with lower values (3 ohmmeters) observed in breccias and higher values (up to 200 ohm-meters) observed in massive basalts. Since these in situ values are lower than the average laboratory value of electrical resistivity for water-saturated basalts from this interval (97 ohm-meters; see Table 4) and markedly lower than the resistivities (10<sup>3</sup> to 10<sup>6</sup> ohmmeters) reported by Hyndman and Hall (1974) for dry basalts at room temperature, it is clear that

the basement in Hole 417D is cracked and that the cracks must be filled with sea water (0.25 ohm-meters).

Turning to the velocity date, it is apparent in Figure 6 that the compressional wave velocities in the hole range for the most part between 4.7 and 5.3 km/sec with lower velocities displayed in breccias and higher velocities (up to 5.85 km/sec) displayed in massive basalts, while the formation velocity derived from integrated transit time data for the entire logged basement interval is 4.8 km/sec (Salisbury et al., in press). Although there may be, under certain circumstances, a small systematic error in data obtained using the Schlumberger BHC velocity tool (Wang and Simmons, in press; S. Raymer, personal communication), we see no compelling reason to question the numerical accuracy of the present data. In fact, the logging velocities measured in relatively unfractured sections of the hole (for example, the massive basalts between 425 and 433 meters sul-bottom) are indistinguishable from the laboratory velocities of samples from this interval measured at the effective confining pressure appropriate to in situ conditions (0.1 kbar).

Interpretation of the porosity data, however, is on less certain ground. Taken at face value. the porosity logs run between 343 and 369 meters before the excentralizer broke suggest that the porosity in the upper part of the hole ranges between 15 and 35% with an average of 21 to 22%. The minimum value recorded as the tool swung against the side of the hole in the 425 to 433 meter section noted above, however, was 10%. Since the basalts in this interval have a measured porosity of 3%, it is apparent that the logging porosity must be corrected by approximately minus 7%. As demonstrated by Salisbury et al. (in press), this correction may be derived independently by comparing the velocity vs. density data obtained by logging to velocity-density data obtained in the laboratory at 0.1 kbar for rock samples from the same interval. A density correction of plus 0.1 g/cm<sup>3</sup> is necessary to superimpose the two sets of data. The porosity correction is then the decrease in porosity necessary to restore the porosity vs. (corrected) density curve obtained by logging to the porositygrain density solution observed in the laboratory. The porosity correction obtained by this means (minus 8%) agrees quite well with that determined above (minus 7%) and suggests that Unit 1A has on average porosity of 13-14% while Unit 3 has a porosity of about 32. By the same token, if the density data shown in Figure 6 is corrected by plus 0.1 g/cm<sup>3</sup>, it is apparent that Unit 1A has an average density of about 2.7 g/cm<sup>3</sup>.

Since the velocity and density values obtained in the laboratory are higher than those obtained by logging, while the laboratory porosities are lower, it is obvious that a comparison of the data may be used to estimate the crack porosity and perhaps the permeability of the upper levels of the crust. Before attempting such a compari-

126 SALISBURY

son, however, the results of the oblique seismic experiment will be reviewed to determine the behavior of the crust in the vicinity of Sites 417 and 415 at a scale of investigation typical of marine geophysical surveys.

# The Oblique Seismic Experiment

CANTE INFINE

As noted above and reported in detail by Stephen et al., (in press), an oblique seismic experiment was conducted in Hole 417D in order to determine the velocity structure of the crust in the vicinity of the borehole, to analyze the role of fissures and large cracks in determining the velocity of the crust, to look for anisotropy caused by cracks with a preferred orientation and to measure crustal attenuation.

The experiment consisted of shooting explosive charges to a three-component clamped borehole geophone lowered into the hole from the GLOMAR CHALLENGER (Figure 2). A cross pattern (Figure 7) with 12 km long arms was fired with the geophone clamped 228 meters into basement (571 meters into the hole or 6060 meters below the rig floor). The cross was oriented with lines parallel and perpendicular to the spreading axis in the area. A single line 24 km long was then fired parallel to the spreading axis (SSW-NNE) with the geophone clamped 8 meters into basement. The shooting was carried out by the VIRGINIA KEY, a research vessel from the Atlantic Oceanographic and Meteorological Laboratories of the National Oceanic and Atmospheric Administration in Miami.

After processing to remove ship noise, the travel times and amplitudes were examimed for evidence of anisotropy, attenuation and topographic effects. The amplitude analysis (Figure 8) was carried out using the reflectivity synthetic seismogram method (Fuchs and Müller, 1971; Stephen, 1977). From the results of such analyses (e.g., Figure 9), it is clear that the velocity model which 1 is reproduces the oblique seismic experiment data for layer 2 at Site 417 is one with a uniform increase in compressional wave velocity from 4.8 km/sec at the top of the basement to 6.4 km/sec at a depth of 1.3 km and a similar increase in shear wave velocity from 2.6 to 3.6 km/sec over the same interval.

Although fissures and large normal faults oriented parallel to the ridge have been observed in the axial zone of the Mid-Atlantic Ridge, no undisputed evidence for preferred crack orientation was found in layer 2 at Site 417 from either velocity or amplitude studies. As can be seen in Table 6 from Stephen et al. (in press), the mean north-south shear wave velocity (2.56 ± 0.04 km/ sec) is not significantly different from the mean east-west velocity (2.66 ± 0.14 km/sec). In general, shear waves are well suited to the study of seismic anisotropy since a) the direct shear wave arrival plots as a straight line for about 3 km whereas the direct compressional wave arrival falls on a curve, b) shear wave amplitudes increase with range in contrast to compressional

Figure 8 Observed N-S horizontal component data from South line of oblique seismic experiment at Site 417; geophone 228 meters into basement (6060 meters below rig floor); amplitudes weighted by (range/7.0)\*\*<sup>2.9</sup> for ranges greater than 7.0 km; time reduced to 6.0 km/sec. Note signal character in regions A-E. Figure from Stephen et al. (in press).

wave amplitudes which decrease (Ergin, 1952) and c) shear waves are the cretically more sensitive to the presence of water-filled cracks than compressional waves (Anderson et al., 1974). Since the present experiment was well suited to the detection of azimuthal anisotropy, it appears that large, oriented fissures are not present at Site 417.

an

n-

ν.

The situation in layer 3, however, is less clear. The average compressional wave velocities for the north-south and east-west lines are 6.71  $\pm$  0.30 and 6.61  $\pm$  0.41 km/sec, respectively, whereas the average shear wave velocities for the same lines are 3.77  $\pm$  0.10 and 3.60  $\pm$  0.09 km/sec, respectively. These values are not convincing evidence of anisotropy in layer 3, but if we assume that most of the spread in the errors is caused by small-scale topography and accept the mean values, then shear wave anisotropy on the order of 0.2 km/sec may exist.

## Data Comparison

The scale of investigation of the three sets of data presented above ranges from approximately  $10^{-2m}$  for the laboratory data through  $10^{0m}$  for the logging data to about  $10^{4m}$  for the data collected by means of the oblique seismic experiment. Since all three types of data were obtained for Hole 417D, it should be possible from a comparison of the data, to determine the volume fraction and scale of open cracks and fractures in the upper levels of the crust at Site 417. To this end a summary of the porosity, density, velocity and electrical resistivity data is presented in Table 7 for the interval in tole 417D examined by all three techniques (Units 1-4). Also shown are summaries of the data for the pillow basalts of Unit 1A (for which all of the logging tools were working) and the relatively unfractured massive basalts at the base of Unit 3 which served as a calibration unit for the logging tools.

Several features of this table are quite strik-First, the average compressional wave veing. locity obtained by logging for the uppermost 100m of the crust (4.8 km/sec for Units 1-4) is virtually identical to that obtained by the oblique seismic experiment but both are considerably lower than the velocity derived for the same interval from laboratory data (5.3 km/sec). This indicates that the crust is fractured on a scale larger than that of laboratory samples but generally less than the spacing between the transmitter and the receiver in the BHC velocity tool (0.6 m). Such spacing would be consistent with the cracks between individual pillows and the radial cracks within them.

Secondly, the average porosity of Unit 1A as determined by logging (132) is about 5% greater than the porosity determined from laboratory measurements (8.3%). This indicates that approximately 5% of the formation by volume consists of open cracks, a value consistent with the 0.1  $g/cm^3$  discrepancy in density observed between laboratory and logging data in the same interval. Since the CNL porosity tool measures porosity by determining the total amount of hydrogen in the formation, these cracks, like those between indi-

SALISBURY 127

vidual grains, are apparently filled with water. Finally, it should be noted in Table 7 that the formation velocity determined by logging for Units 1-4 is identical to that of Unit 1A. We may thus be just 'led in extrapolating the conclusions drawn above for Unit 1A to the entire logged interval.

order to understand the distribution of po-, within the logged interval, however, it is ne. "sary to juxtapose the velocities determined by the three techniques as in Figure 10 in which the velocity profiles reconstructed from zeroressure laboratory data, integrated logging cransit times and the results of the oblique seis mic experiment are shown as a function of depth. Since the discrepancy between the logging and laboratory data is a measure of the volume fraction of cracks, Figure 10 suggests that the formation porosity associated with open cracks resides largely within the pillow basalts while the massive basalts contribute relatively little to the porosity of the formation beyond their measured grain boundary porosity of about 3%. Figure 10 also suggests that thin zones of very high crack porosity (up to 20% at the top of Unit 1C) exist locally in the crust in association with breccias between flows. That the low velocities associated with the case noted here are not due to caving but to an aquifer of some antiquiry is suggested by the high natural gamma ray count seen at this level in Figure 6. It should be noted, incidentally, that in a rigorous comparison, laboratory veloc' s appropriate to in situ conditions would be use instead of the zero-pressure data shown in F pire 10. This procedure was not taken in

# the present case because the velocity correction is variable 'from 0.0 - 0.25 km/sec, depending on density) and because the error in the estimate of porosity (2%) due to a maximum velocity correction of 0.25 km/sec is almost certainly less than those inherent in the Wyllie relation on which the estimate is based.

# Conclusions

Since the beginning of the basement drilling program in 1974, approximately 1200 m of basalt have been recovered in the atlantic, at which 790 m, or more than half, were recovered at DSDP Sites 417 and 418. If the sections drilled at these sites are representative of Cretaceous oceanic basement, it is clear from the presentation above on the nature and physical properties of the core and the res lus of the logging and oblique seismic experiments in Hole 417D, that a number of important conclusions can be drawn concerning the composition and physical state of the upper levels of layer 2 in old oceanic crust:

1) <u>Composition</u>. The upper levels of the crust down to at least 0.5 km consist of approximately 90% basalt, 5% smectite, less than 1% interpillow limestone and 5% open cracks tilled with standing water. Of the basalts, 71% consist of fractured pillow basalt, 22% are relatively unfractured massive basalts and 7% consist of partially cemented basalt rubble. Dikes begin to appear at depths of 350 to 500 meters in the basement but are not volumetrically significant.

Figure 10 Comparison of compressional wave velocities obtained from logging, physical property studies and the oblique seismic experiment in Hole 417D (see text). Discrepancy between laboratory and logging data (stippled area) is a measure of formation porosity due to open cracks. Units 1, 2 and 4 are composed of pillow basalt while Unit 3 (hachured) is composed of massive basalt; insets in lithology column represent abundance of limestone (plain) and s ctite (light gray) on a scale of 0-50%. 2) <u>Internal Structure</u>. Although the crust disrlays marked downhole variations in physical properties, it is unlikely that such variations will be detectable using surface geophysical techniques. It is possible, however, that the low velocity zones associated with breccias within the basement might be detected by deep tow seismic reflection techniques. 3) <u>Resistivity</u>. The <u>in situ</u> electrical resistivity of the basement ranges from 3  $\Omega$ -meters in the breccias to about 200  $\Omega$ -meters in the massive basalts, with most values falling between 30 and 80  $\Omega$ -meters. Since the average laboratory resistivity of water-saturated basalts from the section is 97  $\Omega$ -meters and the resistivity of dry basalts at room temperature ranges from  $10^3$  tc  $10^6 \Omega$ -meters, it is clear that the basement is cracked and saturated with sea water having a low <u>in situ</u> resistivity (0.25  $\Omega$ -meters at 21°C).

4) <u>Velocity</u>. Compressional wave velocities in the uppermost levels of the basement range for the most part between 4.7 and 5.3 km/sec with lower velocities displayed in breccias and velocities as high as 5.8 km/sec displayed in the massive basalts. The average formation velocity derived from both the oblique seismic experiment and from integrated logging transit times is 4.8 km/sec, a value consistent with those reported for layer 2B by Houtz and Ewing (1976). This value is considerably higher than the layer 2A formation velocity of 3.6 km/sec reported by Kirkpatrick (in press) for the basement section drilled in Hole 396B in young crust along the same flow 'ine and is consistent with the observation that layer 2A does not commonly persist in the Atlantic beyond the 60 million year isochron. Examination of the core material from Hole 417D clearly indicates that the increase in formation velocity in the upper levels of layer 2 with age is due to the infilling of cracks and interpillow voids by products of low temperature alteration such as calcite, smectite, and zeolites.

5) Velocity vs. Depth. From the results of the oblique seismic experiment it is clear that the compressional and shear wave velocities at Site 417 increase respectively with depth from 4.8 and  $2.6\ km/sec$  at the top of layer 2 to 6.4 and 3.6 km/sec near its base. This could be due, in varying combinations, to decreasing alteration, to a decrease in cracks or to changing mineralogy with depth. The laboratory velocities shown in Figure 11 suggest that the velocity gradient in layer 2 can be explained in terms of the first two phenomena alone: the laboratory velocities increase with depth in response to decreasing alteration, reaching the velocity of fresh basalt (6.4 km/sec) at a projected depth of about 700 m, which would appear to be the maximum depth of atteration. The discrepancy between the laboracory and oblique seismic experiment data confirms

and the second second

Figure 11 Comparison of laboratory velocities of samples from Hole 418A (Christencen et al., in press) and the results of the oblique seismic experiment in Hole 417D (Stephen et al., in press). Laboratory velocities measured at an effective confining pressure of 0.1 kbar. Vertical dashed line represents velocity of fresh basalt at 1.0 kbar.

that the crust is cracked, but the increase in the formation velocity with depth suggests that the cracks decrease downward until the formation velocity reaches the velocity of a fresh, crackfree basalt at the base of layer 2. Since this velocity is still lower than the velocity of

layer 3, the layer 2/layer 3 transition must be due to a change in mineralogy.

6) <u>Anisotropy</u>. No convincing evidence of seismic anisotropy was found in layer 2 from either velocity or amplitude analysis of the oblique seismic experiment data. Thus the large, open

132 SÄLISBURY

fissures observed parallel to the Mid-Atlantic Ridge in the floor of the median valley have either been filled with rulple and sediments or closed as they evolved into normal faults in the walls of the median valley. There is still weak evidence, however, of seismic anisotropy in layer 2 with  $V_{\rm S}$  slow by about 0.1 to 0.2 km/sec parallel to the direction of spreading. Since open cracks cannot be invoked at this depth, this anisotropy may be due to the grain of sheeted dikes.

7) Porosity, density and permeability. Although the crust at Sites 417 and 418 ha. experienced considerable infilling, the basement is strongly fractured in situ. The total porosity of the logged basement interval in Hole 417D ranges from 3% in the massive basalts to as much as 20% in the breccias, while the average for the pillow basalts and the logged interval as a whole is 13%, of which about 8% is due to grain boundary porosity in basalt and 5% is due to open cracks filled with standing water. These cracks decrease the formation density by about 0.05  $g/cm^3$  to an average of 2.70  $g/cm^3$ .

The most important influence of such cracks, however, is upon formation permeability. This can be estimated from the relation,

$$K = \frac{h^2 R_w}{4\pi S R}$$
(5)

where K is the permeability of the formation in darcies, h is the average crack width in centimeters, R, is the resistivity of the interstitial water in  $\Omega$ -meters, R is the average formation resistivity, and S is a shape factor close to unity (Sheidegger, 1960). Using the formation resistivity determined by logging (50  $\Omega$ -meters), a sea water resistivity of 0.25  $\Omega$ -meters and an average crack width of 0.25 to 0.50 cm (estimated from the crack density and porosity of the formation), the permeability of the upper levels of the crust is found to range between 2500 and 10,000 darcies, in excellent agreement with the results of Johnson (in press, b) from visual estimates of the density and distribution of cracks in the core. Such values imply that convective heat transfer in old oceanic crust is limited not by the permeability of the crust but by the availability of heat and the presence of overlying sediments and that the alteration of submarine basalts is only terminated by subduction.

Acknowledgments. We wish to thank the Captain and crew of the GLOMAR CHALLENGER and the VIRGINIA KEY for their assistance during the drilling, logging and oblique seismic operations, Loïc Beurdeley of Schlumberger, Ltd. for running the logging tools, R. Jones, J. Vohs and S. Bearman for their assistance in processing the logging data, S. Blair, R. H. Wilkens, J. Hull, G. Bussod and R. Prior for their assistance in the laboratory velocity studies and J. Kirkpatrick, K. E. Louden and D. H. Matthe's for their many helpful suggestions during the course of this study. The laboratory velocity studies we supported by <u>Office</u> of Naval Research contract N-00014-75-C-0502.

### GEOMAGNETIC REVERSALS AND OCEAN CRUST MAGNETIZATION

William Lowrie

### Institut für Geophysik, ETH Hönggerberg, CH-8093 Zürich, Switzerland

Abstract. The Cenozoic and Mesozoic history of geomagnetic field reversals is derived mostly from interpretation of oceanic magnetic anomalies. Our knowledge of the magnetization of the oceanic crust is still somewhat incomplete, in particular concerning the sources of the magnetic anomalies. A review is given here of what is known about the polarity, direction and intensity of magnetization of the different layers of the oceanic crust.

Large parts of the oceanic magnetic polarity sequence remain unverified by independent continental paleomagnetic studies. Only the Late Cenozoic and Cretaceous magnetic reversal sequences have been confirmed. Several hypotheses have been offered to explain the origins of oceanic magnetic smooth zones.

The source of oceanic magnetic anomalies has most commonly been identified with basaltic Layer 2. Magnetometer measurements from surface ships or deep-towed vessels have suggested that the entire signal could derive from the uppermost 500 m. of the basalt layer. Accumulating evidence, including power spectral analysis of anomaly amplitudes and direct measurement of dredged and drilled (DSDP) basalt samples with a broad geographic provenance, now indicates that a much thicker source layer is needed. Deep penetration of Layer 2 in recent DSDP holes provides evidence that Layer 2 has a complex structure and history; large variations of magnetization intensity and inclination are found and there are occasional polarity alternations. In none of the deep holes was the bottom of the strongly magnetized layer reached. It now appears likely that the gabbroic Layer 3, although more weakly magnetized than Layer 2, may contribute significantly to the oceanic magnetic anomaly pattern.

#### Introduction

Large areas of the oceanic crust are characterized by lineated magnetic anomaly patterns [Mason and Raff, 1961; Raff-and Mason, 1961], which are interpreted in terms of alternating geomagnetic field-polarity during sea-floor spreading [Vine and Matthews, 1963]. Worldwide correlation of oceanic anomalies yielded a geomagnetic polarity scale which, by comparison with radiometrically dated continental lava sequences, allowed ages to be associated with different parts of the ocean basins since the late Cretaceous [Heirtzler <u>et al.</u>, 1968]. By matching anomalies on both sides of the spreading center at the mid-Atlantic ridge the relative motions of the Atlantic-bordering continents have been reconstructed quasi-continuously during the opening of the Atlantic ocean [Pitman and Talwani, 1972]. From the point of view of geomagnetic theory, frequency analysis of the reversal time scale leads to constraints upon models of the orig.. of the geomagnetic field [Cox, 1968].

The magnetization of the oceanic crust is therefore of considerable geophysical interest. The magnetization polarity sequence has been derived in many marine geophysical investigations. Although mutually consistent reversal sequences are obtained in different ocean basins there are difficulties in verifying the sequence independently. There is not even unanimous agreement as to where and how the anomalies originate. Much effort has been expended to understand the ocean crust magnetization by recording the anomalies in surveys at the ocean surface or from deep-towed instrument packages, and by studying the magnetic properties of rocks recovered from the ocean bottom by dredging, by sampling from submersibles in the FAMOUS project, by shallow drilling and by deeper penetration of the ocean crust in the Deep Sea Drilling Project (DSDP) and its continuation, the International Program of Ocean Drilling (IPOD).

In this paper a review is given of investigations to confirm the oceanic reversal sequence and to establish the origin of the corresponding oceanic magnetic anomaly source layer.

### Geomagnetic Polarity

The magnetization of the oceanic crust is our prime source of knowledge of the history o. reversals of the geomagnetic field since the

LOWRIE 135

Early Jurassic, that is, in the last 180 M.y. Four distinct episodes may be identified. A continuous sequence of well-defined reversals characterizes the time interval from the present to the Late Cretaceous, the Cenozoic sequence [Heirtzler et al., 1968]. In oceanic crust of Middle and Early Cretaceous age the anomalies have generally reduced amplitudes and are uncorrelatable; this is referred to as the Cretaceous magnetic smooth zone. In the Early Cretaceous and Late Jurassic are again found welldefined, correlatable anomalies, the Mesozoic M-sequence [Larson and Pitman, 1972, 1975; Larson and Hilde, 1975]. In crust older than the M-sequence is found the Jurassic magnetic smooth zone. The dating of the two sequences of magnetic anomalies has been periodically revised, and the reasons for the two magnetic smooth zones have been frequently speculated upon.

### The Cenozoic Reversal Sequence

The refinement of the K/Ar method made it possible to date lavas radiometrically with an accuracy of about 2 to 5%. By the middle 1960's a well-defined geomagnetic polarity sequence containing long epochs and shorter events of constant polarity had been developed in Pleistocene and Pliocene lavas for the last 3.7 M.y. [Cox et al., 1966]. The sequence was extended to about 4.5 M.y. with the aid of deep sea sediments data. Beyond this age a 2% error exceeds the duration of some events and derivation of f a polarity-time scale from the combination of K/Ar dating and polarity measurements on stratigraphically unrelated samples becomes limited by the lack of resolution of the radiometric dating method [Cox, 1969].

The polarity-time scale has been extended further by studying the polarity of K/Ar-dated. stratigraphically related samples from thick lava sequences in Iceland, which have been laid down almost continucusly. The errors of indi-vidual dates were partially compensated by linear regression analysis and optimum ages for the magnetic reversals were derived by interpolation. Using this method McDougall et al. [1977] extended the polarity-time scale to 7 M.y. and demonstrated good agreement with the oceanic anomalies polarity sequence of Talwani et al. [1971]. In lavas with ages from 8.7 M.y. to 12 M.y. [McDougall et al., 1976] the age dates were more scattered but the polarity sequence agreed quite well with the oceanic sequence derived for the interval near anomaly 5 by Blakely [1974].

The reversal record in deep sea sediments unequivocally confirms the sequence derived from lavas back to epoch 5, or about 5 M.y. [Opdyke, 1972]. It has been extended to epoch 11 (Late Miocene) in a continuous long core [Foster and Opdyke, 1970]. Further extension of the sequence through the Miocene has also been

136 LOWRIE

attempted in overlapping cores [Opdyke <u>et al.</u>, 1974; Theyer and Hammond, 1974]. The polarity sequence from a single core is less reliable than a sequence confirmed in several cores [Opdyke, 1972] and the correlation of the replicate sections of overlapping cores is not always unambiguous. Nevertheless geomagnetic polarity intervals from deep sea sediments and from oceanic magnetic anomalies have been used to calibrate the Neogene biostratigraphic zonation [Ryan <u>et al.</u>, 1974].

The polarity-time scale derived from oceanic anomalies by Heirtzler et al. [1968] has undergone subsequent refinement and revision, but its correctness is remarkable. Reversals were dated by correlation with radiometrically dated lava sequences for the last 3.5 M.y. at its younger end, and by linear extrapolation to older ages equivalent to 20 times this base.

The oceanic magnetic polarity sequence has not yet been confirmed in land sections for most of the Paleogene. Reversal time scales have been pieced together from a number of partial sections for the Paleocene and Late Cretaceous [Watkins, 1975; Keating et al., 1975]. The first continuous magnetic stratigraphy at a single locality for this period was obtained from paleomagnetic studies in a biostratigraphically complete pelagic limestone section near Gubbio, Italy, where the record of geomagnetic reversals was found to match closely the sequence inferred from marine magnetic anomalies in the Early Paleocene and Late Cretaceous [Roggenthen and Napoleone, 1977; Lowrie and Alvarez, 1977a, 1977b]. Zonation of planktonic foraminifera [Premoli S.\_va, 1977] provided the biostratigraphic framework for the magnetic reversal sequence in the Gubbio section which has been proposed as a magnetostratigraphic type section [Alvarez et al., 1977]. The Late Cretaceous magnetic stratigraphy has been verified subsequently in a check section at Moria [Alvarez and Lowrie, 1976].

The principal conclusions to be drawn from the Gubbio and Moria results [Fig. 1] are: (1) the Cretaceous-Tertiary boundary falls near the top of the reversed polarity interval between anomalies 29 and 30 (as proposed by Larson [1974] and Sclater and Fisher [1974]), (2) the existence of a controversial reversed interval between anomalies 33 and 34 is established, and (3) a long period of normal polarity ending near the Campanian-Santonian boundary and beginning prior to the Cenomanian is correlated with the Cretaceous magnetic smooth zone.

In order to compare the limestone magnetic stratigraphy with the oceanic magnetic anomaly reversal sequence both must be plotted against a common time scale. Radiometric ages are not yet securely established for most major stage boundaries. The numerical ages given by Van Hinte [1976] have been used to prepare Fig. 1, but these may be subsequent to revision.

Fig. 1. Geomagnetic polarity sequence during the Middle and Late Cretaceous. The magnetic stratigraphies of pelagic limestone sections at Gubbio (Lowrie and Alvarez, 1977b) and Moria (Alvarez and Lowrie, 1978) in Umbria, and at Cismon and Cerro Veronese in the Southern Alps (Channell et al., 1979) are combined to form a composite limestone magnetic polarity sequence which is compared to that derived from oceanic magnetic anomalies (Larson and Hilde, 1975; LaBrecque et. al., 1977). Both are plotted against the time scale of Van Hinte (1976).

For example, LaBrecque <u>et al.</u> [1977] assumed two key radiometric ages of 65 M.y. for the Tertiary-Cretaceous boundary and 3.32 M.y. for anomaly 2A and produced a revised magnetic polarity time scale for Late Cretaceous and Cenozoic time. The ages of Cenozoic anomalies 0-29 were obtained by interpolation and those of Late Cretaceous anomalies 30-34 by extrapolation. The age obtained for anomaly 34 which ends the Cretaceous quiet interval is almost exactly 80 M.y., slightly older than the value of 78 M.y. given by Van Hinte [1976] and used in this paper [Fig. 1].

in this paper [Fig. 1]. The revision of the Cenozoic polarity time scale by LaBrecque et al. [19:/] results in a 7% decrease of the age of anomalies dated by the Heirtzler et al. [1968] time scale. Recent recommended revision of the K/År decay constants [Steiger and Jæger, 1977] would cause a partially compensating increase in the radiometric ages of about 2.6%, which is not incorporated in the new Labrecque <u>et al</u>. [1977] time scale.

#### The Mesozoic Reversal Sequence

Few attempts have yet been made to verify the Mesozoic magnetic polarity sequence of the Late Jurassic and Early Cretaceous. The dating of these marine magnetic anomalies (MO to M25) is rather imprecise, and indirect. It is made by determining optimum paleontological ages for the sediment immediately overlying basement at 3 DSDP drillholes in the Early Cretaceous and 2 DSDP drillholes in the Late Jurassic [Larson and Hilde, 1975]. This dating is complicated by the possibility of hiatuses between the formation of igneous basement and deposition of the overlying sediments. Absolute ages have

LOWRIE 137

been ascribed to the paleontological dates by comparison with the Geological Society of London [1954] time scale. The approximate nature of the assignment of numeric ages to the stage boundaries in this time scale naturally compounds the errors of determining absolute ages for the Mesozoic magnetic anomalies.

Recently paleomagnetic stratigraphic studies have been extended backward in time to cover all of the Cretaceous with the exception of the Berriasian. The first successful data have been realized in pelagic limestones from the Cismon section in the southern Alps [Channell et al., 1979]. Although very weak, the remanences possess stable directions and yield a clearly defined magnetic stratigraphy. Ammonites are not present in the section, thus it is extremely difficult to locate the Valanginian-Hauterivian and Hauterivian-Barremian stage boundaries accurately. The polarity sequence in this interval consequently may be stretched or compressed; it does not yet correlate unambiguously with the corresponding M-anomalies. Nevertheless, the distinctive reversal pattern which gives the key anomalies MO to M4 is clearly present [Fig. 1]. The paleontological dating of the section places the youngest of the corre lated M-anomalies (MO) at the base of the Aptian, instead of in the Late Aptian as it was dated by Larson and Hilde [1975].

The Cretaceous Smooth Zone extends from there to anomaly 34 at the base of the Campanian. However, there is a depositional hiatus in the Lower Albian-Upper Aptian part of the Cismon section. Preliminary results from other Lower Cretaceous sections in Umbria show an additional short reversed zone in the Late Aptian. If this unconfirmed reversal proves to be real it might represent an as yet unidentified but correlatable anomaly younger than the rest of the M-sequence. This is a distinct possibility; anomaly MO was not identified in the first world-wide correlation of the Mesozoic anomalies [Larson and Pitman, 1972], and cursory examina tion of the youngest parts of the profiles correlated by Larson and Hilde reveals several fairly large amplitude anomalies within the Cretaceous smooth zone.

### The Magnetic Smooth Zones

At least three sets of magnetic smooth zones may be identified. These are (1) the Cretaceous, (2) the Jurassic and (3) the marginal smooth zones. It is neither necessary nor possible that a single explanation can suffice for all.

The Cretaceous magnetic smooth zones are the best understood. In the Pacific ocean the anomalies are smooth; in the Atlantic ocean more pronounced anomalies exist but they do not correlate to form an extensive lineation pattern, and may only represent bathymetric trends [Larson and Pitman, 1972]. As first suggested by Helsley and Steiner [1968] and

138 LOWRIE

demonstrated in the Gubbio, Moria and Cismon sections [Fig. 1] independent paleomagnetic evidence associates the Cretaceous magnetic smooth zone with a long period of normal geomagnetic polarity lasting from the Early Aptian until the Early Campanian.

The Jurassic magnetic smooth zone can not yet be explained unambiguously. It is probably a geomagnetic phenomenon, but diversely conflicting interpretations as to its nature have been suggested. The amplitudes of anomalies M21 to M25 taper uniformly towards the smooth zone. This tapering amplitude envelope was interpreted by Larson and Hilde [1975] in terms of geomagnetic field intensity increasing away from an anomalously low intensity in the Jurassic smooth zone. Cande <u>et al.</u> [1977] have subsequently proposed that the Jurassic smooth zone represents a period of weak field intensity coupled with rapidly alternating polarity.

Both of these explanations rely on direct interpretation of marine magnetic anomalies and assume that the oceanic crust acts as a perfect recorder of the ancient geomagnetic field. Not all oceanic basalts possess the requisite magnetic stability, however, and many display instability of the remanent magnetization over long time intervals which manifests itself in the acquisition of viscous remanent magnetization [Lowrie and Kent, 1978]. VRM is not a rare phenomenon in oceanic basalts but has been reported at 40% of all DSDP sites (up to Leg 41) for which basalt magnetic properties have been published. Within a few weeks of laboratory observation, VRM in some cases exceeded NRM and in 1/4 of the samples studied exceeded 40% of NRM. These VRM results are probably not representative of all DSDP basalts. However, if it is a substantial and widespread magnetization component in the oceanic crust it may not always be appropriate to interpret the existence, absence or amplitudes of marine magnetic anoma lies in terms of geomagnetic field behavior.

Paleomagnetic data from continental rocks do not definitely resolve the origin of the Jurassic smooth zone. Summaries of Jurassic paleomagnetic pole positions [McElhinny and Burek, 1971; Irving and Pullaiah, 1976] have indicated that the polarity of the geomagnetic field was dominantly, but not exclusively, normal during this period. Recently Steiner [1978] presented an updated summary of Jurassic paleomagnetic studies. Disregarding data whose age uncertainty exceeds two paleontological stages, the Jurassic polarities cited by Steiner are found to represent six unequal time intervals in each of which the number of reports of normal or reversed polarity can be counted [Fig. 2]. The Tithonian-Kimmeridgian mixed polarities correspond to the M-sequence oceanic anomalies. The Toarcian and older polarities are equally divided between normal and reversed but are too old to be observed in the marine record. Probably the mid-Bathonian to Toarcian

JURASSIC NUMBER OF POLARITIES AGE Reversed STAGE Normal (my) 10 10 Port-Kimm 140 ridgiar Oxfordian 150 Callovian Bathonian 160 Bajocian -170 Aslenian Toarcian Pliens--180 bachian Ear Sinemurian 190 Hettanoian

Fig. 2. The number of paleomagnetic normal and reversed polarities for different time intervals in the Jurassic [data after Steiner, 1978].

reversals would be lost in the marginal smooth zone adjacent to the Atlantic continental margins. Only the youngest part of the Jurassic magnetic smooth zone corresponding to the Late Bathonian, Callovian and Oxfordian stages (160-145 M.y.) lends itself to direct comparison with the paleomagnetic record. Unfortunately the data are so scarce for this interval that no conclusions regarding the predominant polarity can be made. The land-based paleomagnetic data are consistent with the interpretation of the Jurassic smooth zone as corresponding to a period of constant normal geomagnetic polarity, but are insufficient to require it [Irving and Pullaiah, 1976]. Once again data from continuous sequences offer the best means of resolving the issue.

Paleomagnetic investigations of the Middle Jurassic Summerville and Curtis formations indicate mainly negative polarity [Steiner, 1978]. Unfortunately these rocks are unfossiliferous, flat-lying red beds which were found to be strongly influenced by secondary components. fold test or rock magnetic evidence concerning the age of the magnetization was presented. Thus the ages of these rocks and of their magnetizations are uncertain. In studies of shallow marine limestones from Franconia in southern Germany Heller [1978, 1977] has eliminated remagnetized sections in the Malm & (Late Kimmer-

idgian) and shown that the Malm  $\alpha$ ,  $\beta$  and  $\gamma$  -equivalent to Oxfordian and Early Kimmeridgian-are normally magnetized. This result is in harmony with associating the Jurassic smooth zone with a long period of normal geomagnetic polarity, but would place the onset of the M-anomalies in the Middle Kimmeridgian at the earliest, a full stage later than inferred by Larson and Pitman [1972].

The magnetic smooth zones found adjacent to the margins of certain continents, such as southern Australia and Antarctica are not iscchrons. Likewise, the landward Jurassic smooth zone boundary appears to cut across magnetic lineations in the eastern North Atlantic [Haves and Rabinowitz, 1975]. Several different explanations have been offered for these marginal smooth zones. Because their landward boundaries are not isochrons they are probably not of geomagnetic origin but are due to a local geological cause related to the time of initial rifting. It has been proposed that these are areas of foundered continental crust rather than true oceanic crust [Talwani and Eldholm, 1972]. Even if true oceanic crust is present the submavine basalts form under conditions that are different from later steady state sea floor spreading. Irving [1970] assumed that conditions at initial rifting would favor formation of coarse-grained basalts with low NRM intensities and stabilities. Such basalts typically develop high VRM and it has been suggested that viscous remagnetization may be an important process in the production of the morginal smooth zones [Lowrie and Kent, 1978].

### Cretaceous Spreading Rates

Larson and Pitman [1972] described the Cretaceous magnetic quiet interval as lasting from 112 M.y. (ancwaly M1) to 85 M.y. (anomaly 34, which they did not number). They found that the computed average spreading rates for this interval were anomalously high at all the spreading centers in both the Atlantic and Pacific oceans. Subsequent discovery of anomaly MO does not affect this conclusion which is based on the dating of anomalies 34 and M1.

Anomaly 34 has been identified in the Gubbio section close to the Santonian-Campanian boundary, whose age according to Van Rinte [1976] is 78 M.y., much younger than ine age used by Larson and Pitman [1972]. Identification of anomaly MO at the base of the Aptian [Channell et al., 1979], on the other hand, makes the youngest of the M-anomalies older than they were estimated by Larson and Pitman [1972] or Larson and Hilde [1975]; the age of M1 becomes approximately 118 M.y. (Early Barresian rather than Late Barremian). The Cretaceous quiet interval therefore lasted for 40 M.y., and Larson and Pitman's spreading rates for this interval are about one third too high.

the M-anomalies were determined by Larson and Pitman [1972] with the aid of only two calibration points--estimated numeric ages of 155 M.y. For DSDP site 105 and 120 M.y. for DSDP site 166. The time interval covering tha anomalies MI to M22 lasted about 36 M.y. After revision of the age of MI as above the spreading rates during formation of the Mesozoic anomalies must increase by about 15%. The net effect of the above considerations is to reduce the difference between Cretaceous quiet interval spreading rates and the spreading rates on either side of it. Recomputed spreading rates are given in Table 1.

In the central Atlantic the spreading rate in the Cretaceous quiet interval is essentially the same as in the Late Cretaceous lineated sequence, but both are still about double the rate in the Early Cretaceous preceding the quiet interval. In the South Atlantic estimates of quiet interval spreading rate are inexact for other reasons. The Cretaceous smooth zone extends there as far as the continental margins (where it may become a marginal type smooth zone) and the onset of spreading can not be timed from magnetic anomalies. Larson and Pitman [1972] assumed initiation of spreading in the South Atlantic at 110 M.y.B.P., but drew attention to the existence of lineated anomalies south of the Walvis Ridge, near the African margin, which could represent the last two or three anomalies of the M-sequence. After revision of the ages of the youngest M-sequence anomalies, the onset of spreading appears to be nearer to 120 M.y.B.P., and the time base for calculating the quiet interval spreading rate becomes 40 N.y. (120-80 N.y.B.P.) instead of 25 M.y. (110-85 M.y.B.P.). However, in spite of these adjustments the quiet interval spreading rate is about 50% higher than in the following Late Cretaceous and Cenozoic period of lineated anomalies.

140 LOWRIE

In the Pacific ocean the re-computed quiet interval spreading rates are higher than in the preceding and following intervals at both the Phoenix-Pacific and Farallon-Pacific spreading centers. Larson and Pitman's [1972] conclusion that spreading rates inc. ased sharply at all Pacific and Atlantic spreading centers during the Cretaceous magnetic quiet interval stands up to this re-examination. However, at the Central Atlantic and Farallon-Pacific spreading centers the higher spreading rate was not confined to the quiet interval but persisted for the remainder of the Cretaceous.

#### Direction of Magnetization of Oceanic Basalts

The source of oceanic magnetic anomalies has long been assigned to the strongly magnetized basaltic Layer 2, which has been sampled in a variety of ways. In basalt samples that were collected by dredging or from a submersible the inclination of remanence was determined relative to orientable volcanic features. DeBoer et al. [1969] found normal polarities in dredged

Fig. 3. Paleolati ude circles defining possible VGP loci for Atlantic DSDP sites. The optimum Early Tertiary-VGP position is indicated by the star in the intersection triangle [from Lowrie, 1977]. basalts from the axial zone of the Reykjanes Ridge. Prévot <u>et al.</u> [1976] reported exact agreement with local axial dipole inclinations in a small collection of 3 dredged basalts and 6 basalts collected from the submersible Archimède. On the other hand mixed polarities were reported in samples obtained by shallow drilling within the MAR axial zone using an ingenious pressure-powered drill [Ade-Hall <u>et</u> <u>al.</u>, 1973].

the

Direct sampling of Layer 2 in the Deep Sea Drilling Project (DSDP) provided a large supply of samples from depths up to nearly 600 m. in which the inclinations of the magnetizations of Layer 2 could be studied. The DSDP samples were not oriented in azimuth, but the inclination could be used to determine the paleolatitude at which the basalt was wagnetized, after applying a correction factor to compensate for the absence of declination data [Briden and Ward, 1966]. The paleolatitude defines a circle as the locus of possible virtual geomagnetic poles (VGP) for a given DSDP site. At a few places anomalies of sufficiently similar age have been drilled so that the VGP posicion could be further located by the intersections of the paleolatitude circles. For example, an Early Tertiary VGP position was found for the Antarctic plate, lying some 15° from the present geographic pole [Fig. 3] and close enough to it to support the concept that the Antarctic plate has occupied its present high latitude throughout the Tertiary [Lowrie and Hayes, 1975; Lowrie, 1977].

At most DSDP sites, however, large discrepancies are found between the paleolatitudes derived from basalt magnetization inclinations and those expected, even after correction for plate motion [Lowrie, 1974, 1977]. There was no overall tendency for shallow or steeper inclinations at 55 geographically distributed DSDP sites [Fig. 4(a)]. At most sites only the top few meters or few tens of meters of basalt were sampled; the paleolatitude discrepencies might not be physically representative of Layer 2 but may result from incomplete averaging out of secular effects.

In recent years, however, some very deep holes have penetrated the basalt layer to depths of half a kilometer, and have yielded very curious results. When occasional samples in earlier shallower holes were found to have different polarities from their neighbors, this was usually attributed to misorientation of the sample. However, in the data iron site 332A of Leg 37, zones of both positive and negative polarities are found, and at any chosen depth there is a very large scatter in the measured inclination [Hall, 1976]. Even after averaging ever units or subunits to reduce this (as yet unexplained) large inclination scatter, there are found to be very large differences down the hole [Ryall et al., 1977]. Nost strikingly, he inclinations are too shallow for the latitude at which the magnetizations were acquired, which

could not be appreciably different from the present site latitude.

120

The inclination distribution that might be expected at a given latitude due to secular variation dispersion is similar to the Fisherian kind. Harrison and Watkins [1977] calculated the inclination expectation distribution for a latitude of 37°N and compared it with the observed inclinations in the deep holes of Leg 37 [Fig. 4(b)]. The observed low inclinations in Leg 37 were attributed by Harrison and Watkins to tectonic rotation about a horizontal axis, possibly as a result of collapse of the material above the magma chamber. The effect of such a rotation depends on the orientation of the rotation axis to the spreading center and on the sense of the rotation. Rotation about an axis parallel to an East-West trending ridge would produce a shallowing of the inclination on one side of the ridge and a steepening on the other side, for example.

Shallow inclinations have been reported at a few other deep holes, as also have some anomalously steep inclinations. Indeed it has not yet been established that shallow inclinations are typical for the oceanic basalt layer. The DSDP data from many shallow holes [Fig. 4(a)] indicate no preference for shallow values over steep values. The argument has been advanced that most of these holes are too shallow to be physically representative of Layer 2. Similarly, however, it is premature to conclude on the basis of the few deep holes that have been studied that they constitute a statistically representative sampling of Layer 2.

As puzzling as the anomalous inclinations in DSDP holes is the discovery of distinct zones with opposite polarities in the same hole. The mixed polarities and anomalous inclinations at hole 332 of Leg 37 appear to result from this hole having been drilled in a transition zone instead of in a negative zone as originally planned [MacDonald, 1976]. However, anomalous inclinations and polarities have also been reported at several other holes for which this explanation does not serve. Harrison [1976] has pointed out that one polarity change in a vertical section would not be surprising if the zone of injection of the dikes feeding the extrusive lavas were narrow; successive lava flows would not extend as far as their predecessors and would lead to an inc ined boundary. However, the DSDP data require a more complex mode of flow emplacement, possibly involving episodic vulcanism at the ridge crest.

The remarkable symmetry of lineated magnetic anomaly patterns on spreading centers--such as the Reykjanes or Juan de Fuca ridges--constitutes one of their most striking features. However, on close examination the individual "stripes" are seen to be irregular in outline and sometimes discontinuous. The width of a given anomaly changes from profile to profile normal to the ridge axis; on certain pro.iles

Fig. 4. (a) Paleolatitudes derived from basalt magnetization inclinations at 55 DSDP sites are compared to the paleolatitudes expected from plate tectonic reconstructions (from Lowrie, 1977). Although scattered, the DSDP values show no preference to be higher or lower than expected. (b) The histogram of inclinations measured in basalt samples from DSDP Leg 37 sites is compared to a theoretical distribution curve (after Harrison and Watkins, 1977). The observed inclinations are predominantly s'allower than expected.

the ancmalies corresponding to the Jaramillo and Olduvai events are missing. This could reflect in part the degree of magnetic resolution in the survey or int 'ference from topographic effects. However, the irregularity and discontinuity of the stripes may also be evidence that accretion of new crust is episodic along the ridge on a time scale of  $10^{4}$ - $10^{5}$  years.

Rock magnetic studies on basalts dredged from the axial zone of the Reykjanes ridge showed systematic variations of titanomagnetite content and magnetic properties with distance along the ridge [deBoer, 1975]. Similarly, variations of remanent magnetic properties were observed in basalts sampled from within the mid-Atlantic ridge axial zone during the FAMOUS project [Prévot and Lecaille, 1976]. Although Curie temperatures--used as an indication of composition--did not vary significantly within the axial zone, local and regional variations in "emanent intensity were attributed to corresponding fluctuations in concentration and grain size of the magnetic minerals. Apparently not only the accretion but also the magnetic mineralogy of the basaltic lavas may fluctuate with time.

### The Magnetic Ancmaly Source Layer

(b)

0

### Oceanic Basalt Magnetic Mineralogy

Oceanic basalts generally correspond to deuteric oxidation class 1, although occasionally higher oxidation classes have been reported [Ade-Hall, 1974]. The primary magnetic mineral is commonly a skeletally shaped titanomagnetite

# $(x E_{e_{7}}TiO_{u} \cdot (1-x)Fe_{3}O_{u})$

with ulvöspinel content (x) in the range 0.4-J.7. The grain size may be as large as 100µ [e.g. Ade-Hall, 1974], but more commonly is finer than 10µ and frequently is micron to submicron size. The grains progressively become converted to titanomaghemite at ambient ocean floor temperatures, which is visible on polished sections as a characteristic whitening along cracks and on the rims of coarser grains. Fine grains may be entirely maghemitized. Alteration also causes volume changes, which manifest themselves as cracks in the grain due to shrinkage. These cracks can be filled secondarily with sulfides [see Ryall et al., 1977 for examples].

The alteration leads to the phenomenon of granulation in older, altered basalts [Ade-Hall et al., 1971]. Accompanying alteration there is a reduction in spontaneous magnetization and in the remanence intensity.

### Intensity of Magnetization

Estimates of the intensity of magnetization, and identification of the magnetic source layer have been made by a variety of methods. Talwani et al. [1971] measured magnetic anomaly profiles parallel to the axis of the Reykjanes Ridge on each of three lineations and estimated the magnetization by correlating the longitudinal anomalies with topricaphy. They deduced magnetizations of 30 k/m for the central anomalies, 12 A/m for the negative anomaly younger than anomaly 4 at distance 75 km, and 7 A/m for anomaly 5 at distance 100 km. Using a value of 12 A/m for the uniform magnetization of a block model they accounted for the anomaly amplitudes on profiles perpendicular to the ridge by assuming an anomaly source layer thickness of 400 m. This implied that the anomalies derived entirely from the thin uppermost, pillow basalt Layer 2A, in contrast to earlier models which, using lower magnetizations, had associated the source of the anomalies with the entire thickness of Layer 2 [e.g. Heirtzler et al., 1968] or even the entire thickness of the oceanic crust [e.g. Vine and Matthews, 1963; Vine and Wilson, 1965].

In subsequent investigations of Pacific ocean spreading centers using deep-towed instruments, the thin 0.5 km source layer was usually adopted. Inese results demonstrated a marked lateral decrease in magnetization intensity with increasing distance from the spreading center. Anomalous magnetizations of 30-50 A/m are found near the axis, and decrease to values around 5-15 A/m on the flanks of spreading systems.

et ed

is

ched

ne

ior

raì

A semi-logarithmic plot of some deep-tow results [Fig. 5(a)] shows that two stages of relaxation are involved, characterized by quite different relaxation times,  $\tau$ . Near the ridge axis the data are significantly correlated and yield relaxation times of around 1 M.y. or less. Over oceanic crust older than about a million years relaxation times of 6 to 20 M.y. are found, but only the Pacific-Antarctic Ridge data are significantly correlated.

In a systematic, detailed investigation of the bagnetic properties of submarine basalts dredged from the North Mid-Atlantic Ridge high NRM intensities up to 100 A/m were measured in axial tone samples [Irving et al., 1970]. Within the axial zone the intensities were quite variable, robably indicating compositional and grain tize variation of the magnetic minerals in the resh basalts. The intensity fell off rapidly to around 5 A/m on the MAR flanks [Fig. 5(b)]. Ingain two processes are involved with relaxation imes of around 1 M.y. near the ridge axis and 20 M.y. further away. However, again the data defining the second process are not significantly correlated.

The similarity of these results from different data sets is striking. The deep tow data represent the total magnetic signal derived from a uniformly magnetized layer assumed to be 0.5 km thick. The NRM intensity data reflect the properties of a surficial rock collection. Evidently the basalt magnetic behavior is fairly representative of the magnetic source layer, and the causal process of the intensity decay affects the entire thickness of the magnetized layer.

The initial rapid decrease of magnetization intensity has been attributed to low-temperature oxidation of the original titanomagnetite as a result of ocean-floor weathering [Irving et al, 1970; Irving, 1970; Marshall and Cox, 1972]. The oxidation is probably assisted by mild hydrothermal activity in the axial zone, and the initial decay may be enhanced by isothermal relaxation of the original thermoremanence [Irving et al., 1970], a process that could continue further away from the ridge. The data of Fig. 5 are generally not significantly correlated beyond an age of 1 M.y. and do not provide experimental support for the supposition that further decrease actually occurs.

The intensities of DSDP basalts are lower than those of dredged basalts. This is because most of the DSDP basalts were drilled in areas away from ridge crests where sediment cover is already thick enough to permit successful drilling, while most dredged basalts have come from axial zor ... The DSDP basalt remanences and susceptibilities display wide variations, reflecting considerable variation in magnetic mineralogy and grain size. Because of the scatter of inclinations at each site, the effective mean remanent intensity must be substantially smaller than the arithmetic mean [Ryall et al., 1977]. The between-site variations in magnetic properties are larger than the within-site variations, which suggests that there must be correspondingly large horizontal variations in magnetization of the magnetic source layer [Lowrie, 1977].

When the DSDP remanences are averaged for the various ocean basins, a remarkably consistent value of around 4 A/m results, except for the Antarctic and South Atlantic oceans where the intensities are much weaker [Table 2]. This average value is close to the 5 A/m observed by Irving et al. [1970] in basalts dredged from the flanks of the MAR, but is much lower than the corresponding value of 5-15 A/m inferred from deep-tow studies.

# The Thickness of the Magnetic Anomaly Source Layer

In a study of DSDP basalts, from the South Atlantic ocean Lowrie <u>et al</u>. [1973] showed that

Fig. 5. The magnetization of the ocean crust decreases with distance from the spreading axis more rapidly than a simple exponential function. Two separate mechanisms may be involved, corresponding to different magnetization relaxation processes (straight line segments) at different distances from the ridge. (a) Data from deep-towed magnetometer surveys in the Pacific ocean (after Klitgord et al., 1974). (b) Data from dredged basalt samples from the mid-Atlantic ridge (after Irving et al., 1970).

the remanent intensities were too low to account for the amplitudes of oceanic anomalies on a nearby profile with a magnetized layer thickness of 0.5 km, and suggested a thickness of about 2 km, corresponding to the entire thickness of Layer 2.

Harrison [1976] compared the layer magnetizations and thicknesses used by many authors in modelling the source layer and demonstrated their inverse relationship. He normalized the magnetizations to equatorial values which are about 40% lower than the observed magnetizations at latitudes  $20^{\circ}-60^{\circ}$  where most DSDP holes have been drilled. Thus the ridge-flank magnetization deduced from deep-tow studies becomes an equatorial value of about 9 A/m in a 0.5 km thick layer; this is equally satisfied by the observed DSDP basalts magnetization (equatorial value of 3 A/m) in a layer 1.5 km thick.

The depth to the source of magnetic anomalies may be determined from the slope at high wavenumbers of a plot of the natural log of power against wavenumber [Spector and Grant, 1970]. The portion of the power spectrum of an aero-magnetic profile over oceanic crust [Blakely

144 LOWRIE

TO ACCESSION OF A STATE

et al., 1973] which was due to lineated magnetic anomalies was limited to wavenumbers less than 0.3 rad/km by noise at higher wavenumbers. Harrison [1976] derived theoretical power spectra for various spreading rates, source depths and source layer thicknesses, and compared their slopes at wavenumbers 0.1 to 0.3 rad/km with the slope measured between these

numbers in the power spectrum of Blakely <u>et al.</u> [1973]. To satisfy the observed slope Harrison deduced that (a) the reversal rate had to be much less than that measured, or (b) the depth of the magnetic source layer was much greater than the surface of the igneous basement, or (c) the source layer was much thicker than 0.5 km. Harrison rejected the first two possibilities as less likely than the third.

Further support for a thicker source layer comes from the deep holes of Leg 37 [Ryall <u>et</u> <u>al.</u>, 1977]. It was found that: (1) the remanent intensity showed no significant correlation with depth (at the 95% confidence level) throughout the 589 m of basement penetrated in hole 332B, or in the other deep holes, and (2) the measured remanent intensities are too low to account for the magnetic anomaly amplitudes in the vicinity of the Leg 37 holes.

Seismic evidence appears to limit the thickness of the strongly magnetized pillow basalt Layer 2A to about 0.5 km, whereas the available evidence from magnetic anomaly modelling or inversion and from rock magnetic studies indicate that at least part of the anomaly sources are more deeply located within the oceanic crust. A realistic model of ocean crust magnetization may need to include deeper layers consisting of other rock types. At present the magnetic properties of these rocks are known only from ophiolite studies and measurements on dredged samples.

A complete ophiolite suite consists of an ordered rock sequence made up of pelagic sediments, pillow basalt, a sheeted dike complex, gabbro, peridotite and serpentinite. Frequently one or more members may be missing. Ophiolites occur on the continents in many parts of the world. Because of the resemblance of their layered structure and physical properties to those of oceanic crust ophiolites are regarded in light of plate tectonic theory as former oceanic crust that has been emplaced tectonically on the continents [see, for example, Moores and Vine, 1971]. The mode of emplacement is obscure, but may involve obduction of oceanic crust at a consuming plate boundary. Whether the ophiolite suite is typical of oceanic crust formed at an accreting plate boundary or in the marginal basin behind a consuming plate boundary is currently a matter of contention. In principle, paleomagnetic investigation of these accessible rock sequences ought to give a vertical profile of the magnetization of the oceanic crust, which would elucidate in particular the contribution of the deeper layers to oceanic magnetic anomalies.

Unfortunately, it is often found that the members of an ophiolite suite have undergone extensive alteration and metamorphism which have modified their magnetic properties to the extent that in many cases they no longer are representative of original oceanic crust. For example, in the Smartville ophiolite complex the remanent intensities of altered pillow lavas averaged only 0.05 A/m [Levi and Banerjee, 1977] which is two orders of magnitude less than the average values reported in DSDP or dredged basalts [Lowrie, 1974, 1977].

承受了了

Rock magnetic studies have suggested that two processes may be active in altering the ophiolite magnetic properties. These are (a) ocean floor weathering and (b) metamorphism. For example, Butler et al. [1976] described thermomagnetic evidence for maghemitization of the original magnetic mineralogy in unmetamorphosed pillow basalts, with complete conversion to magnetite in metamorphosed pillows. Levi and Banerjee [1977] found a correspondence of remanent magnetic properties with degree of lateration. Sheeted dike samples had reversible thermomagnetic curves with magnetite Curie points, and their remanent intensities were higher than in altered pillow basalts. Provided the high Curie points and remanences are not the result of emplacement metamorphism the sheeted dikes complex may make a strong contribution to oceanic magnetic anomalies [Levi and Banerjee, 1977; Butler et al., 1976]. This conclusion is opposite to that of Kent et al. [1978] who concluded from studies of dredged samples that the sheeted dike complex consists of meta-basalts and probably makes no appreciable contribution to oceanic magnetic anomalies, although this point is not crucial to the model they proposed.

The metamorphism in ophiolites could result from hydrothermal processes near an accreting plate boundary, from burial effects, or from the tectonic emplacement of the ophiolites on to a continent. Evaluation and separation of the effects of these different processes requires detailed petrographic and structural geological evaluation of the ophiclite complex. In a study of ophiolite complexes in southern Chile, de Wit and Stern [1976] distinguished two metamorphic episodes. The second, later episode was a lowgrade effect related to regional deformat in of the rocks surrounding the ophiolites. The first, earlier episode represented ocean-floor metamorphism influenced by hydrothermal circulation near a spreading center and produced a metamorphic overprint that determined the physical properties of the respective layers of the oceanic crust. In particular the model of de Wit and Stern [1976] accounts for the seismic layering of the oceanic crust and correlates magnetic properties with each layer. The sheeted dikes and uppermost gabbros are affected by the hydrothermal circulation, while the pillow basalts are little affected and the deepseated gabbros are unaffected. Kent et al. [1978], using a larger data base of dredged samples, invoked the same relationships in a model of the oceanic crust magnetization in which the contribution of the gabbro layer to

LOWRIE 145

oceanic magnetic anomalies is appreciable.

It is apparent from the above discussion that the degree to which ophiolite suites can be used to determine the vertical stratification of magnetization in the oceanic crust hinges largely on the ability to separate samples on the basis of their degree of alteration and its cause.

### Multi-Layer Models of Magnetic Anomaly Sources

Rock types typical of deeper layers of the oceanic crust have not yet been studied as intensively as pillow basalts. Meta-basalts probably represent the sheeted dikes of Layer 2B. Dredged samples have been found to be only weakly magnetized [Fox and Opdyke, 1973] and it is unlikely that they could make an appreciable contribution to magnetic anomalies. Serpentinites are quite strongly magnetized, but there is some conflict of opinion as to whether they occur as a uniform layer or are dispersed throughout Layer 2 or 3. Possibly they are tectonically emplaced along the fracture zones from which dredged samples have been predominantly recovered.

Recently, two-layer models of the sources of magnetic anomalies have been developed independently by different workers [Blakely, 1976;

146 LOWRIE

1

総理なな考えたの引

Cande and Kent, 1976]. A common feature of the models is that the pillow basalts cool by rapid chilling, while the deeper layer cools more slowly by conduction and passes through the Curie point at some distance from the spreading center. The interface between adjacent magnetized blocks in the deeper layer therefore slopes away from the spreading center.

Blakely [1976] observed that the width of the transition zone between adjacent oppositely magnetized blocks of ocean crust appeared to increase with crustal age. He invoked a two-layer model for the anomaly sources, corresponding to the pillow basalt and sheeted dike layers, as in the model of Butler et al. [1976]. A narrow transition zone in the upper layer and a wider transition zone in the lower layer (due to slower cooling) resulted in sloping interfaces between adjacent blocks. The apparent increase in transition width with age was ascribed to progressive deterioration of the magnetization of the upper layer.

Seismic data indicate that Layer 3 is composed of gabbro, and is much thicker than the basaltic Layer 2. Oceanic gabbros have also been dredged mainly from fracture zones and as a result their magnetic properties may not be typical of in situ material. Kent et al. [1978]

found that the average intensities of magnetization of meta-gabbros and unaltered gabbros were approximately 0.9 A/m and 0.8 A/m, respectively, or about one fifth that of the basalt layer. The Curie point of the gabbros was around 550°C, they were in a higher state of deuteric oxidation than the basalts, and their remanences were stable against demagnetization. Kent et al. [1978] integrated these observations in a new model of the magnetization of the oceanic crust [Fig. 6]. Most of the observed magnetic signal derives from the basalts in Laver 2A; the metabasalts in Layer 2B make negligible contribution; the meta-gabbros in Layer 3A and the unaltered gabbros in Layer 3B participate jointly as a gabbroic source layer.

Cande and Kent [1976] showed that the signal contributed by the deeper gabbroic source layer was shifted in phase relative to the signal from the shallower basaltic layer. This results in an anomalous skewness of the magnetic anomalies after they have been transformed to their paleomagnetic pole. By varying the relative amplitude contributions of the upper and lower source layers they best approximated the observed profile EL33 with a ratio 3 to 1. If the upper layer consists of 0.5 km of pillow basalts with average magnetization 4 A/m, and the lower layer of gabbro with magnetization 0.8 A/m, the optimum modelling of the amplitudes and skewness of the magnetic anomalies on profile EL33 would be achieved with a gabbro layer thickness of about 1 km.

### Discussion and Conclusions

The geomagnetic polarity sequence inferred from oceanic magnetic anomalies is of fundamental importance for determining sea-floor spreading rates and for dating relative plate motions and their tectonic consequences. Yet major parts of the reversal sequences in the Tertiary and in the Mesozoic have not been confirmed independently of the anomalies themselves. It is not even known what polarity state the geomagnetic field was in during formation of the Jurassic smooth zones. Paleomagnetic investigations of continental rock sequences are essential to verify and date more precisely the entire reversal sequence of the last 180 M.y. and to clear up the uncertainties associated with it.

The distribution of magnetization in the magnetic source layer is still somewhat uncertain. For example, slow spreading centers appear to have unusually large magnetic anomalies associated with their axial zones, while fast spreading centers do not. At most spreading centers a rapid decrease of crustal magnetization with distance from the spreading center has been inferred. This intensity reduction appears to take place within about a million years accompanying low temperature oxidation of the magnetic minerals. There is no strong evidence that the oceanic crust magnetization continues to decrease in intensity as has occasionally been claimed and in fact, oceanic basalt intensities are as high in some Cretaceous and Jurassic DSDP holes as in much younger Tertiary holes. The gentle decreases over spreading center flanks [Fig. 5] mostly are not statistically significant. Also, the suggestion that old crust is a less faithful recorder of short polarity events [Blakely, 1976] is not well documented. For example, the Cretaceous anomalies 30 and 31 are separated by a very short negative polarity zone [Fig. 1] lasting about 80,000 yrs [LaBrecque et al., 1977], but this reversed zone was found on all oceanic magnetic profiles to which the Gubbio magnetic stratigraphy was correlated [Lowrie and Alvarez, 1977a, 1977b]. In spite of the large amount that is known, our accumulated knowledge of oceanic crustal magnetization is still fragmentary. Generalizations are both inapt and deceptive.

Scattered inclinations (mostly shallower than expected, but also steeper) and occasional polarity reversals have been found in several deep DSDP holes. Although too few deep holes have yet been drilled to establish how prevalent these characteristics are, they indicate a complex magnetic structure in the basaltic layer. Remanent intensities of oceanic basalts within individual DSDP holes and at a broad geographic distribution of holes vary over several orders of magnitude but average around 4 A/m in several oceanic basins. The effective magnetization is reduced further by the complexity of the basaltic layer magnetizations. Deep-tow studies near to the ocean bottom and modelling experiments on anomalies measured at the ocean surface are able to resolve quite short magnetic rever sals and imply that at least part of the oceanic magnetic signature derives from comparatively shallow sources, most probably from the basalt layer. A growing body of evidence now supports the existence of a second, deeper source layer whose effect is to broaden polarity transition zones, and produce phase shifts in the surface magnetic anomalies. It has not been positively established whether the second source layer corresponds to the sheeted dikes or the deeper gabbroic Layer 3, but rock magnetic studies indicate that the gabbros may contribute to oceanic magnetic anomalies [Kent et al., 1978]. Perhaps the most promising means of quickly and inexpensively advancing our knowledge of the magnetization of the oceanic crust is by rock magnetic studies on ophiolites. These will only be meaningful if accompanied by detailed petrographic study of the effects of ocean-floor and emplacement metamorphism on the members of the ophiolite suite.

### MODELING THE OCEANIC MAGNETIC SOURCE LAYER

Hans Schouten and Charles R. Denham

Woods Hole Oceanographic Institution, Woods Hole, Massachusetts 02543

Abstract. The texture of an extrusive magnetic source laver and the variability of marine magnetic anomalies are studied as a function of two statistical parameters,  $\lambda$  and  $\sigma$ , that describe the temporal and spatial behavior of overlarping extrusive units that accumulated in an active spreading center, and subsequently, were transported outside. We use numerical simulations of an extrusive magnetic source layer and associated magnetic anomalies to combine the variability observed in seafloor spreading anomalies and Deep Sea Drilling Project cores with the FAMOUS observations. A simple two-parameter process of statisitcally controlled temporal  $(\lambda = 5-10 \text{ units/km spreading})$  and spatial (o <2.5 km) emplacement of major extrusive units, adequately models most of the marine magnetic anomaly and in situ observations.

#### Introduction

The uppermost igneous part of the ocean crust is predominantly of extrusive origin. The estimated thickness (500 - 1000 m) and the magnetization intensity of recovered pillow basalts and massive flows are sufficient to account for the amplitude of the observed seafloor spreading anomalies.

The marine magnetic anomalies are caused by lateral magnetization contrasts in this source layer. These contrasts can be: changes in magnetized volume (i.e. layer thickness); changes in magnetization intensity or susceptibility (i.e. magnetic properties) of the material that builds the magnetic source layer; and changes in amplitude and direction of the remanent magnetization induced by the field at the time of the emplacement of the magnetic source layer. The most dramatic changes in direction of the remanent magnetization are, of course, induced by the polaricy reversals of the Earth's paleofield.

Seafloor spreading and the emplacement of the magnetic source layer make the marine magnetic anomalies the most continuous record of the Earth's paleo-magnetic field behavior over the past 200 m.y. (Heirtzler et al., 1968; La Brecque et al., 1977; Larson and Hilde, 1975). Analyses of 0-10 mybp subareal paleomagnetic material indicate an essentially geocentric axial dipolar paleo-field (Wilson et al., 1972) changing polarity 2-3 times per m.y., with a polarity transition period of probably less than 10,000 years (Cox & Dalrymple, 1967; Opdyke et al., 1973).

Interpretations of marine magnetic anomalies generally justify the extrapolation of the "squarewave" paleofield behavior beyond 10 mybp. However, the magnetic source layer does not contain an ideal recording of this simple signal. When converted into time, the marine magnetic anomalies indicate polarity transitions longer than 10,000 years (spatial equivalent); also they demonstrate considerable variability between adjacent measurement profiles and between spreading regimes.

### Prevalent Models

Matinews and Bath (1967) and Harrison (1968) modeled the crustal variability and polarity transitions by a process of dike injection randomly distributed over a zone of finite width, the rift valley. Atwater and Mudie (1973) used a more realistic model of a combination of injected feeder dikes and extruded lava flows.

The inner floor of the rift valley contains the bulk of the most recent volcanic activity (Macdonald, 1977). It is bounded by inwardfacing scarps that mark the transition from a regime of predominant volcanic emplacement to one of tectonic deformation (the scarps will effectively constrict the extent of the lava flows). Hence, it is commonly assumed that the width of the original emplacement zone is less than or equal to the width of the inner valley floor.

In the FAMOUS area, the floor of rift valley #3 averages 11 km in width, or five times the average width of the inner floor in the wellstudied rift valley #2 (Macdonald and Luyendyk, 1977). ^or\_siderable floor width variation in space and time thus can be expected. This allows for a wide range of widths of original emplacement of the magnetic source layer, and, consequently, a variable recording of the simple Earth field reversal signal.

SCHOUTEN 151

Another factor which significantly influences the recording is the episodicity of emplacement. FAMOUS observations indicate that the extrusive volcanism which builds the volcanic layer is not continuous; estimates of the frequency of major volcan'c activity rarge from 100 units/my (Ballard and van Andel, 1977) to 30 units/my (Atwater, 1979).

The Deep Sea Drilling cores in the central North Atlantic (Hall et al., 1975; Hall, 1976) have shown that the volcanic layer consists of ≥5 volcanic units emplaced on top of one another. The paleomagnetism of these cores also indicate a number of separate units. The remanent magnetization inclinations are constant within each unit, but they may differ from one unit to the other. neversals have been found in many of the holes. Although the scatter of the observed inclinations cannot all be attributed to the paleosecular variation, the consistency of inclinations within each unit suggests that the units acquired their remanent magnetization in a relatively short time.

#### Statistical Emplacement Model of the Magnetic Source Layer

At the active spreading center, steady state is only acnieved statistically, since the accretion process is a series of discrete successive events (Francheteau and Tapponnier, 1978). Discrete random emplacement (in time and space) of the magnetic source material implies discontinuous recording of the simple reversal signal. Discontinuous recording adds noise to the recorded signal. The noise will increase with decreasing frequency of emplacement.

The random emplacement of extrusives within the limits given by the width of emplacement zone can be described adequately by a Gaussian probability distribution of distances from the mean spreading axis. This Gaussian distribution gives the probability of where extrusives will be emplaced with respect to the mean spreading axis. The flow width will determine the amount of overlap which occurs. The frequency of emplacement can be described by a Poisson probability distribution of intervals between extrusive emplacement. The distribution gives the probability of when extrusive volcanism will take place with respect to the last volcanic event. Kono (1973) has shown that recent subaerial eruptions follow a simple Poisson model; we will adopt it for the oceanic situation.

The spatial distribution of eruptions will be assumed to be Gaussian, centered on the ridge axis. There is a 95% probability that emplacement occurs within the central four standard deviations ( $\sigma$ ) of the Gaussian distribution. The predominance of youngest extrusives in the center of the inner floor, together with rare evidence for the off-axis volcanism beyond the first inward facing scarps, make a Gaussian

152 SCHOUTEN

distribution a fair approximation of the spatial emplacement probability.

The Poisson probability distribution  $\lambda te^{-\lambda t}$ ( $\lambda$  is the frequency of emplacement averaged over an infinite period of time; t is the time interval between consecutive emplacements) is the most general statistical description of an event which cccurs "every now and then", the length of the next time interval being statistically independent of the preceding interval.

The Gaussian and Poisson distributions are the simplest statistical generalizations of the facts known about the process of emplacement and as such are a first-order approximation to a broad band of possible processes and actual distributions.

### Final Distribution vs. Original Distribution, Figure 1

Figure 1 shows the evolution of an original Gaussian distribution of extrusives emplaced at  $T_0$ , from the time of its emplacement  $T_0$  to the final emplacement distributions at T<sub>2</sub> well outside the active rifting zone. At ., the original distribution has been stretched by the process of dike injection, open fissures, and normal faulting which account for the accual spreading of the volcanic layer in the active zone. The most pronounced stretching (spreading) takes place in the center. Stretching tapers off to the sides, leaving the flanks of the original distribution relatively maffected. The outer flanks progressively move outside the active zone of stretching, while the inner flanks continue to be stretched. The small arrows indicate the position of the center (median) of the original distribution, and their separatior indicates the total amount of spreading since  $T_0$ .

The two final distributions  $\pm T_3$  are bellshaped, for which another Gaussian distribution is an adequate first order approximation (Denham and Schouten, 1979); their widths are approximately equal to the width of the original distribution, they are only slightly skewed, tapering toward the active rifting zone and centered about the arrows which indicate the center (median) of the original distribution. The  $T_0$ - $T_3$  distributions are probability distributions. They indicate the probability (as function of time and distance to the spreading center) of finding extrusives that were emplaced during a finite time interval at time  $T_0$ . The actual distribution of extrusives in the

The actual distribution of extrusives in the source layer depends on the frequency of emplaceent and the size of the individual units. This is illustrated in the lower half of Figure 1. All three realizations conform to the same probability distribution T<sub>3</sub>. They overlap source material emplaced earlier, and they are covered almost completely by later extrusives. The least-frequent emplacement distribution (bottom) displays the highest variability (i.e. deviation from the T<sub>3</sub> probability distribution). The shape

Fig. 1a. Evolution of a Gaussian distribution of extrusives originally emplaced in the active rift at time  $T_0$ , to two final emplacement distributions at  $T_3$  when all the  $T_0$  material has been transported outside the active rifting zone by seafloor spreading. In this example the standard deviation of Gaussian stretching (spreading) active within the rift zone is equal to the standard deviation of the  $T_0$  distribution of extrusives ( $\sigma_s = \sigma_e$ ). The arrows indicate the center of the original  $T_0$  distribution, their spreading since  $T_0$ . The bell shape of the final distributions can be described adequately by another Gaussian distribution.

of the final probability distribution T<sub>3</sub> will vary, depending on the standard deviation of the original emplacement ( $\sigma_e$ ) and the standard deviation of stretching ( $\sigma_s$ ). In Figure 1,  $\sigma_3 = \sigma_s$ .

#### Width of the Final Magnetization Distripution

Atwater and Mudie (1973) explored the effect of the emplacement mechanism on the shape and width of the final magnetization transition in an extrusive source layer (the final magnetization transition is the integral of the final magnetization distribution). In their model, the stretching (spreading) is provided only by the dike injection that feeds the extrusives  $(\sigma_e^2 \sigma_s)$ . They show that the final width of the magnetization transition (read also "final magnetization distribution") generated by this model ranges from roughly half the width of the original emplacement zone for a pure lava flow model (flow width >> zone of injection) to roughly equal the width of the original emplacement zone for a pure dike model. Stretching of the magnetic source layer by normal faults (Macdonald and Luyendyk, 1977) and by open fissures (Ballard and van Andel, 1977) decouples the stretching from the emplacement of extrusives. The assumption of significant tectonic stretching outside the original emplacement zone extends the range of possible emplacement models to  $\sigma_e < \sigma_s$ . Denham and Schouten (1979) show that for  $\sigma_p < \sigma_s$  the standard deviation of the final distribution < 0<sub>s</sub>, roughly equals  $\sigma_s$  (i.e. the width of the final

magnetization distribution roughly equals the width of the stretching (spreading)zone).

If significant tectonic stretching also occurs outside the zone of extrusive emplacement of the magnetic source layer, it will be essentially impossible to detect the width of the median valley, or the width of the original distribution of extrusive activity in the median valley, by analysis of the observed magnetic anomalies. However, the addition of tectonic stretching to the source layer emplacement model can explain wide magnetic anomaly transition zones originating from narrow volcanic emplacement zones; also, it can explain why, contrary to Kidd's (1977a) predictions, relatively few feeder dikes have been encountered in the DSDP extrusive layer drill holes, since in this model normal faults and open fissures partly replace injected feeder dikes as the spreading agent of the extrusive laver.

### Computer Simulation of the Magnetic Source Layer and Anomalies

For sake of simplicity in the numerical modeling, we did not simulate the actual emplacement and stretching process in the active spreading center, but rather we made use of the final emplacement distributions (Denham and Schouten, 1979) that evolve on either side of the zone of spreading from the one distribution originally emplaced at the spreading center. Our computer program was designed to sample the reversa. time scale at Poisson distributed intervals and to emplace a magnetized flow, representing each sampling event, in a two-dimensional source layer array, conforming to a Gaussian probability distribution of distances between the center of the flow and the sampled time event-times-spreading rate position. The final distributions resulting from most processes of emplacement and stretching in the active rift can be approximated adequately by Gaussian distributions. The consecutive individual flows will be widely scattered or emplaced almost on top of one another.

Fig. 1b. Cartoon of the final distribution of extrusives in a source layer of thickness  $\Delta Z$ , for continuous, frequent and less frequent extrusive emplacement in the active rift.

SCHOUTEN 153

Fig. 2. Example of the effect of the statistical emplacement parameters  $\lambda$  (average frequency of emplactment) and  $\sigma$  (standard deviation of the final distribution of magnetic source material) on the magnetic anomalies. Curve A is the anomaly over the ideal reversal block model E, 0-10 mybp. In C the reversal time scale is sampled at an average frequency of 50 units/my (this corresponds to 100 unit/my emplacement activity at the spreading center). At this slow spreading (half spreading rate hsr - 10 mm/yr), the Poisson sampling by itself has very little effect on the magnetic anomalies D. The distance of the anomalies to the source (top 3.5 km bottom 4.0 km) effectively suppresses the short wavelength fluctuations in C. The Gaussian distribution ( $\sigma = 2.5$  km) of the Poisson sampled extrusives increases the scatter in the resulting magnetization distribution E, while the 1.0 km flow width acts as a smoothing function. The magnetization distribution E is a poor reflection of the uncontaminated magnetization distribution B, as is its magnetic anomaly F.

### An Example, Figure 2

area and a de Charles and a lot and

の記録のないを通

A sample of the procedure and of the effect of the two emplacement parameters  $\lambda$  and  $\sigma$  on the magnetic anomalies is shown in Figure 2. The Poisson sampling (left side of Figure 2) in itself has very little effect on the magnetic 154 SCHOUTEN anomalies since the distance to the source effectively suppresses the short wavelengths due to the irregular sampling, while the large number of major polarity reversals are dominant at this slow spreading rate. In contrast, the standard deviation of 2.5 km (right side of Figure 2), scatters the individual flows over 10 km, which Provincial Sector

is wider than the average separation between the major polarity reversals, resulting in a poor recording of the reversal signal.

It is interesting to note that the apparent transition widths in the magnetization distribution E of Figure 2 suggest  $\varepsilon$  much smaller value than the actual 10 km (45) that controlled the simulated process of emplacement. The noise caused by infrequent and widely scattered emplacement inhibits the recognition of the true 10 km wide transition zone.

### Sizulated Slow Spreading Anomalies, Figure 3

In Figure 3 we compare the effect of c = 0.0, 0.5 and 2.5 km on the simulated magnetic anomalies (average half-frequency of emplacement of 50 units/my). The anomalies for  $\sigma$  = 0.0 and 0.5 km are not significantly different from the ideal reversal block model and hence display a low variability. However, the three examples of anomalies for  $\sigma = 2.5$  km (zone of emplacement and tectonic stretching is 10 km) are poorly developed and show considerable variability between themselves. These three sets of magnetic anomalies refer to the same reversal time scale and statistical emplacement parameters  $\lambda$  and  $\sigma$ , while their variability is caused by the random character of the Poisson and Gaussian cistributions. They can be viewed as three observed magnetic anomaly profiles over oceanic crust of the same age in a seafloor spreading regime that is determined by the same statistical parameters: average spreading rate, depth, and volume, average frequency  $\lambda$  and standard deviation  $\sigma$  of final emplacement.

The variability of these simulated anomalies is quite similar to the variability that characterizes a large part of the North Atlantic seafloor spreading magnetic anomalies, first noted by Matthews and Bath (1967). Faster spreading rates and higher frequency of emplacement tend to reduce the anomaly variability; the former reduces the  $\sigma$  (scatter) relative to the width of the polarity intervals, the latter provides a more continuous (i.e. less variable) recording of the polarity reversal signal.

The variability of the magnetic source of these simulated slow spreading anomalies (Figure 3) is shown in Figure 4, confirming the obvious: variable magnetic anomalies have variable sources. In the source section for  $\sigma = 0.5$  km, the material representing each polarity interval appears as one magnetic body overlapping the previous one. Each unit consists of an integer number of one km-wide flows. The considerable variation in source layer thickness has no significant effect on the associated near-perfect magnetic anomalies seen in Figure 3. The variable thickness of the source layer, which is a natural consequence of a random temporal emplacement

Fig. 3. The variability of simulated magnetic anomalies as a function of the standard deviation  $\sigma$  of the final emplacement distribution and the average frequency of emplacement  $\lambda$ . The low sampling frequency of 5J units/my (this corresponds to 100 units/my emplacement activity at the spreading center) combined with the large standard deviation of the scatter of the individual emplacement units, create the variability between the top three sets of magnetic anomalies that were calculated from three computer simulated extrusive source layers using the same statistical parameters. The smaller standard deviation generates near perfect(low variability) magnetic anomalies. The high variability between the  $\sigma$  = 2.5 km anomalies is qualitatively similar to the variability that characterizes a large part of the North Atlantic seafloor spreading magnetic anomalies.

process, also indicates the high probability for tilting of extrusives after their original emplacement. Because younger flows only overlap older ones, there will be predominant tilt toward the younger part of the crust, but many cases of opposite tilt also can be observed as a result of the scatter of the infrequent emplacement process. The variability of the source layer thickness is identical for  $\sigma = 2.5$  km and  $\sigma =$ 0.5 km in Figure 3 (the thickness distribution is the Poisson distribution convolved with the

SCHOUTEN 155

texture of the magnetic source layer

The width. of the individual flows is 1 km, the average thickness of the source layer is 5 times the average flow thickness, 40 indicates the scatter of the individual flows and, consequently, the theoretical transition width. The upper 3 layers illustrate the variable texture of the extrusive source layer and the high probability of finding vertical sections of mixed magnetic polarity. The variable texture also indicates the high probability for tilting of the individual flows after their original (horizontal) emplacement. The variability of the source layer thickness depends on  $\lambda$  and the width of the flows only, which are identical for the upper 4 layer simulations. The vertical exaggeration is 2 for an average extrusive layer thickness of 500 m.

width of the individual flows and is independent of the standard deviation of emplacement). The large  $\sigma$  relative to the 1 km width of the flows has scattered the flows emplaced during the same polarity event and there exists a high probabili<sup>+-</sup> of finding vertical sections of mixed magnetic polarity (Denham and Schouten, 1979).

### Simulated Fast Spreading Anomalies, Figure 5

In Figure 5, we show the effect of spatial emplacement frequency on 50 mm/yr simulated magnetic anomalies. The variability of these

`comalies is primarily caused by the variability
the source layer thickness (the anomalies
are normalized to the maximum amplitude and
clearly illustrate the increasing variability
with decreasing frequency of emplacement).

In order to simulate the less variable seafloor spreading anomalies observed in the faster spreading Pacific, the higher half-frequency of emplacement of 500 units/my is required. This represents a spatial emplacement frequency of 10 units/km spreading, which is roughly equal to the Atlantic observations in FAMOUS.

### Simulations and Observations

This simple emplacement model generates an extrusive source layer having the complex nature which has become apparent from the Deep Sea Drilling Project holes into the North Atlantic basement (Hall, 1976). The variability is a direct consequence of the fact that the emplacement of the source layer is not continuous, but rather it is derived from a discrete number of major extrusive events at irregular time intervals and randomly distributed over an emplacement zone of finitz-width. Intrusive dikes and sills, faults, and off-axis volcanism will further contaminate the detailed nature of the source layer, but the magnetic anomalies will suffer only a small amount, due to the smoothing effect of distarce to the source.

In the FAMOUS area the estimated frequency of the emplacement of major volcanic units is 100 units/my (Ballard & van Andel, 1977). At a total spreading rate of 20 mm/yr, this means an emplacement every 200 m of spreading on the average (5 units/km); for an average cross section of the units of 100,000 m<sup>2</sup>, the average thickness of the extrusive source layer will be

Fig. The variability of magnetic anomalies . () mi a for a "Pacific" spreading rate of 50 r!. 3 a function of the average frequency of emp acament  $\lambda$  and a "Pacific" standard deviation of 0.5 km (Atwater and Mudie, 1973). The  $\lambda$  = 500 units/my simulates magnetic anomalies qualitatively similar to the low variability anomalies observed in most of the fast spreading Pacific. The spatial emplacement frequency is 10 units/km spreading, which is roughly equal to the 5 units/ km estimated for the North Atlantic. The arrows indicate the apparent short wavelength information present in the anomaly 5 simulations which is caused by the variable source layer thickness.

500 m; for an average width of the volcanic units of 1000 m, the extrusive layer will be on average 5 units thick. These general statistics based on observations in the presently active FAMOUS rift zone agree quite well with the results of Deep Sea Drilling in the older central North Atlantic crust (DSDP Leg 52 Staff, 1977) which suggest a 500 - 1000 m thick extrusive layer consisting of 5-10 major volcanic units. Estimates of the magnetic source layer thickness based on observed magnetic anomalies (Talwani et al., 1971; Huestis and Parker, 1977) indicate a similar range.

Our anomaly simulations suggest that the variability of slow and fast spreading anomalies car be explained by a spatial emplacement frequency of 5-10 major extrusive units/km spreading For the slow spreading anomalies, an additional standard deviation of final emplacement of ~ 2.5km is needed which, together . . th the low frequency of emplacement, generates ... variable quality of the Atlantic observed an lies. For the faster spreading anomalies, the polarity transitions are more widely spaced and the standard deviation of the final emplacement (<2.5 km) only modifies the individual transitions. The spatial emplacement frequency of 5-10 units/km spreading generates a variability in between the polarity transitions which is qualitatively similar to the short wavelength "wiggles" observed in the faster spreading anomalies (Blakely, 1974; Cande and LaBrecque, 1974).

### Short Wavelength Information in Fast Spreading Anomalies, Figures 5 and 6

Considerable short wavelength information is present in observed anomalies from widely separated regions of equivalent age (Blakely et al., 1975). Cande and LaBrecque (1974) and Blakely (1974) correlated short wavelength anomalies in the Pacific, which they attribute, respectively, to fluctuations in magnetic intensity and to short polarity reversals of the paleomagnetic field.

In Figure 5, the arrows indicate the apparent short wavelength information present in the anomaly 5 simulations which is caused by the fluctuations in the source layer thickness. The average wavelength of the short wavelength anomalies is 12.5 km for all  $\lambda$ 's. This apparent uniform wavelength can easily be understood. The Poisson emplacement of extrusive units generates a random source layer thickness variation. The spectrum of the magnetization distribution representing a source consisting of magnetic units emplaced at Poisson distributed space intervals is white (i.e. equal for all wavelengths) except for the mean value which represents the average layer thickness-timesmagnetization (Lee, 1967, p. 244). The magnetic anomaly observed at a distance to the source layer is a band-passed representation of the source signal (Schouten, 1971; Schouten and

Fig. 6. Short wavelength anomalies observed in Indian Ocean and Pacific anomalies 5 (from: Cande and LaBrecque, 1974). The arrows indicate a dominant wavelength of 10-15 km, independent of the spreading rate at which the anomalies were formed. This apparent uniform wavelength is similar to the wavelength that dominates magnetic anomalies simulated over a white noise source at anomaly 5 basement depth. The amplitude of these short wavelength anomalies relative to the polarity reversal anomalies can be modeled by an average emplacement frequency of 5-10 units/km seafloor spreading.

McCamy, 1972). Depending on the depth and thickness of the source layer (the parameters which determine the shape of the bandpass), the magnetic anomalies will be dominated by a narrow rand of wavelengths that suffer minimum attenuation. At first glance, this composite of a narrow wavelength band appears to be a onewavelength sinusoidal anomaly which is very correlatable to another sinusoidal anomaly of the same apparent wavelength. (Note: Although

SCHOUTEN 157

wavelengths are the same, the phases are not coherent. Consequently, the apparent correlation will break down when submitted to rigorous cross-correlation.)

The short wavelength anomalies observed in Pacific and Indian Ocean anomalies 5, shown by Cande and LaBrecque (1974) ar ' reproduced in Figure 6, display a dominant wavelength of 10-15 km, including anomaly 5 in the Ci306 profile in the Equatorial Pacific which contains twice the number of peaks and troughs at twice the spreading rate. The uniform wavelength of the observed short wavelength in anomalies  $\pm$  (Figure 6) appears to be independent of spreading rate and is similar to the wavelength which dominates magnetic anomalies simulated at the same distance (3.5 km) to a white noise source (Figure 5).

Although the contribution of magnetic intensity fluctuations or short polarity reversals cannot be ruled out completely, it is highly plausible that most of the short wavelength information present in observed anomalies from widely separated regions of equivalent age is caused by the variable source layer thickness resulting from discontinuous emplacement.

#### Discussion and Conclusion

We are dealing only with qualitative estimates in our comparison of computer simulations and actually observed magnetic anomalies. In our model, the temporal distribution of emplacement of an extrusive source layer is treated in the same statistical manner (i.e. emplacement after Poisson distributed time intervals) as the spatial distribution of emplacement (i.e. Gaussian distributed emplacement and stretching at the accreting boundary). Stretching refers to the actual process of spreading of the b.ittle magnetic source layer in the active rift, and is assumed to be normally distributed about the mean spreading center. Stretching occurs by injection of dikes which feed extrusive magnetic source material, injection of dikes which do not feed extrusive volcanism, normal faulting and open fissuring. The latter three stretching activities can also occur outside the zone of initial volcanic emplacement; in that case, the width of the final distribution of magnetic source material will roughly equal the width of the zone of volcanic and tectonic stretching. Consequently, it will be essentially impossible to detect the width of the zone of initial extrusive emplacement (i.e. inner floor) by analysis of the observed magnetic anomaly transition zones.

In the slow spreading Atlantic, the quality of the marine magnetic anomalies is quite sensitive to both the frequency of extrusive emplacement  $\lambda$ , and the standard deviation of final emplacement  $\sigma$ . In the fast spreading Pacific, the frequency of extrusive emplacement is the parameter to which the quality of the magnetic

### 158 SCHOUTEN

MANDARY,

anomalies are most sensitive. An emplacement rate of 5-10 units/km seafloor spreading, and a standard deviation < 2.5 km is a propriate for both the poor quality of the Atlantic anomalies and the easily recognized Pacific anomalies.

The discontinuous emplacement model simulates an extrusive source layer having the complex nature which has become apparent from the Deep Sea Drilling Project holes into the North Atlantic basement (Hall, 1976). A standard deviation  $\sigma$  = 2.5 km scatters the flows emplaced during the same polarity event and there exists a high probability of finding vertical sections of mixed polarity in the extrusive layer. The variable thickness of the simulated source layer, which is a natural consequence of the random temporal emplacement process (and independent of the standard deviation), also indicates the high probability for tilting of the extrusives after their original emplacement (i.e. finding variable magnetic inclinations in basement holes). The variable thickness of the magnetic source layer causes noise which either drowns the subtleties of the reversal time scale signal or masquerades as relevant short-wavelength information on the paleofield behaviour in fast spreading magnetic anomalies.

The apparent wavelength of the "little wiggles" observed in Pacific anomalies 5, is found to be independent of spreading rate and similar to the wavelength that dominates magnetic anomalies simulated over a white noise source (i.e. a random variable thickness magnetic source layer) placed at anomaly 5 basement depth.

Many other processes may effectively influence the recording in the magnetic source layer of the Earth's reversal signal: for example, heterogeneity of the magnetic source material, dike injection, tectonism, off-axis volcanism, hydrothermal alteration of the magnetic source material. However, our model simulations suggest that unless the spatial frequency of major extrusive emplacement is significantly higher than the estimated 5-10 units/km spreading, most of the magnetic anomaly and <u>in situ</u> observations can be modeled by a simple two-parameter process of statistically controlled temporal and spatial empalcement of major extrusive units.

The total source of the seafloor spreading anomalies includes a second layer of relative low magnetization consisting of sheeted dikes and layered gabbro (Kidd, 1977b). Blakely (1976) presented this two-layer model to explain wide transitions estimated from surface anomalies by progressive weathering of the highly magnetized extrusive layer which would reduce its contribution to the observed anomalies. However, the mixed polarities of the extrusives found in the Deep Sea Drilling holes indicate that also wide scatter of final emplacement occurs and that the extrusive layer remains a likely source for the observed magnetic anomalies. We conclude that the discontinuous nature of extrusive emplacement is the

most likely contributor to the variability of the seafloor spreading anomalies. Intrusive emplacement of the second layer will be of a more continuous nature making a smooth and considerably less variable contribution to the observed anomalies.

SCHOUTEN 159

ON THE LIKELIHOOD OF MIXED POLARITY IN OCEANIC BASEMENT DRILL CORES

Charles R. Denham and Hans Schouten

Woods Hole Oceanographic Institution, Woods Hole, Massachusetts 02543

Abstract. The probability of striking mixed magnetic polarities in a deep oceanic crustal drill hole depends most heavily on the spreading rate, the width of the median valley where lavas accumulate and the width of the active spreading (stretching) zone. The temporal rate of extrusive activity has a relatively small effect. Numerical simulations and statistical estimates show that in slow spreading rate crust, mixed polarity is very likely to occur both near to and far away from the polarity boundaries which are inferred from the seafloor spreading magnetic anomalies.

#### Introduction

The variability of oceanic crustal emplacement is vividly demonstrated by the common occurrence of mixed magnetic polarity in basaltic cores raised by the Deep Sea Drilling Project (eg. Hall, 1976). Although some of the mixed polarity observations may be due to sample misorientation, it is now abundantly clear that genuine magnetic polarity reversals have been recorded within the basaltic column. Since geomagnetic polarity reversals probably require several thousands of years to occur (Cox and Dalrymple, 1967; Opdyke et al., 1973), it is reasonable to infer that the emplacement process itself also requires at least a similar length of time to be completed at a particular site.

Schouten and Denham (1979) modeled the oceanic crustal accretion as the combined realization of several statistical processes, to study the variability of marine magnetic anomalies. Here, we will adopt the same model of overlapping lava flows from episodic volcanic activity to investigate the likelihood that two or more magnetic polarity zones would be observed in a vertical basement drill core. The assessment will be based on the ranges of emplacement parameters which are inferred from the magnetic anomalies and from actual geological observations.

### Statistical Model

We will invoke a Gaussian spatial behavior and a Poisson temporal behavior for the accumulation of overlapping extrusive units of finite width. The half-spreading-rate is the parameter which links the various spatial and temporal aspects of the model, including the magnetic polarity timescale. We will calculate the probability of mixed polarity as a function of age for several reasonable values of the key statistical parameters, and will show that mixed polarity is nearly inevitable over substantial portions of the slowly-spreading Atlantic system, but rare in the faster sp. ading Pacific system. The most important parameter here is the characteristic width of the final lava distribution; the least important is the frequency of extrusive activity.

The final spatial distribution of extrusive material depends upon a combination of three factors: 1) the width of the zone of extrusion, which we characterize by the standard deviation  $\sigma_{\rm e}$  of a Gaussian distribution; 2) the widths of the flows, which we assume are a constant w centered on their vents; and 3) the width of the stretching zone, characterized by Gaussian  $\sigma_s$ , where the actual spreading takes place by dike injection, open fissuring, and normal faulting. The extrusion and stretching zones are centered on the ridge axis, and the majority of both activities occurs in its near vicinity (95% within ± 2 standard deviations). Their combined result is itself roughly Gaussian, so we have characterized it also by a standard deviation, The correct probability density curves are derived and illustrated in Appendix I.

### A. Gaussian Spatial Distribution

In order to simplify the calculations, we assumed at the outset that the final probability density distribution of lavas is Gaussian, with

As illustrated at the top of Figure 1, the probability density function is converted to a probability function by convolving it with a unit-height rectangular waveform of width w, representing the flow width. That is, the probability  $P_o(x)$  at distance x is:

$$P_{0}(x) = \frac{1}{\sigma \sqrt{2\pi}} \int_{x-W/2}^{x+W/2} \exp(u^{2}/2\sigma) du$$
(1)

The geomagnetic polarity timescale (converted to distance) is then superimposed on the new curve, whose median is positioned at the drillsite. The result shows the probability that a single flow of a certain polarity from a particular age would affect the site.

#### Poisson Temporal Distribution Β.

By specifying the rate at which successive lavas issue forth under the Gaussian spatial behavior, we can investigate whether a particular site would be affected by any material from a particular geomagnetic polarity (time) interval. The combination of probabilities from all the polarity intervals then leads to the probability for mixed polarity at that site.

As shown in Appendix II, the only values needed for merging a particular polarity interval with the Poisson distributed (temporal) extrusive activity are the average single-flow probability within the interval, and the number of flows likely to issue forth during the interval. The extrusion rate is characterized by  $\lambda$ , the average number of flows per million years.

If the i-th polarity interval is defined between distances  $x_1$  and  $x_2$ , then the probability of at least one flow from that interval touching the site is:

$$P_{i}(x_{1}, x_{2}) = 1 - e^{-\beta(x_{2} - x_{1})}$$
 (2)

where  $\beta$  is a combination of parameters:

ß

$$= \frac{\lambda}{(\text{hsr})} \frac{1}{x_2 - x_1} \int_{x_1}^{x_2} P_0(x) dx \quad (3)$$

161

4

Fig. 2. Probability of striking a polarity reversal in a deep basement drill core, plotted as a function of age. A  $\sigma$  = 2.5 km situation is depicted in this figure for various emplacement parameters. The dashed line marks 3.5 Myr, which was used in the Figure 1 example.

The function  $P_0(x)$  is given in Equation 1. The ratio  $(\lambda/hsr)$  serves to convert flows per time  $(\lambda)$  to flows per distance via the halfspreading-rate hsr. The resultant  $\beta$  then is used in Equation 2, which is the conventional Poisson probability for at least one success (i.e. relevant lava).

From knowing the probability  $P_N$  of a hit by one or more of the j normal polarity (time) intervals, and also the probability  $P_R$  of a hit by one or more of the k reversed intervals, we can merge them to obtain the probability  $P_{Mixed}$  for at least one of each:

$$P_{N} = 1 - \sum_{i=1}^{J} (1 - P_{N_{i}})$$
(4)

$$P_{R} = 1 - \sum_{i=1}^{k} (1 - P_{R_{i}})$$
 (5)

$$P_{\text{Mixed}} = P_{N}P_{R}$$
 (6)

Probabilities for the Figure 1 example are shown at the lower right. It is clear from Appendix I that no distinction needs to be made between polarity intervals from the old-side and from the young-side of the drillsite. The separation in Figure 1 serves only to show the relative influence of each side for that particular

162 DENHAM

example. The results we will now describe are for full, two-side calculations.

 $\mathbf{x}$ 

#### Results

The probabilities of mixed-polarity for various parameter combinations are shown in Figures 2 and 3 for the past 10 million years of the geomagnetic polarity timescale (LaBrecque et al., 1977). We believe that the Atlantic system is most appropriately modeled in curve 2a, where the zone of emplacement and/or tectonic stretching is some 10 kilometers ide ( $\sigma = 2.5$  km), the halfspreading-rate is 10 mm/yr, and the extrusion half-rate is about 50 flows/my. These values are supported by actual geological observations (Ballard and van Andel, 1977; Macdonald and Luyendyk, 1977). For the Pacific system, curve 3d is the most appropriate, with its narrower accumulation zone, faster spreading, and presumably higher frequency of volcanic activity. The narrower zone of accumulation is deduced from the greater sharpness of magnetic anomaly transitions in the Pacific (Atwater and Mudie, 1973; Blakely, 1974). More frequent volcanism is inferred from submersible observations (R. Ballard, personal communication, 1978) that the Atlantic and Parific extrusive bodies are similar in spacing, implying more frequent acti-ity in the Pacific to account for the faster spreading.

In the Atlantic model, high probabilities for mixed polarity dominate almost everywhere rather than only close to the inferred crustal polarity boundaries. For the past 10 my, noteable exceptions occur over the long Brunhes interval, the middle Matuyama, and the anomaly 5 regior.

The Pacific model is very different, with nearzero probabilities everywhere except close to polarity transitions.

The key features which distinguish the Atlantic and Pacific models are the spatia distribution of lava emplacement, and the spreading rate. The temporal rate of extrusive activity has a secondary importance: it strongly influences the local probabilities for mixed polarity, but it does not extend the region of influence laterally very effectively. This finding should be compared with the conclusion of Schouten and Denham (1979) that the rate of extrusive activity is very important to the quality of the lineated seafloor spreading magnetic anomalies.

#### Appendix I. The Stretching Function

The apparent instantaneous center of seafloor spreading is the position at which spreading is actually occurring. If we consider the average spreading center to be fixed at the ridge axis, and further if we assume that the spreading is symmetrically away from the instantaneous center at the half-spreading rate hsr, then the <u>average</u> velocity  $\overline{V}(x_0)$  of motion of material at distance  $x_0$  away from the ridge axis can be expressed as a function of the <u>spatial</u> probability density  $D_s(x)$  of a combination of dike injection, open fissures, and normal faulting.

$$\overline{V}(x_0) = hsr \int_0^{x_0} D_s(x) \cdot dx \qquad (A.1)$$

The average age of material at distance  $\mathbf{x}_{o}$  is then

$$T(x_0) = \frac{1}{2} \int_{0}^{1} \frac{1}{\overline{v}(x)} dx$$
 (A.2)

If an <u>initial</u> spatial probability density of extrusives  $D_e(x)$  were allowed to spread according to the above plan, then the final probability density  $D_f$  would be given by

$$D_{f}(x) = \frac{1}{dT(x)/dx} \cdot D_{e}(x) \quad (A.3)$$

y algan algan - so - so

Figure A1. Gaussian stretching curves for  $\sigma_s = 1$ in a pure dike emplacement model. The average spreading velocity and the average age of crustal material are shown as functions of distance away from the ridge axis (given in units of  $\sigma_s$ ). The straight portion of the time curve is described by t = x + 6.67. The curves are calculated by text Equations 1 and 2.

The slope of the age curve (i.e. dT(x)/dx) is the stretching function.

The magnetization curve after an arbitrarily long time T<sub>o</sub> is given by plotting  $D_f(x)$  as a function of hsr  $\cdot$  (T(x) + T<sub>o</sub>), where hsr is the half-spreading-rate, assumed constant at great distance from the ridge axis. Since T(x) is essentially linear beyond a few standard deviations, this curve shows the relation between the distance and the density of lavas of a certain age.

Appendix Figure A1 shows the velocity and time (age) curves for Gaussian stretching in which the extrusive standard deviation  $\sigma_g$  and the stretching standard deviation  $\sigma_g$  are equal (unity in the graph). It is readily apparent that the spreading rate is constant beyond about  $2\sigma$ , and that the average age of material at any x is slightly greater than would be expected for volcanic emplacement confined to the exact center of the ridge crest only. The reason is that close to the ridge axis, the material undergoes a biased random walk back-and-forth, making slower progress away from the axis than does material already much farther away. For  $\sigma_s = \sigma_e = 1$ , the relation at large x is

$$T(x) = x + 6.67$$
 (A.4)

Appendix Figure 2A shows the stretching which would be experienced by an initial Gaussian lava pile. The final result is non-Gaussian, with skewness toward the ridge axis for  $\sigma_e \gtrsim 2.2\sigma_s$  and skewness away from the ridge axis for  $\sigma_e > 2.2\sigma_s$ . Integration of those stretched-Gaussian curves yields the magnetization curve for a

Participan de

To quantify the probability of striking polarity reversals in deep crustal drill holes, the linal probability density curve of the lava pile (i.e. the stretched-Gaussian here) is the one which should be convolved with the magnetic polarity timescale (converted to a spatial scale via the spreading rate) represented as a (+1, -1) telegraph wave. For  $c_s = \sigma_e$ , Appendix Figure A3 shows the comparison between the final curve and the original Gaussian, with both curves centered at the peak-value and normalized to unit area. The differences between them are not great. Both of them have about 95% of their area within  $\pm$  20<sub>e</sub> of the median, and the peak of the stretched

curve is only 0.30e away from the median position. We took advantage of this similarity by using a Gaussian approximation of the stretched-Gaussian for constructing text Figures 2-3. When  $\sigma_e = \sigma_s$ , the differences are negligible for our purposes.

### Appendix II. Average Probability

Consider a time-interval which has been givided into N partitions, with probability  $\frac{a}{N}$  that an attempt will occur within any particular one of them. Furthermore, assign probability P<sub>i</sub> for a success within the i-th partition if an attempt were actually to occur at that time. The probability that no success will occur in the i-th partition is then  $(1 - \frac{aF_i}{aF_i})$ . (1) (A.5)

The probability that no successes will occur in any of the partitions is

$$\frac{N}{\Pi} \left(1 - \frac{aP_i}{N}\right)$$
 (A.6)

In the limit as N+∞, this expression is equivalent \*\*

$$\lim_{N \to \infty} \left[ 1 - \frac{1}{N} \sum_{i=1}^{n} \right]$$
(A.7)

Note how only the average P  $(\overline{P})$  is needed here. The probability of at least one success during the whole time interval is the one'. complement of the latter expression i.e.:

$$[1 - e^{ar}]$$
 (A.8)

A MODEL FOR THE STRUCTURAL STATE OF THE UPPER HALF KILOMETER OF NORTH ATLANTIC OCEANIC LAYER 1

### J. M. Hall

Department of Geology, Palhousie University, Halifax, Nova Scotia, Canada B3H 3J5

Abstract. A new model is developed to explain indications of considerable tectonic rotations within the upper half kilometer of oceanic layer 2 in the North Atlantic. The model invokes several processes that are likely to occur in the inner median valley of the Mid Atlantic Ridge. It is suggested that the overall process of structural evolution should be viewed as an integral part, with vulcanicity and geothermal activity, of the process of heat loss from the asthenosphere.

#### Introduction

This short paper summarizes a discussion of structural state of oceanic layer 2 given in a review of the main results of North Atlantic oceanic basement drilling (Hall and Robinson, to appear in Science). At the Second Ewing Symposium it was suggested several times that oceanic layer 2 consisted largely of little rotated (but perhaps extensively faulted) material. It is considered valuable to presen are an alternative view--that large ( $\geq 40^\circ$ ) tectonic rotations are not uncommon. The evidence for the model is given below.

### Evidence

A number of lines of evidence indicate that uppermost ocean crust is likely to be tectonically disrupted:

(1) The location of earthquake epicentres along active spreading centers.

(ii) The folding and faulting of ophiolites.
(iii) Fissuring, faulting and minor rotation of the upper surface of layer 2 as observed from submersibles.

(iv) Deviations of several kinds from dipole paleomagnetic directions in drill cores from layer 2.

1 For young crust (< 20 my) ideal dipole inclinations are calculated from I =  $\tan^{-1}$  (2 tan  $\theta$ ) where  $\theta$  is the Site latitude. For older crust the latitude is with respect to a paleomagnetic pole as determined by study as a continent coupled by a passive margin to the ocean crust in question. (v) Distinct lithological and magnetic differences between drill holes separated by 50 to 450 m.

(vi) The occurrence of tectonized plutonic sequences in contact with pillow sequences in upper layer 2.

No single line of evidence indicates directly the structural state of the upper half kilometer of layer 2. Focal mechanism solutions can only be expected to approximate in a gross way to the de-tails of local strain relief. It is often impossible to distinguish between original-ocean-floor and emplacement structures in ophiolites. Surface observations of layer 2 structures can only provide free surface boundary conditions. Paleonagnetic data can often be interpreted in terms of either geomagnetic or geological history. Lateral changes could be accounted for by the limited lateral extent of submarine volcanic units. Additional difficulties are that core recovery in oceanic basement is usually low, particularly so far as fragile horizons are concerned, and that the common pillow basalt sequences of oceanic basement do not contain conventional tilt indicators such as bedding planes.

Since the argument given here in favour of extensive tectonic disruption depends largely on the paleomagnetic evidence it will be necessary to give this in more detail. Three aspects of the paleomagnetic results are thought to be significant.

1. A number of long vertical intervals of up to 580 m extent are characterized by stable magnetic inclinations that are significantly different from ideal dipole inclinations. Significant here means that divergence between measured and ideal inclinations is greater than the expected range of secular variation. (Holes 332, 333A, 396B, 417D and perhaps in some of the shallow holes in the 407 to 413 sequence).

2. Continuous change of stable magnetic inclination with depth, usually within one lithologicalgeochemical unit, is observed in Holes 395, 410A and 418A.

3. One or more reversals within a vertical sequence occur in Holes 332A, 334, 395, 396B, 407, 410 and 418A.

Fig. 1. Structural consequences of the formation of a new volcanic edifice on the floor of the inner median valley of the Mid Atlantic Ridge.

#### The Structural Model

This structural model is based on the assumption that deviations of stable paleomagnetic inclination from ideal dipole<sup>1</sup> are solely the result of tectonic rotations. If this is true tectonic rotations of at least 40° are quite common. This is an extreme assumption since it does not allow for secular variation. It is suggested, however, that it is a justifiable assumption as the present state of knowledge does not allow any other explanation for the phenomena. Thus, stable magnetization directions are demonstratably rather good indicators of original magnetizing field directions, and, there is no reason to believe that the geomagnetic field is essentially different over the oceans and continents.

The model is best explained by observing the evolution of newly formed crust within the inner median valley of the Mid Atlantic Ridge. Figure 1 illustrates the valley at the time of formation of a new volcanic edifice of the form of Mts. Pluto and Venus of the FAMOUS study area. Note that growth faults are active during the accumulation of the thicker parts of the edifice. This feature is based . . ...e observation that the crust directly in front of thick submarine flows yields by normal faulting (Ballard and Van Andel, 1977). This indicates that the strength of very young oceanic crust is less than the stress exerted by loading it with a single thick flow. If a hinge line occurs between a growth fault and another part of the edifice then continuous rotation of the accumulating flow will occur, with the maximum rotation at the base of the flow. It is suggested that this process can account for the continuous change of stable magnetic inclination within a single unit, as noted above.

The other features of the paleomagnetic results can be explained by reference to Figure 2. Here the edifice of Figure 1 has now been transported to the margin of the inner valley. During trans-

port it has subsided by several hundred meters until it is almost awash in sediment, rubble and the distal ends of younger flows. It is suggested that the subsidence is accompanied by large scale rotation and fracturing into a number of fairly large segments. Rotation could be the result of either or both mechanical instability of the edifice or of lateral change in strength of the underlying valley floor. It is during this slow downlimb convection, consisting of transport and subsidence, which may be viewed as part of the process of heat loss from the asthenosphere, that the pattern of large tectonic tilts and rapid lateral lithological and paleomagnetic variability is acquired. It is suggested that the pattern is essentially frozen-in by this position so that the distal ends of flows from newer edifices, which may now cap the subsided older edifice, will be unrotated. It requires from 1 to 2 x  $10^5$  years at a spreading rate of  $\sim 1 \text{ cm.yr}^{-1}$  for an edifice to be sufficiently subsided to be covered by these younger flows and for at least the Neogene this interval will often contain a reversal of geomagnetic polarity. In this way a cap of a different polarity, with close to ideal dipole stable paleomagnetic inclination, can be expected to be present in some crustal sections.

#### Implications and Weaknesses of the Model

If the model is correct a number of implications follow:

1. That slow spreading, Atlantic type crust consists of a large scale tectonic mélange to a depth of at least half a kilometer.

2. That reliable plate motion estimates are unlikely to be obtained from Atlantic type crustal sections. This follows since most of a section is likely to be considerably tectonically rotated, without the prospect of unique tilt correction,

while unrotated caps where they occur, will contain too little paleomagnetic information to allow secular variation effects to be removed by averaging.

The main weakness of this model is the present difficulty in checking the basic assumption--that deviations from ideal dipole paleomagnetic inclinations are solely the result of tectonic tilting, by an independent means. It will be of great value in furthering our understanding of the structure of oceanic layer 2 if another tilt indicator can be identified. It will also be of value if original (ocean floor) and emplacement structural features of ophiolite sequences can be distinguished.

<u>Acknowledgments</u>. Most of the ideas presented here have developed as the result of discussions

since DSDP Leg 37 (1974) with Paul Robinson. Others who have added to and productively criticized the model are Peter Lonsdale, Matthew Salisbury, Ian Gibson and Clinton Milligan.

Abstract. The correlation between submarine weathering and magnetic properties of ocean floor basalt has been studied on samples from 12 different oceanic sites: 10 sites in the Atlantic, 1 in the Pacific and 1 in the Mediterranean sea. In agreement with earlier studies it has been found that the natural magnetization of ocean floor basalts is carried by small grains of titanomagnetites with average volume content of 1%.

These titanomagnetites are oxidized grandually under suboceanic conditions and form thereby cation deficient spinels, the so-called titanomaghemites. This oxidation proceeds at low temperatures, most likely at bottom water temperature.

The primary composition of oceanic titanomagnetites varies only within narrow limits. From the samples studied in this paper a primary composition of

 $Fe_{1.50}^{2+}Fe_{0.77}^{3+}Fi_{0.58}^{A1}$ .07 $^{Mg}$ 0.06 $^{Mn}$ 0.02 $^{O}$ 4 is deduced. Microprobe analyses of titanomagnetites in combination with Curie temperature measurements indicate that the dominating mechanism of titanomagnetite oxidation under oceanic conditions is ironmigration: Fe migrates out of the spinel lattice and is either incorporated in the surrounding clay minærals, or transported elsewhere by sea water. The process of Femigration is limited by the amount of Fe2+ left is converted to Fe3+. Fe-migration causes the Fe/Ti ratio of titanomagnetite to change during oxidation.

A correlation between the Curie tempe-

rature  $T_C$  and the oxidation parameter z has been determined from the analysis of

**NASSESSESSESSESSESSESSESSE** 

### Fe<sub>2</sub>O<sub>3</sub>/Fe<sub>2</sub>O<sub>3</sub> + FeO

of separated titanomagnetites. This correlation does not agree with the corresponding one derived from the data of Readman and O'Reilly (1972).

The Curie temperature of ocean floor basalts increases with increasing age of the oceanic crust. Although there is considerable scatter in the data, it seems that  $T_c$  increases proportionally with the logarithm of age. The upper 600 m of the predominantly pillow basalts of the Atlantic ocean floor are alterd more or less uniformly with respect to the magnetic minerals. However within single lithological units there is a slight decrease of oxidation rate with depth.

The saturation magnetization of oceanic basalts first decreases with increasing low temperature oxidation until the oxidation parameter reaches z = 0.60. Beyond this z-value, for further increasing oxidation, it increases again. This variation of magnetization can be explained qualitatively by a simple model assuming Fe-migration first from the octahedral spinel lattice sites and then from the tetrahedral sites. The high amplitudes of the mesozoic marine magnetic anomalies could possibly be caused by this process. The jurassic magnetic quiet zone could then be explained by inversion of the completely oxidized titanomagnetites to non-magnetic mineral phases.

The direction of the natural remanent magnetization of ocean fluor basalts is changed by sea floor alteration.

#### Introduction

Studies of cores from the ocean crust recovered by the Deep Sea Drilling Project's ship Glomar Challenger have made it clear that the ocean floor is permeable to seawater. These studies suggest that all the crust down to at least 60Cm depth, the deepest crustal penetration sofar, has have alterd to some deg ee by cold, rather than hot, seawater. Seawater has percolated into the crust over millions of years and slowly reacted with the rocks, producing chemical changes quite different from those ocurring at high temperatures.

This process, generally termed submarine weathering, is characterized by marked increases of the  $K_2O$ ,  $H_2O^+$  and  $H_2O^-$  contents, and the Fe<sub>2</sub>O<sub>3</sub>/FeO ratio, while the MgO, CaO and, to a lesser extent, the  $\leq iO_2$ contents decrease (S. Hart 1969, 1971; Miyashiro et al. 1969;R. Hart 1970, 1973 a, b; Hekinian 1971; Mathews; Shido et al. 1974; Honnore: et al. 1978). The changes with respect to  $Al_{2O_3}$ , MnO, total Fe, TiO<sub>2</sub> and Na<sub>2</sub>O are generally much smaller and quite variable; the various authors present contradictory data for these oxides.

Also the magnetic minerals, predominantly titanomagnetites, are affected by the submarine weathering which consequently influences the magnetic properties of the ocean floor basalts. Various characteristics of the marine magnetic anomalies are ascribed to the process of submarine weathering of the titanomagnetites, in particular the prominence of "he central anomaly and the gradual decrease in amplitude of the anomalies with increasing age on both sides of an active spreading ridge (Irving 1970).

Compared to the studies of the alteration of silicate minerals the effect of submarine weathering of the opaque, magnetic minerals has been somewhat neglected. It is our aim to contribute to the question of how submarine weathering and magnetic properties of ocean floor basalts are correlated.

# Samples

All ocean floor basalt samples studied in this paper can be very broadly termed oceanic tholeiites. They come from 11 different Deep Sea Drilling Project (DSDP) sites and from the FAMOUS area. The locatities are displayed in fig. 1. The majority of the samples comes from the atlantic ocean. The samples from sites 332 A and B, 395 A, 396 B and 417 A are from the deepest DSDP sites drilled so far in the atlantic, with basement penetrations between about 200 and 500 m. The other sites used in this study have much shallower penetrations, apart from the Mediterranean site 373 A (see table 1).

## Experimental methods

Reflected light microscopy: Polished sections were studied under reflected light using a Leitz Ortholux Pol microscope. Volume content of the opaque phases and their mean grain diameter were measured on a Quantimet image analyzing device. Conventional point counting was also done on some samples for comparison. The result: deviate systematically, point counting giving values higher by a factor of 1.5-2.5, depending on the grain size and the number of grains unalyzed per unit area.

To aid the identitication of the magnetic minerals and their variable stages of maghemitization magnetic colloid has also been used.

Some of the samples were treated by ionic etching (Soffel and Petersen 1971) to enhance the optical contrast for the observation of the size and structure of volume change cracks ("shrink cracks") in the titanomagnetite grains. The volume change cracks have also been observed under a scranning electro microscope (Sterecscan, Cambridge Instr.).

### X-ray measurements:

Lattice constants of separated Fe-Ti spinels were determined by the conventional Debye-Scherrer technique. The uncertainty in the determinations is of the order of 0.005 Å.

Microprobe analysis: The instrument used during this study was an ARL - SEMQ electron microprobe equipped with 5 spectrometers, located ac the Department of Physics, University of Lausanne-Dorigny, Switzerland, and also a Geoscan, Cambridge Instruments electron microprobe equipped with 2 spectrometers and located at the School of Physics, University of Newcastle, England.

The titanomagnetite grains selected for the microprobe analyses had to be homogeneous and larger than 10 ucrons in diameter. The latter criterion limited the number of analyzed samples to 23. The 23 samples were prepared as polished sections and coated with a thin carbon layer. Accerleration voltage of the ARL instrument was 15 kV, and of the Geoscan 20 kV. Specimen current was 40nA. These condi.ions gave an analysis spot area of about 1-2 microns. The counting period was chosen as 20 sec. All titanomagnetite grains were analyzed for Fe, Ti, Al, Mg, Mn, Cr and Si. The last element was measured to estimate the contribution of the surrounding silicate matrix to the analysis, and we rejected analyses giving apparently high Si contents, assuming

that titanomagnetite does not contain Si. As reference for the analyses synthetic spinels were used with the following compositions:

A Contract of the second second second second second second second second second second second second second s

 $^{\text{Fe}}$ 2.24 $^{\text{Ti}}$ 0.64 $^{\text{Al}}$ 0.05 $^{\text{Mg}}$ 0.07 $^{\text{Mn}}$ 0.01 $^{\text{V}}$ 0.01 $^{\text{O}}$ 4

Fe2.29<sup>T1</sup>0.64<sup>A1</sup>0.03<sup>Mg</sup>0.04<sup>O</sup>4

<sup>Fe</sup>2.1<sup>Ti</sup>0.64<sup>Al</sup>0.03<sup>Mg</sup>0.04<sup>O</sup>4

The analyses were corrected for dead time, drift, X-ray absorption and X-ray fluorescence. The results are given as weight percent of the elements, instead of the usually given oxides, as oxygen cannot be measured with the microprobes used in this study.

### Chemical analysis:

he FeO/Fe<sub>2</sub>O<sub>2</sub> ratio has been determined for separated titanomagnetites and for the corresponding bulk rocks. For the determination of ferrous iron the rock powder was dissolved in a mixture of hydrofluoric and sulfuric acid. The FeO content was measured by titration with potassium bichromate, the total iron content by atomic absorption. The Fe<sub>2</sub>O<sub>3</sub> content was derived by subtractifing the titrated FeO from total iron. For the separated titanomagnetites the silicon content was also measured by atomic absorption to determine the degree of purity.

Separation of magnetic minerals: The magnetic minerals(predominantly titan magnetic) were separated from a number of samples. The separation vas carried out in two steps: first by a hand magnet from a acetone slurry of finely crushed rock powder, then by centrifuging the material in Clerici's solution. Due to the fine grain size and the skeletal shape of the titanomagnetites the purity of the extracted material was on average only about 50%. The degree of purity has been determined by a chemical measurement of the s licon content of the separate.

# Thermomagnetic curves:

Thermomagnetic curves (temperature dependence of strong field induced magnetization) were measured with a Forrertype automatically recording translation balance, the sample environment being argon. For the Curic temperature measurement

a magnetic field of 1800 Oe was chosen to reduce the influence of pa-

172 PETERSEN

ramagnetism. From the thermomagnetic curves the Curie temperatures were determined by a graphical method following Grommé et al. (1969). The uncertainty in the absolute value of the magnetization is about 3%.

The Néel curve-type of the magnetic spinel phase has been determined by measuring the magnetization of the rock samples in the temperature range between liquid nitrogen temperature and the Curie temperature in a magnetic field of 10.100 Oe. In this case the paramagnetism of the silicates and the super-paramagnetism of very fine titanomagnetite grains has to be taken into account. Their contribution was determined from the linear field dependence of the magnetization, obtained after saturation of the ferrimagnetic mineral phase, and measured at constant temperatures.

Natural remanent magnetization: The natural remanent magnetization (NRM) was measured with a Digico Spinner Magnetometer. The "stable" remanence direction was determined after removing the unstable magnetization components by stepwise alternating field demagnetization.

Opaque minerals contained in ocean floor basalts.

The opaque minerals in ocean floor basalt are p'edominant y <u>titanomagneti-</u> <u>tes</u>. They are initially stoichiometric members of the solid solution series

Fe  $_{3-x} Ti_x O_4$  (0  $\le x \le 1$ ) with magnetite (x=0) and ulvöspinel (x=1) endmembers (fig.2).

As we will discuss further below, the range of compositions of the primary titanomagnetites in ocean floor basalts, prior to any alteration, is very limited, with most of the x-values between 0.58 and 0.65.

The titanomagnetite volume content in ocean floor basalts varies between 0.1 and 5%. A volume content of 1% is typical for the pillow basalts from the Atlantic ocean floor.

Titanomagnetite is the main carrier of remanent magnetization, the contribution of the other opaque minerals can be neglected normally. Figs. 3 and 4 show titanomagnetite grains in oceanic tholeiite, of typical skeletal shape. This is a general feature in ocean floor tholeiites. Titanomagnetite skeletons even occur in thick flows with low cooling rates in the center parts,

with grain sizes upto 1 mm in length. However such large grain sizes are the exception in the Atlantic ocean floor, where pillow basalts predominate. Here the titanomagnetite grain size is usually very small, between submicroscopic (i.e. sub-micron) and a few tens of microns ( $\mu$ m). (The most detailed description of skeletal forms of titanomagnetite in basalts is still the early work of Lindley 1926). The skeletal form indicates either rapid cooling of the liquid basalt of very late crystallization of the titanomagnetites due to low oxygen fugacity.

In the coarser grained basalts two size fractions of titanomagnetite are observed normally, a larger generation up to 150 microns grainsize, usually with skeletal to subhedral forms, and a smaller, down to the limit of visibility. Iron sulfides are also commonly present, but their volume content is normally less than 10% of the titanomognetite phase.

Contracy to extrusive subaerial basalts <u>sulfides</u> can be observed in nearly all ocean floor basalts (grain size between 1 and 100 microns, volume content on average 0.1%). They consist of a primary phase (pyrrhotite) and a secondary phase (pyrite and chalcopyrite). The primary sulfide phase consists of small droplets resulting from the immiscibility of silicate and sulfide melt (fig. 4). The roundish droplets can be considered as indices

of restricted outgassing of submarine basalts (Ade-Hall et al 1976). The main portion of the sulfides consists of pyrrhotite and intergrowths of pyrrhotite with pyrite and subordinate chalcopyrite. Fig. 5 shows the oxidation of initial pyrrhotite to pyrite and magnetite, and simultaneous dissolution into chalcopyrite and pentlandite. In many other cases iron hydroxides give evidence for the or.ginal existence of sulfides. Other opaque phases which are sometimes also present are chromium spinels, ilmenite, hematite and iron-hydroxide, the later two phases only is strongly altered rocks.

Euhedral cubic chromium spinel (grain size between 5 and few hundred microns) is present in many ocean floor basalts as a rare phenocryst (volume content about 0.01%). It seems to be more common in phyric than in aphyric basalt3 (Graham et al. 1978) although there is no significant difference in the overall shromium content between these two types of basalts. Chromium spinels totally surrounded by clinopyroxenes are optically homogeneous. On the other hand crystals surrounded by the groundmass show margins of resorption and corrosion and transition to a more iron rich chromium spinel. Fig. 6 shows an example, but here it is difficult to decide whether the graphical texture is actually caused by corrosion or whether it is a primary phenomenon. When ilmenite is

Fig. 3. Skeletal titanomagnetite grains (white) in ocean floor basalt. Sample: 395A-11-1(56-66).

present as primary mineral, it normally forms separate laths (grain size between 5 and 30 microns, volume content between 0 and 0.5%). But also pseudomorphic growth can be observed. An example is shown in fig. 7 where it is easily distinguished from similarly shaped titanomagnetite by the treatment with magnetic colloid, ilmenite being non-magnetic at room temperature. Another widespread phenomenon are ilmenites mantled by titanomagnetite (fig. 8°. Ilmenite also occurs as a secon-

Ilmenite also occurs as a secondary mineral produced by high temperature oxidation of titanomagnetite, when it forms the tv .cal ilmenite "exsolution" lame \_\_e along the (111) planes of the host titanomagnetite (fig. 9). However compared to subaerial

174 PETERSEN

basal.s secondary ilmenite is a rare phenomenon in ocean floor basalts, restricted to the conter parts of thick flows.

# Oxidation of titanomagnetite

Oxidation is the most important form of alteration of the primary Fe-Ti oxides under natural conditions. According to Verhoogen (1962) the equilibrium oxygen partial pressure of magnetite and ulvöspinel at 298°K is

 $10^{-68.2}$  atm and  $10^{-80.3}$  atm respectively, which means that there exists a strong tendency for oxidation under conditions at the ocean floor. Whether the deep ocean oxidation is caused by dissolved oxygen in seawater or by the dissocia-

tion of water is still a matter of controversy and will not be discussed here.

The way titanomagnetite oxidizes depends critically on the temperature where it takes place. We may distinguish schematically between high temperature and low temperature oxidations. The following gives a simplified picture of these two types of oxidation:

a) high temperature oxidation
 (T > 500 C):
 rutile (or pseudobrookite

ilmenite hematite titanomagnetite

magnetite ----> hematite

if oxidation takes place above 700°C) This form of oxidation is most common in subaerial basalts. It is rare in ocean floor basalts, where it is only observed in the center parts of thick flow units (Ade-Hall et al. 1976). The well known regular intergrowths of ilmenite lamellae in magnetite is typical for this kind of high cemperature deuteric oxidation (see for example fig. 4). The very restricted development of deuteric high temperature oxidation in ocean floor basalts is consistent with a suggestion of Sato and Wright (1966) that hydrogen from dissociated water vapor must first be lost from a flow for deuteric oxidation to be able to proceed. The high confining pressure of the deep ocean environment must considerably reduce gas loss from

PETERSEN 175

a cooling flow and hence inhibit this process to occur. Another fact supporting the restricted outgassing of submarine extrusives is the presence of primary sulfides.

The magnetic consequences of high temperature oxidation of titanomagnetite are the increase of Curie temperature (Curie temperatures between 500 and 550°C are typical after deuteric oxidation), of magnetization intensity and of magnetic stability (Chevalier and Pierre 1932, Petersen 1962 and 1966, O'Reilly and Banerjee 1967, Lewis 1968, Ade-Hall et al. 1968).

176 PETERSEN

This is the dominant form of titanomagnetite alteration in ocean floor basalts where it most likely proceeds at ambient temperatures. The result is the production of increasing cation deficiency in the titanomagnetite spinel lattice with increasing low temperature oxidation. The product becomes more and more unstable as the cation deficiency increases.

The monophasic non-stoichiometric spinel products of this low temperature cxidation are referred to as titanomaghemites and the oxidation process itself as magnetization.

Low temperature oxidation of titanomagnetites has been thoroughly studied on synthetic samples by Readman and O'Reilly (1972). From their experiments it can be seen that Curie temperature increases with oxidation, as also does the magnetic stability; the magnetization intensity and the lattice constant, on the other hand, decrease. Using the results of Readman and O'Reilly and assuming that the influence of impurities like Mg, Al and other cations that normally occur in natural samples, can be neglected,

Fig. 6. Euhedral, cubic chromium spinel with graphical textures. It is difficult to decide whether this texture is caused by corrosion or whether it is a primary crystallization phenomenon. Sample: 395A-18-2(35-37).

it is possible to determine the composition and oxidation state of titanomagnetites from the Curie temperature and the lattice constant measurements.

It is commonly assumed that low temperature oxidation of titanomagnetite does not alter the Fe/Ti-ratio, which means that the oxidation product proceeds along a straight line Fe/Ti= const. (see fig. 2), the so called oxidation line (e.g. Akimoto et al. 1957, Readman and O' Reilly 1972, Petersen 1976, Ade-Hall et al. 1976). If this assumption is true, it should be possible to determine the original titanomagnetite composition prior to any alteration by reducing the sample in the appropriate gas a tosphere. We have carried out such experiments heating a number of ocean floor basalts samples up to 900°C in an oxygen atmosphere of  $10^{-10}$  atm which is close to the equilibrium condition for a titanomagnetite composition of Fe<sub>2.4</sub>Ti<sub>0.6</sub>°<sub>4</sub> (the corresponding Curie temperature 1s  $160^{\circ}$ C).

We will see later that such a composition comes close to the natural original titanomagnetite composition in ocean floor basalts. To our surprise we found that the composition of the thus reduced titanomagnetite samples varied in a systematic way: the higher the original oxidation state of the sample, the higher was the final Ti/Fe ratio. This is reflected in the

Fig. 7. Pseudcmorphic growth of ilmenite (not covered by magnetic colloid) after skeletal titanomagnetite. Also present skeletal titanomagnetite (covered by magnetic colloid). Sample: 395A-14-2(125-134).

Curie temperature of the reduced samples: the samples that were most oxidized yield a lower Curie temperature, far below room temperature. As the Curie temperatures of the titanomagnetite solid solution series  $Fe_{3-x}Ti_x0_4$  de-

crease with increasing x (Pouillard 1950), this made us suspicious that the mechanism of low temperature ocean floor oxidation of titanomagnetite might involve a process of titanium enrichment relative to iron, or a iron depletion relative to titanium.

Also in the literature there is growing evidence that low temperature oxidation of titanomagnetite involves a diffusion of Fe-cations out of the original spinel lattice into the surrounding silicates, which would result in an increase of the Ti/Fe ratio for the remaining titanomagnetite phase (Prévot et al. 1976, Johnson and Melson 1978, Marshall and Cox 1972). Before we pursue this question, the microscopic characteristics of low temperature oxidation are treated in the following section.

> Ore microscopy of altered titanomagnetites in ocean floor basalts

The first indication of low temperature oxidation of titanomagnetites under the microscope is a slight change in colour, a transition from the original redish brown to a more greyish colour, eventually becoming bright grey-

10 C M

Fig. 8. Ilmenite grains (darker grey) mantled by titanomagnetite (light grey). The grain in the lower left corner may possibly represent a sandwich texture and not be primary ilmenite. Sample: 395A-14-2(125-134).

ish. The grain shown in fig. 10 a and b gives an example of this transition. When covered with magnetic colloid it becomes evident that the oxidized zones have a lower magnetization intensity than the unoxidized zones and therefore attract less of the colloid. However, the main characteristic of low temperature oxidized titanomagnetites in ccean floor basalts is the formation of irregular, curved cracks, also visible in the grain of fig. 10. These cracks have already been observed in mildly metamorphosed continental basalts (Katsura and Kushiro 1961).

Larson and Strangway (1969) were the first to interpret them as due to the volume change associated with the process of magnetization. In ocean floor basalts they were first described by Cockerham and Ade-Hall (1976).

The basic process underlying this cracking is the reduction of lattice constant with increasing oxidation (see fig. 26). If we assume that the kinetics of low temperature oxidation of t:tanomagnetites is the same as the oxidation of magnetite to maghemite it can be explained in the following way. Feitknecht and Gallagher (1970) investigating the mechanism of the oxidation of magnetite assume a diffusion of

Fe out of the crystal to the surface of the magnetite grain where it combines

with oxygen to be oxidized to Fe<sup>3+</sup>, thus forming lattice vacancies, but leaving the internal oxygen structure unchanged.

ange

.qi

0-

Fig. 9. High temperature oxidation of euhedral titanomagnetite with ilmenite "exsolution" lamellae also along the margins of the grain. Sample: 395A-63-1(0-10).

For each Fe<sup>2+</sup> ion diffusing out the magnetite lattice, two more are converted to Fe<sup>3+</sup> to maintain constant total cationic charge within the structure. Feitknecht and Gallagher further maintain that during oxidation a high concentration gradient of cation holes would develop in the monocrystalline particles, leading to a gradient in the lattice constant, thus developing strain, whereby the effect on large particles must be greater than on small particles.

We observe the cracks mainly in larger titanomagnetite grains which have already undergone some degree of low temperature oxidation and interpret them consequently as due to shrinkage of the lattice constant. They are called "shrink cracks" in the follo-180 PETERSEN wing parts of this paper.

There is a correlation between the amount of shrink cracks and Curie temperature as can be seen clearly in fig. 11 a, b, c. The expanding cracks of the grain of fig. 11 c produce a sponge-like structure. Grains of this advanced low temperature oxidation state are often surrounded by a hal  $\circ$  of red stained silicates which is most likely caused by Fe<sup>3+</sup> that migrated out of the titanomagnetite crystal. This question will be discussed below in detail.

Most interesting is the titanomagnetite grain shown in fig. 12 where the shrink cracks are filled wich secondary pyrite. This provides evidence that the cracks are open to solution and very likely also to sea water.

# Primary composition of titanomagnetites

As outlined abore, the major magnetic mineral in almost all submarine basalts recovered to date is a member of the titanomagnetite solid solution series that has commonly undergone variors stages of posteruptive low temperature alteration. Only relatively seldom has it retained its original unoxidized composition.

Two variables, x and z, are needed in order to define the composition of this type of magnetic mineral (fig. 2). Upon initial eruption, the mineral that is originally formed is a stoichiometric member of the solid solution series between magnetite and ulvöspinel, which is defined by "x" in the formula  $Fe_{3-x}Ti_x 4$ . Normally the natural titanomagnetites contain a minor amount of metal ions other than Fe and Ti, mainly Mg and Al. The second variable "z" must be determined in order to characterize the degree of oxidation of titanomagnetite to titanomagnemite. The degree of oxidation, the so-called oxidation parameter "z" ( $0 \le z \le 1$ ) is defined as the fraction of the initial  $Fe^{2+}$ ions converted to Fe<sup>-</sup> ions (Readman and 0' Reilly 1971).

For all considerations of alteration of titanomagnetites it is essential to know the original composition prior to any alteration. The first step in the present consideration shall be therefore the evaluation of the "x"value. To date there does not exist a large number of analyses of titanomagnetites contained in ocean floor basalts. Johnson and Hall (1978) give an average value of  $x = 0.65 \pm 0.2$ . This value agrees very closely with the value of x = 0.64 obtained from continental tholeiite basalts by Petersen (1976).

so-

a٠

i٠

2

2

Table 2 gives a compilation of the primary composition of titanomagnetites in tholeiite basalts, both continental and oceanic, as found in the literature. In this table the x-values have been obtained assuming that low temperature oxidation of titanomagnetites does not change the cation-ratio. The only exception are the data of Johnson and Melson (1978) who argued that progressive low temperature oxidation causes a reduction in the iron content and consequently a decrease in the Fe/Tiratio. In this case the simple averaging technique of both unoxidized and oxidized samples would lead to x-values that are too high.

Prevot (1968), analyzing a partially maghemized titanomagnetite grain in basalt, was the first to suggest that the process of low temperature oxidation involved a change in the Fe/Ti · ratio.

For our consideration of the chemical composition of titanomagnetite we use the respective Curie temperature as reference value, as it is a convenient indicator of the degree of progressive low temperature oxidation, increasing Curie temperature indicating increasing oxidation. The results of our microprobe analyses are shown in table 3 and figs. 14, 15, 16 and 17.

Apart from Fe and Ti the analyzed titanomagnetites contain Al, Mg and Mn. The amount of other cations is much lower compared to these and hence they are not represented in this compilation. We have taken care not to include samples with signs of deuteric high temperature oxidation (visible under the microscope as ilmenite exsolution).

We observe a distinct decrease of the Fe-content and also of the Fe/Tiratio with increasing low temperature oxidation. Obsiously the spinel lattice becomes iron depleted with respect to the other cations. We interpret this phenomenon as Fe-migration out of the original titanomagnetite lattice, probably into the surrounding silicates. This agrees with the frequent microscopic observation of red staining of the silicates in the vicinity of oxidized titanomagnetite grains (Ade-Hall et al. 1976).

The process of Fe-migration is also well documented in the single titanomagnetite grain of fig. 18 and table 4 that is only partially maghemized. We observe the distinct iron depletion in the oxidized part of the grain (also characterized by lower magnetization compared to the unoxidized part as documented by the attraction of magnetic colloid) whereas titanium remains more or less constant. There may even be some slight increase in titanium, but this may be only an apparent increase due to the decrease of the lattice parameter associated with machemitization (see also fig. 26). Although titanium is rather mobile at

X Z CONTRACT

Fig. 10 a. Titanomagnetite grain with different stages of maghemitization. The central parts of unoxidized titanomagnetite (grey) grade into titanomaghemite (light grey) that forms along the grain margins and also along irregularly formed cracks, so-called "volume change cracks" or "shrink cracks".

higher temperatures (Petersen 1970), we did not observe any indication of Ti-migration at low temperature oxidation in ocean floor basalts.

The same trend as for iron is visil's for Mg, although not so clear (fig. 16). There is further indication that Ti and Al are replacing each other. We also observe a slight increase of the cation sum Ti+Al+Mg+Mn with oxidation. Very conspicuous is the increase of Mn in the strongly oxidized samples (fig. 17), a result that has also been observed by Prévot (1968).

From these results it is evident that the primary titanomagnetite composition cannot be deduced by simply averaging the Fe/Ti-ratios of the different samples. 182 PETERSEN The primary composition has been determined by taking into account the observed trends and making a best fic of all the data to produce a stoichiometric spinel. The composition thus derived is indicated in figs. 14 and 15 and also give: in table 2 and 5. Taking into account the oxidation trend it is remarkable how small the scatter of data is although the samples come from very different localities. Fi

For comparison the synthetic equivalent of the above inferred primary titanomagnetite was then produced. The appropriate amounts of  $Fe_2O_3$ ,  $TiO_2$ , MgO,  $Al_2O_3$  and MnO have been sintered for 10 h at 1300<sup>O</sup>C in an appropriate gas mixture of H<sub>2</sub> and CO<sub>2</sub> corresponding to an oxygen fugacity of  $fo_2$ =

Fig. 10 b. The same grain as in fig. 10 a covered by magnetic colloid. The maghemized parts have lower magnetization and attract less magnetic colloid therefore. Sample: 395A-32-1(140-150).

10<sup>-8</sup> atm. After the first sintering process, the material was reground, pressed and then reheated under the same conditions. In this way two samples were prepared independently from each other which had in the end identical properties. Curie temperature, saturation magnetization at room temperature and lattice parameter were then determined. These values are listed in table 5. The actually measured Curie temperature of 125°C falls well into the range of Curie temperaturcs which we would expect (Richards et al. 1973) from the chemical analyses (see figs. 14 and 15).

Mechanism of low temperature oxidation

From the chemical trends described in the foregoing chapter we deduce the following model of low temperature oxilation of titanomagnetites in ocean floor basalts: The process of oxidation starts from an original titanomagne ite composition close to

 $^{\text{Fe}}2.27^{\text{Ti}}0.58^{\text{Al}}0.07^{\text{Mg}}0.06^{\text{Mn}}0.02^{\text{O}}4$ 

The basic process underlying the oxidation is the migration of Fe-ions, out of the spinel lattice of the titanomagnetite, thus producing cationvacancies. In this model the oxygen lattice of titanomagnetite remains untouched by the process of oxidation. It is interesting to note that Hoernes

and Friedrichsen (1977) from measurements of the oxygen isotope ratios of altered titanomagnetites from DSDP-Leg 37 come independently to the same conclusion.

To maintain the charge balance in the spinel crystal the process requires the transformation of the appropriate number of  $Fe^{2+}$  into  $Fe^{3+}$ . The process of Fe-migration comes to an end when

all the available Fe<sup>2+</sup> has been exhausted by this transformation.

This model of iron-emigration can be characterized by Τ

| $\operatorname{Fe}^{2+} \rightarrow (1-z) \operatorname{Fe}^{2+} + \frac{2z}{3} \operatorname{Fe}^{3+} + \frac{z}{3} \square +$ | $\frac{2z}{3}e^{-}+\frac{z}{3}Fe^{2+}$ |
|---------------------------------------------------------------------------------------------------------------------------------|----------------------------------------|
| or                                                                                                                              | ^                                      |
| $\operatorname{Fe}^{2+} \rightarrow (1-z) \operatorname{Fe}^{2+} + \frac{2z}{3} \operatorname{Fe}^{3+} + \frac{z}{3} \square +$ | $ze^{+\frac{7}{3}Fe^{3+1}}$            |

where z is the oxidation parameter defined by O'Reilly and Banerjee(1966)

as the fraction of the initial Fe<sup>2+</sup> content converted to Fe<sup>3+</sup>. To make this definition of z applicable also to the first of the above two equations we treat the migrating Fe<sup>2+</sup> formally like a converted Fe<sup>2+</sup>ion.

The final composition of the cation deficient spinel is independent of

whether iron migrates as  $Fe^{2+}$  or  $Fe^{3+}$ . On the other hand we have no means of deciding between these two types of Femigration. But judging from the ionic radius (Fe<sup>2+</sup> = 0.81 Å, Fe<sup>3+</sup> = 0.67 Å,

 $Ti^{4+} = 0.69$  Å) a higher mobility of Fe<sup>3+</sup>

and consequently  $Fe^{3+}$  rather than  $Fe^{2+}$ -migration seems to us the more likely mechanism. This model of titanomagnetite low temperature oxidation due to iron migration is different from the commonly accepted concept of constant Fe/Ti-ratio during the process of oxidation (e.g. Akimoto et al. 1957, Sakamoto et al. 1968, Ozima and Larson

1970, Ozima and Sakamoto 1971, Readman and O'Reilly 1971 and 1972, Bleil and

Petersen 1976, Ade-Hall et al. 1976, O'Donovan and O'Reilly 1977).

In the following discussion we will call the two models as "Fe-migration model" and "Readman - O'Reilly model" respectively.

T > Readman-O'Reilly model, which pertails to experiments with artificial materials, assumes that Fe<sup>2+</sup>-ions diffuse out of the original oxide lattice and are combined with external oxygen at the crystal surface forming the same spinel lattice as the inside material. The other cations are thereby rearranged resulting in no net change in the Fe/Ti ratio.

The Readman-O'Reilly model can be characterized by

$$\operatorname{Fe}^{2+} + \frac{z}{2} \circ \longrightarrow (1-z) \operatorname{Fe}^{2+} + z \operatorname{Fe}^{3+} + \frac{z}{2} \circ^{2-} + \frac{3z}{8} \square$$

where z is the oxidation parameter again.

In the ternary system FeO-Fe<sub>2</sub>O<sub>3</sub>-TiO<sub>2</sub> (fig.2) the Readman-O'Reilly model can be represented by lines of Fe/Ti = const, the Fe-migration model by lines of Ti/O = const.

> Correlation between Curie temperature and oxidation parameter z

The oxidation parameter z of titanomagnetites in ocean floor basalts is usually determined by Curie temperature and/or lattice parameter measurements using the Readman and O'Reilly (1972) contour lines in the ternary system FeO-Fe<sub>2</sub>O<sub>3</sub>-TiO<sub>2</sub>, cbtained from synthetic cation deficient titanomagnetites (e.g. Ade-Hall et al. 1976, Bleil and Petersen 1976, Grommé and Mankinen 1976). To avoid this indirect method of z-determination we extracted the titanomagnetites from po.'dered ror's samples and measured directly the oxidation ratio Fe203/(Fe203+Fe0) of the extracted material by chemical analysis.

As the grain size of tits omagnetites in most of the samples is very fine (between 1 and 20 microns) an

Fig. 11. Different titanomagnetite grains with increasing amount of "shrink cracks". Such shrink cracks are characteristic for low temperature oxidized titanomagnetites. A correlation exists between the amount of shrink cracks and Curie temperature T<sub>c</sub>.

- a. Large titanomagnetite grain with curvelined and ramifying shrink cracks. Also visible in this grain are two single ilmenite lamellae, product of a high temperature oxidation.  $T_c = 240^{\circ}C$ . Sample: 417D-69-2(35-37). Euhedral titanomagnetite with typical shrink cracks,  $T_c = 250^{\circ}C$ .
- Sample: 417D-68-5(89-92).
- The expanding cracks produce a sponge-like structure in the highly oxidized c. titanomagnetite grain.  $T_C = 320$  °C. Sample: 417D-68-3(64-66).

PETERSEN 185

appreciable amount of silicate impurity was associated with the extracted material, even after centrifuging in Clerici's solution. The Fe<sup>2+</sup>/Fe<sup>3+</sup> ratio of the silicate impurities is normally higher than that of the pure titanomagnetite grains. As the degree of impurity of most of our extracted material is as high 50% we had to correct the measured oxidation ratio of the extracted material for the silicate impurities. For such a correction it is necessary to know the total iron content of the wnole rock and of the extracted material, the microscopically determined titanomagnetite content in the extracted titanomagnetites (determined from a chemical Si analysis). The thus corrected  $Fe_2O_3/(Fe_2O_3+FeO)$ values together with the uncorrected

186 PETERSEN

values are given in table 6 and fig. 19, where they are plotted against the Curie temperature. For comparison we have also included in fig. 19 the data of Ozima et al (1974) which show considerable scatter, but fall into the same range. Our corrected Fe<sub>2</sub>O<sub>3</sub>/(Fe<sub>2</sub>O<sub>3</sub>+ FeO) values fit well a smooth curve.

Knowing the initial Fe<sub>2</sub>O<sub>3</sub>/(Fe<sub>2</sub>O<sub>3</sub>+ FeO) ratio of 0.36 (corresponding to z=0) from the above determined primary titanomagnetite composition, and taking into account the process of Femigration we can then convert the Fe<sub>2</sub>O<sub>3</sub>/(Fe<sub>2</sub>O<sub>3</sub>+FeO) ratios into z-values.

We thus obtain the Curie temperature versus z curve shown in fig. 20. It can be seen from this figure that none of the investigated samples has reached complete oxidation.

Fig. 14. Microprobe analyses of titanomagnetites contained in ocean floor tholeiites plotted against Curie temperature  $T_C$ . The Curie temperature indicates the degree of low temperature oxidation of the titanomagnetites: As higher  $T_C$ , as higher the oxidation state. Samples with indication of high temperature titanomagnetite oxidation are excluded. A distinct iron depletion with increasing oxidation is observed. Also indicated in this diagram is the composition and Curie temperature of a synthetic spinel with a composition equivalent to the primary titanomagnetite composition as deduced from the microprobe analyses.

Fig. 15. Microprobe analyses of titanomagnetites contained in ocean floor tholeiites. A distinct variation of the cation ratio with low temperature oxidation is observed. As in fig. 14 also the synthetic equivalent of the primary titanomagnetite composition is indicated. The lower dashed line represents the minimum value of the Fe/(Ti + Al + Mg + Mn) ratio to be expected according to the model of Fe-migration (see text) when complete oxidation is reached.

Fig. 16. Microprobe analyses of titanomagnetites contained in ocean floor tholeiites. Magnesium shows a similar trend of depletion as iron.

We will use this curve in the following section for other samples to determine the oxidation parameter z from Curie temperature measurements.

Finally, a comparison is attempted between the thus determined Curie temperature versus z curve of fig. 20 and the corresponding data of Readman and O'Reilly (1972) obtained from synthetic samples:

First we take account of the impurities in our natural samples by selecting the equivalent pure titanomagnetite composition having the same Curie temperature of  $125^{\circ}C$  as our natural primary spinel composition. The equivalent pure titanomagnetite composition is x=0.63.

We have seen from the microprobe analyses that our investigated samples when transferred into the ternary system FeO-Fe<sub>2</sub>O<sub>3</sub>-TiO<sub>2</sub> follow a line Ti/O = const (Fe-emigration). We therefore compare our T<sub>c</sub> versus z curve with the Curie temperature and z-values taken from Readman and O'Reilly's (1972)

Fig. 17. Microprobe analyses of titanomagnetites contained in ocean floor tholeiites. There exists a conspicuous increase of manganese content in the strongly oxidized samples.

fig. 7 b correspondingly along the line Ti/O=const, starting from an original composition x=0.63. This comparison makes visible a distinct discrepancy between the two curves, which is much greater than the uncertainty of our measurements and calculations. On the other hand we find remarkable agreement when we compare Readman and O'Reilly's Curie temperature and z-values taken along the line Fe/Ti=const. instead. This result, also shown in fig. 20, is contrary to what we would expect.

93.8

Rel.Total

From this comparison we can draw the conclusion that either we have misinterpreted our microprobe data, the Fe/Ti ratios actually being constant, or that Readman and O'Reilly have misinterpreted their data, or that natural and synthetic samples cannot be compared in this way.

We think that the microprobe data give overwhelming evidence for the ironmigration model and against a process that proceeds along Fe/Ti=const, at least so far as the present samples are concerned. It seems to us to be more likely that in Readman and O'Reilly's synthetic samples Femigration had actually occured as oxidation mechanism. If this is the case, their samples cannot have been single phase oxidation products, the migrated iron must have formed a second mineral, most likely thin films of Fe<sub>2</sub>O<sub>3</sub>. As the amount of emigrating Fe is relatively small (a maximum of about 10 wt% for x-values around 0.60)

192 PETERSEN

it can easily be overlooked in x-ray diffraction data. However, at this time this is merely a suggestion and has not been substantiated by any direct measurements.

95.6

Variation of Curie temperature with age

Given a certain grain size of the titanomagnetitos in submarine basalt, the process of maghemitization increases with increasing age of the rock. Ozima et al. (1974) assumed a first order rate process of the following form

$$z = 1 - e^{-t/t}$$

where z denotes the oxidation parameter, t the age of the rock and  $\pi$ the time constant of the process. From their data they derive a time constant of  $\tau = 5 \times 10^7 y$ .

The actual maghemitization process in ocean floor basalts must be very complicated depending on various factors such as grain size, chemical composition, depth below basement, temperature etc. Hence the actual maghemitization is probably much more complicated than that described in the above expression of Ozima et al. (1974).

If we plot the Curie temperature  $(T_C)$  as a measure of maghemitization against age for a number of Atlantic sites, we observe actually an increase with age for the mean values of T<sub>c</sub>

(fig. 21). However, the scatter of individual Curie temperatures within a site is considerable. The most important factor causing this scatter seems to be the grain size. Inspite of a large scatter in the data fig. 22 shows clearly that there is an inverse relationship between grain size and Curie temperature. Nevertheless it seems that such factors average out if the number of samples for a certain site is large enough. However our data cannot be fitted to the above relationship of Ozima et al. (1974).

In fig. 23 arc plotted the mean values of Curic temperature against the logarithm of age. The maximum Curie temperature that can be obtained by maghemitization prior to any inversion of the cation deficient spinel phase is probably close to 400°C. This can be taken from fig. 15, where the theoretically possible minimum value of Fe/Ti is reached at  $T_c = 400^{\circ}C$ . Therefore the age -  $T_c$  relationship of fig. 23 leads to the suggestion that ocean floor basalt of jurassic age is liable to the inversion of the magnetic spinel phase into non magnetic or only weakly magnetic phases like iron hydroxide or hematite. The socalled jurassic quiet zone could therefore be the result of this mineral instability.

Variation of maghemitization with depth below basement

Direct evidence about the depth variation of maghemitization exists only from the few holes with deeper penetrations of the oceanic crust. The depth limit to date is about 600 m. Judging from the few data we have available, it seems that the whole portion of the upper 600 m basalt has been maghemitized more or less uniformly, at least so far as the pillow basalts are concerned which obiously predominate in the upper 600 m of the atlantic ocean crust. Fig. 24 shows the downhole Curie temperature variation in the Atlantic DSDP hole 396B.

No overall decrease of the Curie temperature is observed here. However, within individual lithological units there seems to be a tendency of slight decrease of  $T_c$ . For lithologic unit 1 of site 396B we determine a Curie temperature decrease of

# 0.57 <sup>9</sup>m

Similar Curie temperature gradients have been determined by Bleil (1976) from the sites 332 A and B of DSDP Leg 37.

# Variation of magnetization intensity

Irving (1970) and Irving et al. (1970) were the first to study different magnetic and mineralogical properties of ocean floor basalt samples taken along a profile across the Midatlantic Ridge at 45°N, extending about 150 km away from the ridge axis. They found a drastic decrease of the NRM intensity with increasing distance from the ridge axis and correlated this with the similarly increasing whole rock oxidation ratio. The explanation for this correlation is given by experimental results obtained from synthetic titanomagnetites (Sakamoto et al. 1968, Ozima and Larson 1970, Readman and O'Reilly 1972) that clearly demonstrate a decrease of magnetization intensity with increasing low temperature oxidation. The decrease of magnetization intensity, both NRM and saturation magnetization, with increasing low temperature oxidation, has consequently been used for an explanation for the general decrease of the amplitudes of marine magnetic anomalies away from a ridge axis.

ti

101.11

We too have tested for this relationship in our samples, excluding those samples which indicate that high temperature deuteric oxidation took place.

For this purpose the titanomagnetite content was determined microscopically using a Quantimet image analyzing device. The magnetization intensity was then referred to the magnetic mineral. In fig. 25 the specific saturation magnetization of the magnetic mineral at room temperature is plotted against Curie temperature. From this diagram we find actually a decrease of magnetization with increasing oxidation, but only up to a z-value of about z = 0.6(corresponding to a Curie temperature

k - Fe<sub>2</sub>O<sub>3</sub>/FeO+Fe<sub>2</sub>O<sub>3</sub> Corrected for the Impurity of the Separated Titanomagnetites

z - Oxidation Parameter Derived from the Corrected Fe203/Fe0+Fe203

+) Curie Temperature of Separated Titanomagnetites

X) Curie Temperature of Whole Rock

of 250°C). For higher z-values the magnetization increases again. Part of the scatter in fig. 25 is probably due to errors in the optical determination of the magnetic mineral content. It is interesting to note that the lattice parameters  $a_0$  of the titanomagnetites when plotted against the Curie temperature  $T_c$  (see fig. 26 and table 7) also

display an anomaly at  $T_c = 250^{\circ}C$ . If the observed trend of magnetization increase for z-values higher than 0.6 is a general feature of the oceanic crust, we may speculate if this would cause the high amplitudes of the mesozoic M-anomalies. Two explanations seem possible

Fig. 19. Curie temperature  $T_C$  versus oxidation ratio  $Fe_2O_3/Fe_2O_3$  + FeO of extracted titanomagnetites. The dashed curve gives the uncorrected oxidation ratios where the influence of silicate impurities adhering to the titanomagnetite grains is not eliminated. The solid line is the curve for the corrected  $Fe_2O_3/Fe_2O_3$  + FeO values. Also included are the data of Jzima et al. (1974) which show considerable scatter, but fall into the same range. They are not corrected for silicate impurities.

450 Fe/Ti = const. Fe 400 Readman and O'Reilly 1972 Ti/O = const. 350 300 250 200 150 100 0.1 0.2 0.3 0.4 0.5 0.6 0.7 0.8 0.9 1.0 oxidation parameter Z Fig. 20. Curie temperature  $T_C$  versus oxidation parameter z. The shaded curve has been derived from the solid curve of fig. 19 by conversion of the  $Fe_2O_3/Fe_2O_3$  + FeO values

Fig. 20. Curle temperature  $T_c$  versus oxidation parameter z. The shaded curve has been derived from the solid curve of fig. 19 by conversion of the Fe<sub>2</sub>O<sub>3</sub>/Fe<sub>2</sub>O<sub>3</sub> + FeO values of the e tracted titanomagnetites into z-values (see text). This curve represents an oxidation mechanism due to Fe-migration which is equivalent to a process whereby Ti/O is kept constant. Also shown in this diagram are two curves with  $T_c$  and z-values taken from Readman and O'Reilly's (1972) fig. 7b along the line Ti/O = const (dash-dotted) and along the line Fe/Ti = const (dashed). Assuming Fe-migration for the samples studied in this paper the shaded curve would consequently be expected to follow the dash-dotted curve Ti/O = const instead of the curve Fe/Ti = const. This obvious discrepancy is discussed in the text.

for the magnetization increase at high z-values:

Curie temperature

°C

 Inversion of the metastable cation deficient titanomagnetite to an intergrowth of magnetite and other stable Fe-Ti oxides (Readman and O'Reilly 1970). This process is realized probably only in a few of the investigated samples, for example in 112-17-1(99-100) (see fig. 27). However the majority of the samples plotted in fig. 25 and 26 with Curie temperatures higher than 250°C seem to be cation deficient single phase titanomaghemites as for example 332A-12-1 (81-83) and 114-9-1 (8-9) in fig. 27. This conclusion can be drawn from the shape of their thermomagnetic curves and their x-ray diffraction pattern. Also their lattice parameters are much too small for being magnetite (see table 7 and fig. 26).

low

Fig. 21. Curie temperature  $T_C$  versus age of ocean floor basalts from different Atlantic sites.

- 2. Formation of cation-vacancies in the spinel lattice due to Fe-migration.
  - a)We first consider the case where vacancies are formed only on the octahedral sites of the spinel lattice. This results in a de-

crease of the set magnetic moment first, but eventually the magnetic moment reverses sign and then grows in the opposite direction. (This is correct only at  $O^{O}K$ , at room temperature the situation may be different, de-

Fig. 22. Curie temperature  $T_{C}$  versus mean grain size of titanomagnetites contained in ocean floor basalts. An inverse relationship between the two variables seems to exist.

pending on the Néel type curve. See for example fig. 27). This case is demonstrated in table 8 for our primary titanomagnetite composition assuming a cation distribution according to the 0'Reilly and Banerjee model (1966). We also make the simplifying assumption that Ti, Al, Mg, Mn

and cation vacancies are located on octahedral sites only. The reversal occurs at z=0.60 which corresponds to a Curie temperative of 250°C. This actually coincides with the minimum of saturation magnetization of the natural titanomagnemites as shown in fig. 25 For such a model we would theo言語を見ていていた。

The The Local States

Fig. 23. Mean values of Curie temperatures taken from fig. 21 plotted against the logarithm of age of the rocks. As deduced from fig. 15 extreme degree of maghemitization is reached at a Curie temperature around 400°C. Ocean floor basalt of jurassic age is therefore liable to an inversion of the cation deficient magnetic titanomagnetics to non-magnetic phases.

retically expect a sequence of Q-P-L-N-Q Neel curves with increasing oxidation parameter z (Ozima and Sakamoto 1971, Readman and O'Reilly 1972, Schult 1978). This prediction is tested for a number of samples in fig. 27. There the saturation magnetization has been measured in a magnetic field of 10,100 Oe between liquid nitrogen temperature and the Curie temperature of the sample. From fig. 27 it can be taken that we cannot observe the expected sequence of Neel curves; instead the measured curves let us suggest the sequence

P - L - P

b) In table 9 we consider the case that vacancies are formed on octahedral sites first, until z = 0.60 is reached, and then, beyond this z-value, vacancies shall be formed on tetrahedral sites only.

This model also gives a decrease of magnetization until z = 0.60 is reached, and then for higher z-values, an increase of magnetization again. For such a model we expect theoretically a sequence of

P - L - P Néel-curves

what we actually observe (fig. 27). O'Donovan and O'Reilly (1977) observed a similar sequence of Néel curves measuring the oxidation sequence of a synthetic titanomagnetite of the composition

Fig. 25. Specific saturation magnetization of the magnetic minerals plotted against Curie temperature. The specific mineral magnetization has been determined from the specific rock magnetization and the optically measured titanomagnetite content. For the conversion a rock density of 3 and titanomagnetite density of 5 has been assumed: spec. mineral magnetization = spec. rock magn.  $(3/5) \cdot (100/timag. vol)$ .

They report P-type behaviour for this composition that becomes more pronounced with increasing z until it is almost L-type at z = 0.59 and then, beyond this z-value, becomis less pronounced Ptype again. This agrees well with our observations. However, we are well aware

日本のようななないのないではないないです。

However, we are well aware that our simple "mode! b" is by far not the only one that can suffice the experimental data. The actual mechanism of Fe-migration may be much more complicated in nature. But we wanted to demonstrate that it is easily possible to develop a physically feasible model that yields the main characteristics observed in our samples.

PETERSEN 201

Fig. 26. Lattice parameter  $a_0$  of separated titanomagnetites versus Curie temperature  $T_C$ . There is a general decrease of  $a_0$  with increasing Curie temperature. The anomaly at  $T_C = 250^{\circ}C$  corresponds to a z-value of 0.6. It is not clear if we observe two different trends for  $T_C$ -values higher than 250°C or if the scatter becomes so large although the accuracy of the individual measurements is by far better.

Variation of magnetization direction with low temperature oxidation

Most of the magnetic parameters measured on ocean floor basalts change with increasing degree of maghemitization of the contained titanomagnetites. In the context of interpretation of the marine magnetic anomalies it is important to know if also the direction of natural remanent magnetization is affected by low temperature oxidation.

Following Vine and Matthews (1963) it seems reasonable to assume that the unaltered oceanic crust close to the axial rift, containing primary titanomagnetite, carries a thermoremanent magnetization acquired soon after deposition of the rock. However the primary titanomagnetite is substantially changed chemically by the process of maghemitization that constantly proceeds in the ocean floor environment at temperatures far below the Curie temperature. One may argue therefore that this oxidation gives rise to a secondary chemical remanent magnetization (CRM) acquired in the ambient earth magnetic field long after the deposition of the rock, with a magnetization direction in general different from the original thermoremanence. CRM forms in small grains of magnetic

µre ly

> When we consider under this point of view the Fe-migration model as the basic process of ocean floor titanomagnetite alteration, it seems unlikely that a chemical remanence should develop, because no new magnetic material is growing by this process, the magnetic grains are only losing iron that either is incorporated in non-magnetic clay minerals (Honnorez

et al. 1978) or transported away by sea water. Laboratory experiments by Marshall and Cox (1971) also come to the conclusion that the original remanence direction of ocean floor basalts is not destroyed by oxidation if the oxidation occurs below the original Curie temperature of the titanomagnetite. On the other hand, Butler (1973) has argued that low temperature oxidation of oceanic basalts will cause a significant portion of the titanomagnetite grains, originally stable

carriers of the remanence, to become superparamagnetic and thus lose their initial magnetization. Increase of the spontaneous magnetization at high z-values would then shift the superparamagnetic particles back into the field of stable single domain particles which thereby would actually acquire a new chemical remanence.

We have tested this question by studying the variation of NRM directions within single lithological units of the oceanic crust, where it can safely be assumed that all the samples acquired

their original thermoremanent magnetization within a short time interval. The samples should correspondingly posses the same original magnetization direction.

Fig. 28 shows the stable inclination values for two lithological units from the atlantic DSDP site 396B, plotted against the oxidation parameter z. Although there is a wide spectrum of zvalues, particularly within unit 1, we cannot observe any corresponding variation of the magnetization direction. In particular no self-reversal is observed when passing through the critical z-value of 0.6. Hall (1977) describes similar studies and thereby comes to the same conclusion: The initial direction of thermoremanent magnetization is not significantly altered by sea floor oxidation.

### Conclusions

- 1. Carrier of the remanent magnetization of ocean floor basalts are small grains of titanomagnetites which have varying degrees of cation deficiency.
- 2. The primary titanomagnetite composition in oceanic tholaiites varies onl; within narrow limits and is close to

 $Fe_{1.50}^{2+}Fe_{0.77}^{3+}Fi_{0.58}^{A1}0.07 Fi_{0.06}^{Mg}0.06^{-1} + 0.02^{O}4$ 

The corresponding primary Curie temperature  $T_c = 125 \pm 3^{\circ}C$ , the lattice parameter  $a_0 = 8.475 \pm 0.003$  A 206 PETERSEN

- 3. The dominating mechanism of titanomagnetite sea floor oxidation is Fe-migration. Contrary to the oxidation model of Readman and O'Reilly (1971) this assumes a constantly changing Fe/Ti ratio in the spinel lattice with oxidation. The migrated iron may either be incorporated in surrounding clay minerals or be transported elsewhere by sea water.
- 4. The correlation between Curie temperature  $T_C$  and oxidation parameter z of natural oceanic titanomagnetites is different from the corresponding correlation derived from the data of Readman and O Reilly (1972).
- 5. The Curie temperature of ocean floor basalts increases with increasing age of the oceanic crust. Although there is considerable scatter, it does seem that  $T_C$  increases proportionally with the logarithm of age.
- 6. The upper 600 m of the predominantly pillow basalts of the Atlantic ocean floor are more or less uniformly altered so far as the magnetic minerals are concerned. However within single lithological units there is a slight decrease of the oxidation state with depth.
- 7. The magnetization intensity of oceanic basalts first decreases with low temperature oxidation until the oxidation
parameter reaches z = 0.6. For z-values higher than 0.6 it increases again. The variation of saturation magnetization can be explained qualitatively by a simple model assuming Fe-migration first form octahedral sites and then from tetrahedral sites.

The high amplitude of the mesozoic marine magnetic M-anomalies could possibly be caused by this process. The ju-rassic magnetic quiet zone could then be explained by inversion of the completely oxidized titanomagnetites to non-magnetic mineral phases.

8. The direction of the natural remanent magnetization of ocean floor basalts is not changed by sea floor alteration.

Acknowledgments. This study is a contribution of the Institute of Geophysics and the Institute of Geology, both University of Munich, and the Institute of Geophysics, Ruhr-University, Bochum. We thank Prof. G. Angenheister, Prof. D. Klemm and Prof. H. Baule for generously making available the facilities of the above named institutions and for their support throughout the study.

We would like to thank Prof. L. Rinderer (Lausanne, Switzerland) and Dr. W. O'Reilly (Newcastle, England) for making possible the use of the electron microprobes of their institutions. We also thank Dr. A. Stephenson, W. Davidson and J. Burri for help during the microprobe measurements. Dr. G. Schönharting made part of the thermomagnetic measurements. His assistance is gratefully acknowledged. We also want to express our thanks to Dr. J. Heirtzler, Dr. W. Bryon, Dr. F. Fabri-zius and Dr. P. Vogt who made it possible for us to obtain samples from the Famous area, and from DSDP  $\bar{\text{L}}\text{egs}$  42 and 43. We also acknowledge discussions with other members of our research group, in particular Dr. J. Pohl, Dr. E. Schmidbauer, Dr. A. Schult and Prof. H. Soffel. The financial support for this project was supplied by the Deutsche Forschungsgemeinschaft.

Abstract. Comparison of magnetic properties of pillow basalts from the Rift Valley (FAMOUS area) and from the Crest Mounteins (site 332 of DSDP Leg 37) of the Mid-Atlantic Ridge near 37°N shows that major differences in magnetic structure and properties of the oceanic crust occur between these two sites.

Mean effective intensity of magnetization of the pillow basalt layer drops from  $1.4 \times 10^{-2}$ emu cm<sup>-3</sup> (14 A m<sup>-1</sup>) at the axis to about  $0.4 \times 10^{-2}$  emu cm<sup>-3</sup> (4 A m<sup>-1</sup> at site 332. While the magnetic anomaly over the spreading center may be accounted for by a magnetized layer less than 500 m thick, deeper seated material contributes to the magnetic anomalies over the Crest Mountains.

The large reduction of the intensity of magnetization of the magnetized layer appears to be a general feature resulting from low-temperature oxidation (maghemitization) of titanomagnetite. The effect of maghemitization is a reduction by 2/3 to 3/4 of the remanence intensity, accompanied by a comparable decrease of the Q ratio. Correlative increase of Curie temperature and decrease of saturation magnetization agree with experimental data for synthetic titanomagnetites. However, contrary to previous conclusions deduced from magnetic studies on submarine basalts, almost no changes in susceptibility and coercivity parameters result from maghemitization. It is also pointed out that maghemitization of the top of layer 2A runs over too long a time con-

stant to account for the occurrence of the "magnetization high" found in the FAMOUS Rift Valley. This feature corresponds to eruptions of finegrained olivine-rich basalts, which are on the average usice as magnetic as the surrounding plagioclase or pyroxene-rich basalts. The high remanence of olivine-rich basalts results from their smaller magnetic oxide grain size: A similar relationship between petrology and magnetism is also observed for Leg 37 basalts at site 332.

The thickness of the highly magnetized layer found at the ridge.axis is less than the approximately 1 km thick pillow basalt layer (2A). This implies that some process strongly reduces the intensity of magnetization of the pillows at depth. A moderate elevation in temperature resulting in a rapid and intense maghemitization seems to be the best explanation. At Leg 37 sites the isotherm corresponding to the mean Curie temperature (300°C) is at least at 2 km depth, which indicates that the whole layer 2 can contribute to the magnetic anomalies.

Within the FAMOUS Rift Valley the mean inclination of magnetization fits the dipole inclination, while anomalously shallow inclinations are commonly observed at DSDP and IPOD sites from the Mid-Atlantic Ridge Crest. This is in agreement with tectonic models of rifted midoceanic rises, which assume block tilting within or at the edges of the rift valley as a result of normal faulting. However, tectonic rotations required for explaining paleomagnetic result for Cretaceous North Atlantic IPOD sites may indicate a more complex structural evolution of the upper part of the oceanic crust.

Fig. 2. Histogram of the Q ratio of 103 pillow basalts of the FAMOUS rift valley.

37 yielded large collections of pillow basalts that have been studied in great detail. The extensive magnetic results obtained provide a unique opportunity to compare the magnetism of the upper part of the oceanic crust at and near a ridge axis, in the present-day accretion zone and at 30 km from the spreading center.

The FAMOUS program was mainly devoted to the study of the Rift Valley near 37°N. This area was extensively sampled either by dredging (Needham and Francheteau, 1974) or by using manned submersible (Bellaiche et al., 1974; Arcyana, 1975; Ballard et al., 1975). Figure 1 shows the location of the dredge stations where most of the rocks studied magnetically by the French team (Lecaille et al., 1974; Prévot et al., 1976; Prévot and Lecaille, 1976) were recovered. A total number of about 160 samples was studied, including 120 large samples about 300 g in weight. Experiments include weakfield susceptibility and natural remanent magnetization (NRM) measurements, alternating field treatment, magnetic hysteresis studies, thermomagnetic analysis and electron microprobe analysis (carried out on only 10 samples with titanomagnetite crystals large enough for such studies). Detailed experimental procedures and results will be given elsewhere (Lecaille and Prévot, 1979). Fission-track ages obtained by Storzer and Selo (1974, 1976) indicate these rocks are less than .0.1 m.y. old.

Another magnetic study has been carried out by <u>Johnson</u> and <u>Atwater</u> (1977) on rock samples from the Rift Valley, most of them recovered by submersibles. Their results are restricted to small specimens with mean magnetic grain size larger than 1 µm and include NRM and susceptibility measurements, alternating field treatment and thermomagnetic enalysis. This sampling bias results in a systematic rejection of the specimens with mean grain size below the singledomain to pseudosingle domain threshold (about 1  $\mu$ m for titanium-rich titanomagnetites, e.g., <u>Day</u>, 1977). There is therefore some doubt that the mean values they obtain for grain size-related magnetic parameters (intensity of remanence, susceptibility, Koenigsberger ratio, median destructive field) are really representative of the overall FAMOUS pillow basalts.

Regarding the Leg 37 cores magnetically studied by several authors (in <u>Aumento, Melson et al.</u>, 1977) and in greatest detail by <u>Hall</u> and <u>Ryall</u> (1977), we will consider the data from holes 332A and 332B, the nearest site to the ridge axis, for comparison with FAMOUS results. Site 322 is located at  $37^{\circ}N$ , only 30 km west of the present-day plate boundary. Estimated age of the crust at this site is about 3.5 m.y. (<u>Aumento, Melson et</u> <u>al.</u>, 1977).

The comparison of these two magnetically well documented sets of submarine basalts will be made in regard to three problems: (1) the contribution of pillow basalts to the observed magnetic ancmalies; (2) the magnetic effects of the low-temperature oxidation (maghemitization) of titanomagnetites and (3) the relationship between petrology and magnetism of the basaltic layer.

## Pillow basalts as a source cf magnetic anomalies

The magnetic anomalies produced by pillow basalts depend on several magnetic parameters: Firstly, the Koenigsberger (or Q) ratio, the ratio of the intensity of remanence to the intensity of magnetization induced by the geomagnetic field at the site. As a first approximation, it may be considered that the Q ratio must be larger than one for the <u>Vine</u> and <u>Matthews</u> (1963) interpretation of magnetic anomalies to be valid. Secondly, we have to consider the characteristics of the remanent magnetization itself: intensity, polarity and direction.

## 1. FAMOUS pillow basalts

The <u>Q ratio</u> is quite high (figure 2) with a geometric mean value of 151 (table 2). Individual Q ratios range from 20 to 680.

The mean Q value found by Johnson and Atwater (1977) for their specimens from the Rift Valley is about one order of magnitude smaller, due to their higher susceptibility ( $3.5 \times 10^{-3}$  emu cm<sup>-3</sup>), about 10 times that listed in table 2. Such a high susceptibility is difficult to accept for unoxidized pillow basalts. It is several times larger than the susceptibility of unoxidized massive flows (Johnson and Hall, 1978). However, the magnetic susceptibility of the latter should be higher, due to both a larger grain size and a higher content of magnetic minerals. We note also that the susceptibilities given in the same paper by Johnson and Atwater (1977) for samples

PRÉVOT 211

dredged near DSDP site 332 are similarly one order of magnitude higher than the mean value for the pillow basalts drilled at this site (table 2).

200 Sec. 200 Sec. 4

There is therefore no doubt that the Q value is quite high and that the magnetic anomaly over this spreading center is not due to lateral changes of the induced magnetization carried by the pillow lava sequence.

It has been pointed out by <u>Harrison</u> (1976) that the arithmetic mean (and not the geometric mean) has to be used to estimate the <u>intensity of rema-</u> <u>nence</u> as a source of magnetic anomalies. The arithmetic mean value of the intensity of remanence of the pillow basalts is  $1.9 \pm 0.3 \times 10^{-2}$ emu cm<sup>-3</sup> (19 A m<sup>-1</sup>). The histogram (figure 3) shows only one maximum, indicating that probably this mean value is meaningful. <u>Johnson</u> and <u>Atwater</u> (1977) found approximately the same value for a less extensive collection of rocks from the median valley.

Polarity and inclination of remanence have been determined for 18 partially oriented pillow basalts from the Rift Valley (Prévot et al., 1976; Johnson and Atwater, 1977). For most of the samples, the criterion used for orientation was the occurrence of frozen-in lava levels resulting in the formation of ledges assumed to be horizontal. During the diving operation in the FAMOUS area of the Mid-Atlantic Ridge near 36°50', field observations have shown (Ballard et al., 1975; Heirtzler, 1975) the existence of a series of ledges or shelves on the walls of collapsed feeder tubes. The outer surfaces of these tubes or pillows are glassy and the interior ledges or shelves are cryptocrystalline and not as glassy as the exteriors. Hence it is believed that cold sea water did not enter into the cavities defined by the ledges. These shelves and cavities are formed when the feeding lava is cut off intermittently at its source, permitting partial drainage of the remaining flow and quenching of lower lava levels within the cooling pillow (Ballard and Moore, 1977). The upper surface of the ledges is smooth while the bottom surface has a rugose texture due to the presence of septa and lava stalactites (Prévot et al., 1976). The cavities between shelves vary in width from a few centimeters to about twenty centimeters and are often elongated in a preferential direction (Fig. 4). However, the cavities are not always continuous but may be interrupted by internal walls (Bideau\_et al., 1977). Usually several levels of cavities may be seen in a single pillowed flow. In the interior of the pillows, a series of elongated cavities with a smoother floor and a more rugose roof gives an indication of the vertical at the time of cooling. Hence in order to orient a fragment of such a pillow basalt showing cavities, the vertical at the time of cooling is taken to be normal to the flattish ledge or normal to a line of small elongated cavities. In both cases the polarity of the vertical is deduced from the relative position of the smooth and rugose surfaces of the cavities (Prévot et al., 1976).

Fig. 3. Histogram of the intensity of magnetization  $J_r$  (natural values) of 111 pillow basalts of the FAMOUS rift valley (10<sup>-2</sup> emu cm<sup>-3</sup>).

The difficulties with this method of rock reorientation are related to the facts that the cavities are often irregular in shape, that the ledges may be missing, and/or the cavities may be scarce. Thin sections made across the pillow fragments from the surface to the interior show only textural variations accompanied by an increasing degree of crystallinity towards the inner part of the flow. However, the most significant variations are found within the first 3 centimeters from the surface. Examples of reorientation using the method of the cavities were tested on various types of basalts recovered by dredging and by submersibles from the ocean floor. Plagioclase-pyroxene--ich basalts (ARP 73-10-02, ARP 74-17-40), olivine basalt (ARP 74-11-17, CH 31-DRI-111), and plagioclase-rich basalts were used (Fig. 4).

This criterion has been used for 13 samples. For the remaining samples, two were collected by Alvin divers from outcrop, then reoriented according to diver description after the return to the surface. The other three samples were drilled and reoriented assuming the drilling barrel was vertical and the pillows did not move after cooling. Figure 5 shows the location and polarity of oriented samples.

The nine samples studied by <u>Prévot et al.</u> (1976), broadly distributed within the median valley, are normally magnetized. The mean inclination is equal to  $56^{\circ} \pm 10^{\circ}$  (s.d.), which corresponds to the expected inclination for an axial centered dipole at this latitude. Similarly, <u>Johnson and Atwater</u> (1977) found a mean inclination equal to  $53^{\circ} \pm$  $8^{\circ}$ . But a major difficulty arises from the fact that two of their nine samples, all collected within the median valley, exhibit a negative inclination.

Fig. 5. Location and polarity of oriented samples from the median valley (from <u>Prévot et al.</u>, 1976, and <u>Johnson</u> and <u>Atwater</u>, 1977). Black dots: positive inclination; circles: negative inclination. Heavy lines with black dots correspond to dredge hauls samples. Boundaries of the crust formed during the Brunhes epoch are indicated by heavy dashed line.

with their Brunhes are. Similarly, paleomagnetic studies of the Afar rift valley--which is interpreted as an accreting plate boundary--showed that all samples are normally magnetized (<u>Harrison</u> <u>et al.</u>, 1977; <u>Smith</u> and <u>Sichler</u>, personal communication).

Assuming that the fraction of non-magnetic material is 0.2 at the ridge axis (<u>Salisbury</u>, personal communication) and that the standard deviation of the directions of NRM is 20° (<u>Marshall</u> and <u>Cox</u>, 1971), the overall mean intensity of magnetization of the pillow-lava layer is  $1.4 \times 10^{-2}$  emu cm<sup>-3</sup>. A magnetized layer less

than 500 m thick is enough (Lecaille et al., 1974)

214 PRÉVOT

自然に発明

to account for the amplitude of the axial anomaly at 37°N (<u>Needham</u> and <u>Francheteau</u>, 1974). Hence the pillow basalt layer is responsible for the magnetic anomaly observed at the axis of the Mid-Atlantic Ridge near 37°N.

# 2. Leg 37 pillow basalts

The numerous magnetic studies carried out on Leg 37 basalts (<u>Hall</u> and <u>Ryall</u>, 1977a and b; <u>Bleil</u> and <u>Petersen</u>, 1977; <u>Dunlop</u> and <u>Hale</u>, 1977; <u>Plessard</u> and <u>Prévot</u>, 1977; <u>Kent</u> and <u>Lowrie</u>, 1977) showed large differences in magnetic properties with respect to the FAMOUS rocks.

The relatively high Q ratio of Leg 37 basalts (approximately equal to 35 according to Ryall et al., 1977) seems to indicate that -- as found for FAMOUS rocks--the remanence dominates over induced magnetization. However, it must be noted that Leg 37 basalts are often magnetically viscous (Dunlop and Hale, 1977; Evans and Wayman, 1977; Kent and Lowrie, 1977; Plessard and Prévot, 1977) in contrast to FAMOUS basalts (Lecaille et al., 1974). Magnetic viscosity results in the fact that not only the remanence (viscous remanent magnetization or VRM but also the induced magnetization (viscous induced magnetization or VIM) increases significantly with t, the time of application of the field. If we neglect short-lived geomagnetic excursions, the acquisition time to consider in nature is 0.7 m.y., the beginning of the Brunhes polarity epoch, except for younger rocks. The measurements carried out by <u>Hall</u> and <u>Ryall</u> (1977) using a high frequency susceptibility bridge, yield an induced magnetization definitely smaller than the induced magnetization carried in situ by the specimen. The actual mean Q value is therefore smaller than 35. Plessard and Prévot (1977) showed that the VIM of Leg 37 basalts increased almost linearly with log t. According to a tentative estimation of the intensity of induced magnetization for t = 0.7 m.y., they concluded nevertheless that for a large majority of their samples, the induced magnetization carried in situ is noticeably smaller than the NRM.

The properties of NRM are also quite different from those observed in the FAMOUS rift valley. The magnetic polarity is mostly reversed (Ryal1 et al., 1977) in accordance with interpretation of seasurface magnetic profiles suggesting that site 332 is within the 3.32-3.78 m.y. old negative polarity block (Aumento, Melson et al., 1977). The approximately 100 m thick normally magnetized layer occurring at the top of hole 332A may correspond to a normal polarity event preceding the Gilbert-Gauss boundary (Aumento, Meison et al., 1977). The mean inclination is shallower by a much as 25°-30° from the expected dipole value suggesting considerable tectonic tilting (Ryall et al., 1977; Harrison and Watkins, 1977). The effective intensity of the drilled basaltic lager is only 0.37 x 10<sup>-2</sup> emu cm (Ryall et al., 1977), about four times weaker than. that calculated for the rift valley. Hence, contrary to our conclusion for the FAMOUS Rift Valley, the layer responsible for magnetic anomaly at site 332 probably exceeds the accepted thickness of 2 km for layer 2 (Ryall et al., 1977).

## The low-temperature oxidation of titanomagnetites

## 1. Magnetic effects of maghemitization: comparison of FAMOUS and Leg 37 pillow basalts.

Low-temperature oxidation of titanomagnetites (maghemitization) is probably the main process explaining the decrease of the contribution of the pillow lava sequence to magnetic anomalies outwards from the ridge axis (<u>Irving</u>, 1970).

All evaluations of the magnetic effects of naturally occurring maghemitization are based on the assumption that the two specimens or the two rock units und r comparison were identical before alteration. This can never be demonstrated. It may be hoped that a favorable situation for comparing two collections of pillow basalts would occur when the rocks were erupted at the same latitude from the same accreting plate boundary and close to each other in time. The FAMOUS and Leg 37 rollections meet these conditions. Moreover, many petrographical similarities were noted between Leg 37 basalts and those in the FAMOUS area (Bryan and Thompson, 1977). We shall restrict the comparison between the FAMOUS and Leg 37 collections to pillow basalts. Hence, for Leg 37, we shall consider only the magnetic data of the petrological units identified as pillow lava sequences by Aumento, Melson et al., (1977). Because NRM intensity and Q ratio have a log normal distribution, we shall compare their geometric mean values.

Comparison of electron-microprobe and thermomagnetic data indicates that the FAMOUS pillow basalts contain only slightly oxidized titanomagnetites (table 1). This is demonstrated by the absence of significant difference between measured and calculated Curie points for most of the samples. The latter Curie point is deduced from chemical analysis, assuming that no oxidation occurred and using Curie point data for synthetic titanomagnetites (see review by <u>Smith</u> and <u>Prévot</u>, 1977, for pure titanomagnetite, and experimental data by <u>Richards</u> <u>et al.</u>, 1973 for suf-Ciruted titanomagnetites). Note that estimated uncertainties about calculated values are  $\pm$  30°C (<u>Smith</u> and <u>Prévot</u>, 1977).

Sample DR06-104A is certainly oxidized, and perhaps also samples DR02-102A<sub>2</sub>, DR03-103 and DR03-105 B<sub>3</sub>. Moreover, the mean calculated Curie point of the samples is about 40° lower than the mean measured Curie point for the entire collection (table 2). This suggests a slight maghemitization of the FAMOUS pillow basalts, the mean oxidation index z being about 0.2 according to <u>Readman</u> and <u>0'Reilly's</u> (1972) data for synthetic titanomaghemite.

The Leg 37 pillow basalts are largely maghemitized as demonstrated by the irreversibility of the thermomagnetic curves of most of the samples (<u>Blei1</u> and <u>Petersen</u>, 1977; <u>Dunlop</u> and <u>Hale</u>, 1977; <u>Hall</u> and <u>Ryall</u>, 1977b; <u>Schwarz</u> and <u>Fujiwara</u>, 1977; <u>Murthy et</u> al., 1977; <u>Kent</u> and <u>Lowrie</u>, 1977) and the high mean Curie point (table 2).

For most of the magnetic parameters (except Curie temperature and saturation magnetization), the estimation of the magnetic effects of maghemitization requires the two suites of rocks under consideration to contain titanomagnetites with the same grain size. The condition seems fulfilled here, as shown by the absence of significant difference in the  $H_{\rm TC}/H_{\rm C}$  ratio (remaneat coercive force to coercive force) for FAMOUS and Leg 37 pillow basalts (table 2). The  $J_{\rm TS}/J_{\rm S}$  and  $H_{\rm TC}/H_{\rm C}$  ratios found may

Error bars indicate the 952 confidence interval for the average (brackets for log normally distributed parameters). Leg 37 data from <u>Blei</u>) and <u>Petersen</u> (1977), <u>Dunlop</u> and <u>Hale</u> (1977), <u>Hall</u> and <u>Ryall</u> (1977a and b) and <u>Murthy et al</u> (1977). Note that the MDF of the FAMOUS pillow basalts is about 80% higher than that found by <u>Johnson</u> and <u>Atwater</u> (1977) for a collection restricted to samples with a mean titanomagnetite grain size larger than 1 µm (see text).

be interpreted at corresponding to small pseudosingle domain grains (<u>Lecailie</u> and <u>Prévot</u>, 1979).

Magnetic effects of maghemitization are as follows:

i) Large decreases of saturation magnetization, remanence and Q ratio occur (table 2). The decrease in spontaneous magnetization is compatible with the trend observed at  $0^{\circ}$ C for synthetic titanomaghemites (Prévor, 1973).

It must be pointed out that  $J_r$  and Q changes are overestimated because the shallow-reversed primary remanent magnetization of Leg 37 basalts is often reduced in intensity by overprinted normally direc-

PRÉVOT 219

Fir 5. Generalized distribution of five basalt t, ) in the FAMOUS rift valley (from <u>Hekinian</u>, <u>Mo.</u> : and <u>Bryan</u>, 1976) with superimposed magnetization calculated from the inversion solution of near-botrom magnetic profiles (5 A/m contour in-

'rval; from <u>Macdonald</u>, 1977). Letters indicate copographic highs: V, Mount Venus; P, Mount Pluto; J, Mount Jupiter. The fields of plag. ol. basalts (plagioclase-olivine-pyroxene basalts) and of the aphyric basalts refers here to the pyroxene-rich basalts discussed in the text. The picritic and the olivine basalts correspond to the olivine-rich basalts.

ted VRM (<u>Bleil</u> and <u>Petersen</u>, 1977; <u>Ryail et al.</u>, 1977). <u>Prévot</u> and <u>Grommé</u> (1975) showed that for subaerial basalts with a viscosity index (<u>Thellier</u> and <u>Thellier</u>, 1944) comparable to that of Leg 37 basalts (Plessard and Prévot, 1977) the intensity of the VRM acquired since the beginning of the Brunhes epoch is, on average, equal to 1/5 of the intensity of the primary remanence.

.1) Quite small changes in susceptibility and coercivity parameters (H<sub>c</sub>, H<sub>rc</sub> and MDF) are observed (table .

220 ± ..ÉVOT

1

.,

It can be demonstrated from theory (<u>Prévot et al.</u>, 1979) that maghemitization of single-domain grains results in a large decrease in coercivity and a large increase in susceptibility whereas the opposite trends are expected for true multidomain particles. The later trends have been observed by <u>Ade-Hall et al.</u>, (1976) for coarse-grained basalts from Leg 34.

The small changes observed here in coercivityrelated parameters are probably a characteristic of small , seudo-single domain particles.

## 2. Development with time of maghemitization

At some spreading centers, and in particular within the FAMOUS rift valley 2, deep tow magnetic profiles indicate the occurrence of a "central anomaly magnetization high" (<u>Klitgord</u>, 1976; <u>Macdonald</u>, 1977). In the rift valley 2 it is described as a sharp, narrow maximum in crustal magnetization occurring near the axis of the inner floor and coinciding with large volcanic features such as Mount Pluto and Mount Venus (Fig. 6). According to Klitgord and Macdonald the magnetization high indicates the youngest eruptions on the sea-floor. The less magnetized surrounding lava flows are supposed to be older, their weaker magnetization being interpreted as a result of weathering. In other words, maghemitization is supposed to occur intensively within the rift valley. Only direct magnetic measurements can verify this hypothesis. From a comparison of preliminary magnetic dat for "axial basalts" (dredged within 1 km from the axis: dredge hauls 1, 4, 5, 8, 9, 11 and 12) and for "more distant basalts" (dredge hauls 2, 3, 6 and 10), Prévot and Lecaille (1976) concluded that the magnetization high cannot result from an alteration process. The more complete data now available (Table 3) confirms their conclusions:

1

1) fhe axial basalts are about twice as magnetic as the more distant basalts. In other words, direct magnetic measurements are compatible with intensity variations deduced from deep-tow profiles.

2) This change in intensity of remanence cannot be explained by any maghemitization process because of the absence of change in Curie temperature and the larger saturation magnetization (which decreases through maghemitization) of the more distant basalts.

It is obvious therefor, that such a magnetization high is not necessarily e warker of the most recent extrusions on the sea floor and may not be useful in detecting prepent plate boundaries.

#### Relationship between petrology and magnetism of the basaltic layer

## 1. FAMOUS pillow basalts

The idea that the magnetization high could be due to petrological variations of the magma at the time of eruption came from the observation that highly

magnetic hills found in the inner floor (Fig. 6) of the FAMOUS Rift Valley correspond mainly to olivine-rich basalt while plagioclase and pyroxenerich basalt occurs on the eastern and western walls

(Bougault and Hekinian, 1974; Hekinian and Hoffert, 1975; Hekinian, Moore and Bryan, 1976; Arcyana, 1977; Bryan and Moore, 1977).

To test this hypothesis, thin sections from each of the 120 large samples studied magnetically were examined and half of the samples were chemically analyzed. We compare the magnetic properties of two groups of basalts:

- olivine-rich basalts (Bougault and Hekinian, 1974) which include both olivine and plagioclase as early formed mineral phases. These are aphanitic, aphyric or slightly phyric basalts. The picritic basalts, which are less common, will be considered here as olivine-rich basalts.

- <u>pyroxene-rich basalts</u> (plagioclase-pyroxeneolivine basalts) and <u>plagioclase-rich basalts</u> (moderately phyric and highly phyric plagioclase basalts). The pyroxene-rich basalt may contain small amount of olivine.

Results listed in table 4 show that the intensity of remanence of olivine-rich basalts is statistically twice as large as other basalt types. This does not result from any difference in the chemical composition of the titanomagnetite, as attested by the absence of any difference in the mean Curie temperature. Neither can the difference in remanence intensity be due to changes in the magnetic oxide content. On the contrary, titanomagnetites are more abundant within the group with the smallest intensity of remanence as shown by their higher saturation magnetization (which is proportional to the oxide content). The difference in intensity of remanence may result either from changes in the intensity of the paleofield or from a variation in the grain size of the magnetic minerals. For titanomagnetites, the intensity of

the thermoremanent magnetization decreases within the pseudosingle domain range when particle size increases, the total diminution in intensity corresponding to a factor of ten (Day, 1977). We think that the difference in intensity of remanence between olivine-rich basalts and pyroxenerich or plagioclase-rich basalts is mainly due to a statistical grain size difference, the smallest magnetic oxide grains being found in the olivinerich basalts. This view is substantiated by the trends of the grain size-dependent magnetic parameters (H<sub>c</sub>, H<sub>rc</sub>, IDF and Q) which all indicate that, statistically, the finest titanomagnetites occur within the olivine-rich basalts (Table 4). Microscopic observations lead to the same conclusion.

It must be pointed out that this correlation between magnetism and petrology is only valid at a statistical level. Moreover, it is not an unequivocal relationship: within each of the two magnetically different groups, basalts which are petrologically quite distinct coexist. The differences in magnetic properties observed are in fact related to the textural features of the rocks rather than to their petrology as a whole.

Figure 7 shows a ternary diagram giving the relative amount (vol %) of phenocrysts, matrix minerals and mesostasis in the rock. The term mesostasis as used here refers to the glassy portion and the cryptocrystalline (< 0.02 mm in length) material not identified under a righ power microscope. The matrix minerals range between 0.02 and 0.9 mm in length and include plagioclase laths, pyroxene, and olivine granules. The phenoc "vsts consist mainly of cumulate plagioclases hav. -g a grain size larger than 1 mm in length. On the same diagram the value of the coercive force H<sub>c</sub> is superimposed for each sample. It is apparent that the largest coercive forces (corresponding to the finest grains) are found for the least crystalline rocks, which are the olivine-rich basalts.

## 2. Leg 37 pillow basalts

Petrographic studies of Leg 37 basalts led to the recognition of petrological types similar to those found in the FAMOUS area (<u>Bryan</u> and <u>Thompson</u> 1977; <u>Dimitriev</u> and <u>Aumento</u>, 1977). Using these studies and geochemical data from <u>Aumento</u>, <u>Melson</u> et al. (1977) we were able to classify Leg 37 pillow basalts from hole 332B into the two groups previously defined: olivine-rich basalts and plagioclase or pyroxene-rich basalts.

Table 5 shows that the relative variation of the magnetic parameters between these two groups are the same as those for 1 for the FAMOUS pillow basalts; olivine-r n basalts are about twice as magnetic as plagic clase and pyroxene-rich basalts. Again, this cannot result from variations of oxide content (oxide content is lower in the olivine-rich basalts) and has to be attributed to the smaller magnetic oxide grain size (attested by a larger median destructive field) in the olivinerich basalt.

The fact that low-temperature oxidation affects these two groups of basalts to the same degree is demonstrated by the absence of any significant difference between the two mean Curie points. Hence maghemitization does not modify the relative contribution of olivine-rich basalts and of plagioclase or pyroxene-rich basalts to magnetic anomalies.

# IV <u>Conclusions</u>

Extensive magnetic studies carried out at the Mid-Atlantic Ridge Crest near 37°N show that the magnetic properties of the pillow basalt layer are

222 PRÉVOT

Fig. 7. Ternary diagram of the relative amount (vol %) of phenocrysts, matrix mineral and mesostasis (see text for precise definitions). Number indicates coercive force of the sample (Oe). Olivine basalts and picritic basalts are olivine-rich basalts. Plagioclase-rich basalts are divided into moderately phyric plagioclase basalts (MPPB) and highly phyric plagioclase basalts (HPPB). PL. PRX (OL)B are called pyroxene-rich basalts in the text. See text for references about these different types of basaltic rocks found in the rift valley.

petrology dependent and change notably with time as a result from sea-floor weathering and tectonic tilting. In addition the thickness of the magnetized layer increases rapidly outwards from the ridge axis. All these features seem to be typical of the behavior of the basaltic layer of the oceanic crust.

1. A relationship between petrology and magnetism was first suggested by Vogt and Johnson (1973) in order to explain high-amplitude anomalies zones located close to some postulated "hot spots". Chemical and magnetic studies of rocks from the Reykjanes Ridge (de Boer, 1973; Day et al., 1979), the Galapagos spreading center (Vogt and de Boer, 1976) and high-amplitude zones in the Juan de Fuca area (Vogt and Byerly, 1976) seem to support this conjecture. The highest magnetizations of these Fe-Ti enriched basalts are supposed to result from a larger titanomagnetite concentration, contrary to our observations in the FAMOUS area. However, the rock magnetic study carried out on seven pillow fragments from the Galapagos spreading center showed a poor correspondence between the titanomagnetite abundance and the remanence intensity (<u>Anderson et al</u>., 1975). These workers suggest that in addition to having twice as much titanomagnetite, the samples from the Galapagos rift zone have five times more intense remanence than the samples from the Costa Rica ridge because the former have a greater proportion of smaller grains. As it is true for the magnetization high in the FAMOUS rift valley, variations in the grain size of the magnetic minerals seem essential to interpret the high-amplitude anomalies zones found in other parts of the oceans.

2. <u>Maghemitization of titanomagnetite</u> is probably the major cause for the decrease in the amplitude of magnetic anomalies outwards from the ridge axis. However, according to the Curie temperatures of the rocks collected within the FAMOUS Rift Valley, the maghemitization of the top of the basement is a progressive process. Samples collected as far as 4 km west of the axis yield Curie temperatures near 150°C (Johnson and <u>Atwater</u>, 1.777), which is not significantly different from the mean value at the axis (table 4). This confirms our

conclusion that the magnetization high found in the TAMOUS Rift Valley 2 does not result from an alteration process and cannot be used <u>a priori</u> as a marker of the present plate boundary.

and a local state

たたるに総理論が変換する

のためのである。

From the FAMOUS area to DSDP 332 site, the mean intensity of NRM decreases by a factor of 4. Taking into account the reducing of NRM of reversely magnetized Leg 37 basalts due to VRM overprinting, the reduction of the intensity of the primary remanent magnetization must be slightly less, probably between 2/3 and 3/4. There is an excellent agreement between intensities of remanence measured and intensities calculated from direct modeling of near-bottom magnetic anomalies at  $37^{\circ}N$ (<u>Macdonald</u>, 1977). In both cases the intensity decreases from 2 x  $10^{-2}$  emu cm<sup>-3</sup> right at the axis (effective average intensity of remanence of axial basalts) to about 0.4 x  $10^{-2}$  emu cm<sup>-3</sup> for 3.5 m.y. old crust (holes 332).

The 2/3 to 3/4 reduction due to maghemitization is the same as that found by <u>Prévot</u> and <u>Grommé</u> (1975) for dredged basalts from the whole North Atlantic basement. The larger decrease observed at 45°N (<u>Irving</u>, 1970) probably results from some combination of maghemitization and local vari-

224 PRÉVOT

ations in magnetic oxide content and/or size, between basalts from the median valley and from the flanks (<u>Prévot</u>, 1973). It is worth noting that moderately magnetized pillow basalts have also been recovered within the median valley at  $45^{\circ}N$  (<u>Ade-Hall et al.</u>, 1973). et

3. Tectonic rotations due mainly to normal faulting at the edges of the median valley have been suggested by Van Andel (1968) and Van Andel and Bowin (1968). Another geologic model by Moore et al. (1974) assumes that the subsidence of the ridge center induces a substantial tilting (of 20° to 40°) towards the rift-valley wis. The paleomagnetic data so far obtained in the North Atlantic strongly support such models. It has been frequently observed at DSDP and IPOD sites that, even after cleaning, the mean magnetic inclination of the magnetic units differs from the value expected from paleolatitude: sites 332A, 332E, and 333A (Ryall and Hall, 1977); sites 395 and 396 (Johnson, 1979), site 396B (Petersen, 1979); sites 407, 408, and 410A (Luyendyk, Cann et al., 1977), site 317D (Donnelly, Francheteau et al., 1977) and site 418A (Flower, Salisbury

et al., 1977). Expected and anomalous inclinations, which generally differ by 20 to 30°, have been observed several times in a single hole.

It is difficult to explain the e anomalous inclinations by any non-dipole behavior of the geomagnetic field (secular variation or geomagnetic excursions or transitions) at the time of cooling because the probability of recording such directions is very low (<u>Harrison</u> and <u>Watkins</u>, 1977). Decisive geological and paleomagnetic observations in favor of tectonic rotations of crustal blocks have been reported recently (<u>Donnelly</u>, <u>Francheteau et al.</u>, 1977; <u>Flower, Salisbury et</u> <u>al.</u>, 1977).

The axis of spreading of the North Atlantic Ridge, trending approximately N-S, is more or less parallel to the horizontal component of the Upper Tertiary and Quaternay geomagnetic field. Rotations around the horizontal axis parallel to the ridge axis postulated by the two geological models reported above would reduce the magnetic inclination. The unexpectedly low inclinations frequently observed along the North Atlantic Ridge Crest (Ryall and Hall, 1977, Johnson, 1979; <u>Petersen</u>, 1979; Luyendyk, Cann et al., 1977) can therefore be readily explained by tectonic rotations.

Qualitatively different inclination discrepancies have been obtained for older oceanic crust. At the Cretaceous North Atlantic sites (IPOD megaleg 51-52-53) magnetic units with a mean inclination larger than expected dipole inclination were found, the difference being about 25°-35° (Donnelly, Francheteau et al., 1977; Flower, Salisbury et al., 1977) In such cases, horizontal rotation axes have to be more or less oblique with respect to the horizontal component of the paleofield. Taking into account the Cretaceous pole position for North America (Mankinen, 1978) and the 10-20° East strike of the ridge crest, rotations about axes parallel to the ridge crest can, at the most, increase the expected dipole inclination to 43°-50°. This seems insuf-32° ficient to account for the observed discrepancy. It may be suggested that large faulting occurred along directions oblique with respect to the spreading axis strike or that some rotations are due to large scale slumps rather than to norual faults (Francheteau, personal communication).

Another unsolved question is whether the postulated rotations parallel to the spreading center axis take place within (Moore et al., 1974) or at the edges of the median valley (van Andel and Bowin, 1968). The paleomagnetic data so far obtained for rocks collected within the median valley cannot settle this point because the magnetic inclinations calculated are in most cases relative to the horizontal plane at the time of cooling rather than to the present horizontal plane. Drilling within the rift valley is probably the only way to solve this problem.

An argument against the interpretation of anom-

alous inclinations in terms of tectonic rotation is that it would require extreme tilting of the blocks (Lowrie, 1977). Assuming that the rotation axis was in the plane of the paleofield vector, Harrison and Watkins (1977) found that the amount of rotation needed to account for the excessively shallow inclinations at the Leg 37 sites is 55°. However, the tectonic studies of the Afar accretion zone (Morton and Black, 1975) show that in several large areas extension tectonics resulted in normal faulting with blocks strongly tilted. Dip angles up to 60° and locally up to 90° have been observed. Probably as a result of successive stages of normal faulting, the faults were sometimes observed dipping at only shallow angles. In view of these results, there is no doubt that the tectonic complexity of the oceanic crust has been so far underestimated.

Thickening of the magnetized layer outwards 4. from the ridge axis. It is now well established (Harrison, 1976) that the mean magnetic intensity of DSDP cores is several times less than the values calculated from magnetic anomaly profiles assuming the magnetized layer is only 500 m thick. DSDP sites recently studied along the MAR (Johnson, 1979, Petersen, 1979) confirms Leg 37 results (Ryall et al., 1977) that the magnetized layer is several kilometers thick away from the ridge axis. On the other hand, the high average magnetic intensity of the FAMOUS pillow basalts seems to indicate that the magnetized layer is less than 500 m within the median valley (Lecaille et al., 1974).

Three processes can result in a decrease of the intensity of remanence with depth at the MAR axis: 1. transition from pillow basalts to possibly

less magnetic intrusive units.

2. geothermal gradient.

3. Intense maghemitization at depth. Regarding the first interpretation, the main transition between intrusive and intrusive rocks is supposed to correspond to the 2A/?B interface within layer 2 (<u>Talwani et al.</u>, 1971) <u>Fowler</u> (1976) showed that beneath the median valley at 37°N layer 2A is about 1 km thick. Similarly, in a detailed geophysical study of the Reykjanes Ridge Crest <u>Talwani et al</u>. (1971) found that the thickness of the pillow basalts varies from 0.6 to 1.1 km in the crestal zone. This figure is to compare with the 400 m thickness they assign to the magnetized layer.

The second interpretation is that the bottom of the magnetized layer corresponds to the Curie point isotherm (160°C at the axis). This is supported by some thermal models of the oceanic crust. <u>Sleep's (1975)</u> study of the thermal structure of mid-ocean ridge axes suggests that the 300°C isotherm would be as shallow as 300 m at the axis of the MAR near 37°N. According to <u>Sclater</u> and <u>Francheteau's (1970)</u> cooling model of lithospheric plate, the variation of heat flow

 $q = \frac{12}{\sqrt{t}}$ 

where q is in Heat Flow Unit (1 HFU= $10^{-6}$  cal sec<sup>-1</sup> cm<sup>-2</sup>) and t in m.y. The thermal conductivity of pillow basalts being 4.0 mcal °C<sup>-1</sup> cm<sup>-1</sup> sec<sup>-1</sup> (<u>Hyndman</u> and <u>Jessop</u>, 1971; <u>Hyndman et al.</u>, 1977) the depth of the 160°C isotherm can be calculated. This depth is approximately 400 m for t=0.5 m.y. and 500 m for t=1 m.y. At site 332, the calculated depth of the relevant 300°C Curie point isotherm is approximately 2 km, in agreement with Ryall et al.'s (1977) suggestion that the entire layer 2 contributes to the magnetic anomaly. As the plate cools the lower part of layer 2 becomes progressively magnetized. Such a cooling by conduction results in the formation of blocks of alternating polarity with broad sloping transition zones as described in <u>Cande</u> and <u>Kent's</u> (1976) magnetic model of layer 3. Such thermal models provide therefore a straightforward explanation of the thickening of the magnetized layer near the ridge axis.

There are however two major objections regarding this interpretation. The first one deals with the importance of nonconductive processes, in particular hydrothermal circulation, in the oceanic crust. Percolation by sea water extends down to several kilometers in depth (Ribando et al., 1976) and may cause significant loss of heat near the ridge axis (e.g. Talwani et al., 1971), which is not considered in Sclater and Francheteau's and Sleep's models. This idea led Cande and Kent (1976) and Kusznir and Bott (1976) to suggest that layer 2 as a whole is at 0°C at ridge axes. However, according to a numerical study of hydrothermal circulation in the oceanic crust (Ribando et al., 1976), percolation alters the spatial distribution of surface heat flow but not its mean value, unless circulating water leaves the porous crust as extensive hot springs with a temperature in excess of 50°C.

The second objection is that any rise in temperature will increase the reaction rate of maghemitization. It has been shown by Readman and O'Reilly (1970) and by Ozima (1971) that the reaction rate of maghemitization observed for 0.1  $\mu$ m size titanomagnetites heated in air yields a time constant of the order of 10<sup>6</sup> years at 0°C, in agreement with the time dependence of maghemitization near the MAR axis (Irving, 1970; Johnson and Atwater, 1977). Pillow basalts at ridge axes are highly vesicular and are buried with trapped water, as shown by their very low seismic velocity (Talwani et al., 1971). As is true for the top of the oceanic basement, maghemitization at depth can proceed in the presence of sea water. Calculations following  $\frac{Ozima's}{Ozima's}$  (1971) procedure yield time constants of about 10<sup>3</sup> years at 50°C and a few years at 100°C for completion of maghemitization. Hence

226 PRÉVOT

the lower boundary of the magnetized layer corresponds probably to a decrease in magnetiza~ tion due to an intense maghemitization at depth at ridge axes. A further contribution comes from the decrease of the spontaneous magnetization as temperature increases. The geothermal gradient within the rift valley is therefore les: important than the gradient needed to interp the lover boundary of the magnetized layer term of the Curie point isotherm. However, depending upon the hydrothermal circulation pattern, and the depth of the eventually transient magma chamber (Nisber and Fowler, 1978) at the ridge axis, the possibility remains that the lower part of layer 2A is heated at some places above its Curie point and becomes remagnetized as the plate moves away from the ridge axis.

Acknowledgments. Discussion with R. S. Coe, J. Francheteau, S. Grommé, E. A. Mankinen and J. G. Moore were very helpful as were the reviews of C. G. A. Harrison and H. P. Johnson. We thank also B. Bregman for typing the manuscript. This work was supported by the CNRS, the Université de Paris 6, and the CNEXO.

METAMORPHISM IN THE OCEAN CRUST

Johnson R. Car.n

Department of Geology, The University, Newcastle upon Tyne, NEl 7RU, England

<u>Abstract</u>. Ocean floor rocks can be assigned to five mineral assemblage facies, brownstone, zeolite, greenschist, amphibolite and gabbro. The rocks characteristically preserve igneous textures and are little deformed. Changes in bulk chemistry are controlled by congruent mineral reactions, in which one phase is transformed into another. Overall bulk crustal changes cannot easily be calculated. Metamorphism to high grades follows on very shortly after crustal formation, during an intense period of hydrothermal activity as the ridge-crest-parallel faults form. Brownstone alteration continues as the crust ages during less intense, lower temperature hydrothermal episodes.

#### Introduction

Metamorphosed igneous rocks are recovered relatively frequently from the ocean floor by dredging, and are to be expected as the solid components of the rock-water hydrothermal systems that have been predicted on geophysical grounds (Lister, 1972), observed indirectly (Williams et al., 1974), and recently observed directly as emerging jets of hot water (Weiss et al., 1977). However, metamorphic rocks have very rarely been recovered by drilling, and none of the deep holes in the ocean crust, such as those on legs 37 and 45, have shown any clear-cut increase in the degree of alteration with depth. This paper sets out to examine this paradox, by first giving an outline account of the nature of the metamorphic rocks from the ocean crust, and then examining the processes by which they form.

## Characteristics of Ocean-floor Metamorphics

All of the metamorphic rocks so far described from the ocean floor are metamorphosed igneous rocks, either basalts, gabbros and related basic rocks, or peridotites and related ultramafic rocks. Metamorphic deformational fabrics are only poorly developed. Though these rocks are described as belonging to, for example, the greenschist or amphibolite facies, this refers to mineral assemblage only and does not imply that the greenschists are schistose, or that the amphibolite facies rocks are made up of lineated lustrous black prisms of hornblende. Almost all of the metamorphics preserve a vell-developed igneous texture, with a characteristic lath shape to the plagioclase demonstrating an origin by crystallisation from a liquid. Chilled margins preserve variolitic and skeletal crystal forms, now pseudomorphed by other minerals, clearly indicating very rapid cooling and rapid crystal growth. Zones of shearing may cut across areas where primary textures are well-developed, but these make up only a small proportion of the bulk of most rock samples. chei the earl basi stal repl adva pots adul

Table 1 gives a summary of the mineral assemblages observed in ocean floor metamorphics for both basic and ultramafic compositions, over the range of metamorphic conditions encountered. Specific features are discussed in the following paragraphs.

The brownstone facies, newly defined here, is the facies of low temperature ocean floor weathering or cool hydrothermal alteration. It is the facies of most older oceanic crust, and persists through most of the drilled sections of ocean crust. Its products have characteristically a yellowish brown tint (from which the name is derived) when conditions are, as they usually are, oxidising, but are a dark bluish grey under reduction. Secondary minerals are closely related to particular primary phases, and cannot be demonstrated to form equilibrium assemblages. The most widespread mineral in oxidising conditions is a K-rich dioctahedral iron illite, resembling celadonite in composition, but not always showing a true illite X-ray diffraction pattern (Kempe, 1974; Bass, 1976; Robinson et al., 1977; Scarfe and Smith, 1977; Andrews, 1977). This mineral replaces olivine, lines and fills vesicles, replaces interstitial glass, and eventually, under extremc alteration, replaces augite. Under reducing conditions its place is taken by a magnesium-rich trioctahedral smectite, a true saponite, which gives a good X-ray diffraction pattern characteristic of this mineral. This phase fulfils the same mineralogical functions as the illite, but with a very different

empe, carfe eral

y, under

a rue tion his ions

chemical character. Where both phases occur in the same rock, the saponite appears usually to be earlier than the illite. The plagioclase of the basalt remains little affected during the early stages of this alteration, except for some replacement by the appropriate clay, but at more advanced stages of alteration becomes replaced by potassium feldspar, probably best described as adularia (Mellis, 1952; Matthews, 1962, 1971). Secondary pyrite is very characteristic of the reduced zones in this facies, aeveloping as irregular cross cutting stringers.

Where basalt glass is abundant, as in the glassy rinds of lava pillows, a rather different style of alteration is found. Orange palagonite, a mineral resembling in composition the illitic mineral described above, but very poorly crystalline, forms from the glass in association with phillipsite or other low temperature zeolites and calcium carbonate. At the upper limit of the brownstone facies, the celadonitic phase becomes very rare, so that it is seldom seen in the zeolite facies rocks, and phillipsite disappears. New minerals that appear at or near the bottom of the zeolite facies are zeolites characteristic of rather higher temperatures, such as analcite and natrolite (Miyashiro, Shido and Ewing, 1971). To judge from similar, but not identical, mineral transitions in the Icelandic geothermal fields (Krismannsdottir, 1975), the temperature of the brownstone-zeolite facies boundary would be in the region of 50-100°C.

The zeolite facies has been well described by Miyashiro, Shido and Ewing (1971). As is the case with the brownstone facies, it is characterised by the presence of relict igneous phases which have only rarely been completely replaced by alteration phases. The most characteristic mineral of this facies is a magnesium-rich trioctahedral saponite or saponite-chlorite mixed layer mineral. This is in many ways similar to the mineral of the reduced assemblage of the brownstone facies, but is usually more coarse-grained, and may contain chlorite interlayers (Miyashiro, Shido and Ewing, 1971). occurs replacing olivine and glass, and filling vesicles and cracks. It is cormonly found partly replacing plagioclase, which is also often reflaced by zeolites. Augite is usually unreplaced in this facies, retaining its igneous appearance clear and unclouded even when secondary minerals replace nearly all of the rest of the rock.

The upper limit of the zeolite facies is marked by the disappearance of zeolites and saponite and the appearance of albite and chlorite. These changes happen nearly synchronously, though in some rocks near the border the assemblages albite + saponite or zeolites + chlorite may be found (R.A.Heath, personal communication). Again the Icelandic analogy suggests temperatures of about 250-300°C for this transition (Sigraldason, 1962; Tomasson and Kristmannsdottir, 1972). This is supported by preliminary results from Hawaii (Stone and Fan, 1978). Nothing is yet known of the mineralogical chiracteristics of ultramafic rocks such as peridotites and serpentinites under brownstone or zeolite facies conditions. It is possible that particular forms of serpentine may be recognisable, or that Mg-rich clays such as saponite may be formed as in rocks of basaltic composition. Freliminary investigations (Prichard, personal communication) suggest that both types of mineral may be present, though their relative conditions of formation are not yet clear.

With the incoming of greenschist facies mineralogy characterised by the assemblage albite + chlorite  $\pm$  actinolite  $\pm$  epicote + spnene, the extent of alteration of the primary assemblage increases. Usually less than half of the primary phases remain, and complete replacement by the secondary phases is not uncommon. In contrast with the situation in the brownstone and zeolite facies, here it is possible to conclude from the close spatial juxtaposition and wide development of secondary phases that they represent some sor. of equilibrium assemblage. Augite is the phase most commonly appearing as a relict, and sometimes it occurs as water-clear crystals which have apparently been completely unaffected while the rest of the rock is extensively replaced. It is often, however, closely associated with bluish green needles of actinolite which may replace it completely. Numerous veins are characteristic of greenschist facies material, containing usually some of the secondary minerals present in the rock, often in association with quartz. Within the rock there is a close association of individual secondary phases with particular primary phases, so that albite replaces calcic plagioclese, which may also be replaced by chlorite. Chlorite may also replace olivine and glass, and fill vesicles. This relationship is described in more detail by Cann (1969).

The upper limit of the greenschist facies is marked by the disappearance of albite, chlorite and actinolite, and the appearance of green aluminous hornblende associated with calcic plagioclase. Miyushiro, Shido and Ewing (1971) suggested that the assemblage actinolite + calcic plagioclase might form an intermediate assemblage in this complex change, on the basis of some of their observations from the Atlantis collection, and this has been supported by observations of Heath (personal communication) on Palmer Ridge metamorphics (Cann, 1971).

The amphibolite facies, which succeeds the greenschist facies, also shows well developed igneous textures, but instead of those of the basalts and dolerites of the preceding three facies, these are of dolerites and gabbros, demonstrating its development deeper in the ocean crust, where lavas no longer occur. Even dolerites are rare in the amphibolite facies, suggesting that the full development of the facies begins near the level at which the doleritic part of the ocean crust gives way to gabbros. The mineralogy of this facies is very simple, consisting of hornblende + calcic

plagioclase + titanomagnetite ± epidcte. The plagioclase is frequently zoned in a style exactly analogous with the plagioclase in the corresponding unmetamorphosed rocks, suggesting that its composition has bee. little affected by the metamorphism in general, though the plagicclase must have contributed some Al to the hornblende. Ocean floor gabbros sometimes show the assemblage hornblend: + calcic plagioclase as a clearly igneous product (Prinz et al., 1976), though when the assemblage is clearly igneous, with euhedral bornblesde -ssociated with euhedral plagioclase, the hornblende is chestnut brown and titaniferous. However, amphibolite facies assemblages clearly persist in this environment into the ignecus regime, where they are perhaps best called diorites. Every gradition is seen within such rocks from hornblendes that are clearly primary, through varieties that are pale brown or brownish green that are probably late magnetic, to green hornblendes with textural relationships that show them clearly to be secondary. Such a gradational relationship demonstrates clearly that metamorphism has followed very closely upon the crystallisation of the gabbros from the melt, and hence that it takes place very early in the history of the ocean crust.

Many metamorphosed gabbros appear to have been through no such period of primary crystallisation of hornblende. In these, clearly secondary green hornblende develops at the expense of primary anhydrous phases, producing a uralitic product, where primary plagioclase survives relatively unaffected and ferromagnesian minerals are replaced entirely by green hornblunde (Cann, 1971).

The most important metamorphic event to affect the ultramafic rocks is serpentinisation. Most serpentinisation probably occurs under greenschist facies conditions, since the upper temperature limit for the formation of serpentine is about 500°C (Kitahara et al., 1966; Scarfe and Wyllie, 1967). In ocean floor serpentinites, lizardite is the first polymorph to form, and is followed by chrysotile at a later stage, after serpentin-isation is essentially complete (Prichard, personal communication). Serpentinisation seems to take place with a considerable increase of volume so that low density serpentinite carintrude upwards through the ocean crust as diapirs, often bringing with them fragments of the lower oceanic crust (Cann and Funnell, 1967; Barrett and Aumento, 1970). Other mineral phases are known from altered peridotites, including carbonates, talc, tremolite and brucite (Cann, 1971; Aumento and Loubat, 1971), but the controls on their appearance have yet to be precisely established.

## Facies nomenclature

Objections have been raised to the continued use of the terms "greenschist" and "amphibolite" to refer to the products of ocean floor metamorph-

ism, since the greenschists are not schistose, nor the amphibolites the typical amphibolites of orogenic belts. In the case of he greenschists, the mineral assemblage is exactly the same, as far as can be determined, as that of the schistose greenschists, and it would certainly be difficult to find a means of distinguishi . the two on mineralogical grounds. Such a distinction would seem to be essential if a new facies name is to be used. It could be argued that the distinction could be made on textural grounds, reserving the term "greenschist" for schistose materials. This This would, however, lead to the objectionable result that, in orogenic environments, the sheared margins of massive metabasalt units would be assigned to the greenschist facies, while adjacent unsheared material, metamorphosed under identical conditions, would receive a different facies name. I would argue that the problem here is a psychological one, not a scientific one, and that petrologists should reconcile themselves to the proper application of facies terms on the basis of mineral assemblages as indicating conditions of metamorphism (Miyashiro, 1973, p. 67), and refrain from worrving about implications of names which are merely the result of historical accident.

The apphibolites are a slightly different case. There is a definite, though not very useful, mineralogical difference involved, and there is one alternative name of respectable pedigree available (with another possibility, too). The mineralogical distinction from conventional amphibolites is that almandine garnet is not seen in ocean floor amphibolite facies rocks. The difficulty of applying this distinction is of knowing how hard you have to look before saying that almandine garnet is absent from a particular suite of rocks, especially as garnet is not present in all normal amphibolite facies metabasites. This distinction is one of those (the othersinvolve pelitic compositions) by which a hornblende hornfels facies has been distinguished from the amphibolite facies (Turner and Verhoogen, 1960, p. 511). However, the use of this facies term has never been very widespread, possibly because rocks belonging to it are not cozmon, but most probably because of the difficulty of making the distinction clearly and reliably. In addition, the use of a facies name which includes the term 'hornfels" raises just the problem that we are trying to avoid, since if the ocean floor rocks are not amphibolites, neither are they hornfelses.

The other possibility is to use some term such as the adjective "uralitic" (or the Scattish equivalent noun "epidiorite") for metamorphic rocks with hornblende-plagioclase mineralogy and igneous texture. But this is not a facies term, and runs into the same problems as were considered in connexion with the greenschist facies, above. I conclude, therefore, that there are no good grounds for changing the application of facies names to ocean floor rocks, and that "greenschist" and "amphibolite" should continue to be used. Eowever, petrologists should be careful, if there

is any char-e of confusion, to qualify their descriptions with rock name terms such as spilite (for the greenschist facies), or epidiorice (or the use of "uralite" for the hornblende) for the amphibolite facies, so as to leave no room for confusion.

As has already been indicated in the descriptions of individual facies. the primary mineralogy exerts a very strong, perhaps dominant, effect on the occurrence and distribution of the secondary minerals, and hence on the bulk chemical composition of the rock. Such an effect has been appropriately called "congruence" by Amstutz (1968). The vay in which congruence affects mineral relationships in the greenschist facies has been described by Cann (1959). It leads to the replacement of plagioclase by albite, olivine by chlorite, basalt glass by chlorite, titanomagnetite by iron ore and augite by actinolite. The result is a clear change in composition from basaltic to spilitic, with a dccrease in Ca, Sr and K, and an increase in Na and perhaps Si. The mobility of elements implied by the effects of congruence has been used by several authors to calculate elemental fluxes into and out of the ocean crust, and may, as in the case of magne.jum, make up a source or sink that is significant on a global scale (Hart, 1970; Humphris and Thompson, 1978; Wolery and Sleep, 1976). From this point of view congruence has an important role to play, but interpretation is not always as simple as some authors would wish.

Fig. 1 gives a summary of the different congruent relationships for primary basaltic minerals in the different metamorphic facies. This is rather simplified by comparison with the real world, but it couveys its essential features. Note that there is not a one to one correspondence between primary and secondary minerals. Some primary phases may be replaced under different circumstances by more than one secondary phase, and more than one primary phase in a particular rock may alter to a single secondary phase, so that, for example, a basalt may become largely chloritised in the greenschist facies. The composition of the resulting material may depend critically on the relative proportions of the different primary phases present, and particularly on the proportion of basaltic glass present (Cann, 1969). Glassy pillow rinds and interstitial hyaloclastite may end up with a very different composition from holocrystalline pillow cores, and the overall composition of a pile of pillows may depend critically on the relative proportion of glass in the pile as a whole. It is not, therefore, easy to make deductions about the magnitude of elemental fluxes in particular cases from the analysis of a few samples unless these samples are truly representative, and unless the results are weighted by the relative proportions of the different materials in the original rock body.

When elemental fluxes are sought for a typical

piece of oceanic crust, the problem becomes more complex. Now, in addition to the requirements for a particular body of rock, some estimate is required of the relative proportions of the different facies present in a typical piece of ocean crust. That this is crucial can be seen from Fig. 1. Brownstone facies alteration leads typically to a bulk increase in K in the rock, while greenschist facies metamorphism releases K. Is the net flux of K into or out of the crust? Similarly, zeolite facies alteration usually involves uptake of Mg by the rock, sut extreme trownstone facies alteration releases Mg into solution. The net flux can be changed by altering the proportion of the different facies in the crust.

A few years ago, it seemed that this question was not the difficult to answer. The relative proportions of rocks of different facies in dredge hauls could be estimated, a correction applied for the chances of recovering material from progressively aceper in the oceanic crust, and the two combined to give an answer that was not very precise, but probably good enough for its purpose. Such a calculation was not made, probably because a very similar answer was derived at the same time from ophiolite complexes, in particular from the Troodos complex (Gass and Smewing, 1973, 1978; Stern et al., 1976). Here, detailed field work led to the view of metamorphic facies boundaries lying more or less parallel to the or ginal ocean floor, with the brownstone facies (not specifically recognized as separate) forming a layer a few hundred metres thick,

Fig. .. Congruent mineral reactions in different facie. of alteration in the ocean crust, shown schematically. The different reactions in different facies lead to considerable variation in the elemental flux from facies to facies.

the z olite facies extending new ly to a kilometre, and the greenschist facies forming a layer about one kilome re thick beneath. The degree of alteration is more or less uniform, and extensive. Such a pattern seems characteristic of ophiolites, where they are unaffected by later metamorphism and undeformed, so that it can be recognised today.

However, drilling in the ocean crust has given a very different picture. Here, some noles have now reached depths of several hundred metres into the crust, such as at site 332 on leg 37 (Aumento and Melson, 1977), site 395 on leg 45 (Rabinowitz et al., 1976) and sites 117 and 418 on legs 51-53 (Donnelly et al., 1977; Flower et al., 1977). In all of these holes, the extent of alteration has been very small. Fresh basaltic glass persists, even though not in great amounts, to the bottom of the holes, and the proportion of primary phases is rarely less than 50%, except there brownstone facies alteration is highly developed in parts of the core from legs 51-53. No sign is f and of transition to a uniform, highly altered, freenschist facies layer which, if the ophiolite mode' is correct, mus' lie only a short distance below the bottoms of the mes. This evidence gives a very different picture of the proportion of the different metamorphic facies that make up the ocean crust, an . if it proved characteristic of the crust a a whole, would have a drastic effect on the calculation of elemental fluxes. A useful unde: anding of the problem would require some reconciliation c? the evidence from dredging and from drilling, and an integration of this with that from ophiolites. The last section of this paper attempts the first of these, but not the second.

One final point must be made in relation to the calculation of elemental fluxes. The congruent replacement reactions summarised in Fig. 1 are classical metasomatic reactions, and it has long been commonplace in metasomatic calculations that knowledge of the composit... n of the initial and final states is not enough in itself to calculate the elemental flux into or out of the system. Some third piece of knowledge is necessary, usually expressed as the volume of the initial system relative to the final system (Turner and Verhoogen, 1960, p. 563) or that one or more components has remained inert during the transformation(Loughnan, 1969, p. 51). Thus, if quartz (SiO<sub>2</sub>) is transformed to wollastonite (CaSiO3), Ca has certainly entered the system, but whether Si has come in, remained constant, or left the system is not contained in the bare statement that one phase has transformed to the other.

One common way of making the necessary bridge is to assume that volume remains constant during the transformation. Certainly when primary • textures  $aw_2$  well preserved, as with ocean floor metamorphics, then the assumption seems well justified. A classic application of this approach is seen in the serpentinisation of peridotite (Turner and Verhoogen, 1960, p. 318), where the constant volume assumption is justified by arguments from the preservation of primary textures. However, constant volume serpentinication of peridotite requires the removal of large quantities of relatively insoluble Mg and Si from the system, and thus quantities of water orders of magnitude greater than that necessary for the formation of the serpentine minerals themselves. If about 40% expansion in volume is allowed, then the amount of element transport is much reduced, and the result seems altogether more reasonable in terms of water-rock geochemistry. Preservation of texture alone, then, is not enough to justify a constant volume assumption without further evidence. Ta

A more useful approach, especially for the low temperature reactions of the brownstone and zeolite facies, is to assume that some elements have been virtually immobile during the transformation. Cann (1970), Pearce and Cann (1973), Wood et al. (1976) and Humphris and Thompson (1978) have shown, by looking at altered and unaltered rocks, that elements with a high formal ionic charge, such as Ti, Zr, P, Nb, Ta and Hf, are least mobile in such an alteration situation. This is confirmed by analyses of thermal waters, which ar? characteristically very low in such elements, and also in Al (Rittenhouse et al., 1969). Such waters must have formed in association with hot, altering rock, and their poverty in these elements suggests a low solubility in hydrothermal fluids at low temperatures.

Adopting this approach does change radically ones view of elemental fluxes, as is shown by comparing the results of Andrews (1977), who adopts a constant volume approach to the formation of palagonite, with those of Pritchard et al. (1978), using very similar data, by approaching the problem using immobile elements.

#### Modelling metamorphic processes

In this last section I want to construct a model of metamorphic processes within the oceanic crust at mid-ocean ridge crests. I shall first discuss the constraints on any such model, and then put them together to form a single pattern.

The fundamental constraint for such a model must be the relationship between the occurrence of metamorphism and the cooling of the upper oceanic lithosphere by penetrative hydrothermal convection (Elder, 1965; Lister, 1972). Though some of the water for the metamorph. 2 hydration reactions may come from magmatic water, the amount available from that source is strictly limited (c. 0.35%; Moore and Schilling, 1973; Bryan and Moore, 1977), and cannot supply the several percent needed by metamorphic rocks where the degree of alteration is high. Most of this must come from the ocean, some, perhaps from water trapped between basaltic pillows during the initial eruption, but more, especially that reaching the lower crust and upper mantle, from hydrothermal circulation.

The pattern of such circulation will be controlled by the thermal gradient before it

starts, the structure of permeability within the oceanic crust, and the effective thermal diffusivity of the less permeable parts of the crust. The convection will be most .igorous along zones of brecciacion, such as faults, where the permeability will be orders of magnitude greater than through the regions between faults. Heat will be transferred to the fault planes by subsidiary more sluggish convection cells or by conduction. Not only does the ocean crust have a very inhomogeneous structure of permeability, but the structure is also very anisotropic. The most abundant ridge-crest faults are rarallel to the ridge crusts, with a spacing of about 1 km (Searle and Laughton, 1977; Klitgord and Mudie, 1974; Macdonald and Luyendyk, 1977), so that the main convection should be in thin, vertical zones paralleling ridge crests. Transform faults are less sabundant, occurring every few tens of kilometres, and should contribute relatively little to the tctal pattern of hydrothermal circulation.

Lister (1972) has pointed out that hydrothermal convection of this kind is likely to be so efficient at removing heat that it will probably be episodic, with short episodes of active convection alternating with longer episodes of repose while the thermal gradient necessary to restart convection is restored. Another factor affecting the occurrence of convection in time is that permeability changes with time. Thus, in very young crust, faults have yet to develop, and, when faults have been inactive for some time, continued convection will result in the reduction of permeability by the precipitation of materials from solution in the voids of the fault planes. Convection will thus be most active when active faulting is taking place, renewing the highly permeable zones as fast as they are clogged. Such en effect is clearly seen in the hydrothermal veins of the continents (see for example Park and McDiarmid, 1975, p. 122).

Further constraints on metamorphic models come from estimates of water-rock ratios based on isotopic measurements (Heaton and Sheppard, 1977; Spooner et al., 1974, 1977; Muchlenbachs and Clayton, 1972) and hydrothermal experiments (Bischoff and Dickson, 1975; Hajash, 1975). There has been some problem in understanding the meaning of the idea of water-rock ratio in this context, and the confusion seems an essential part of fitting a simple concept to the complexity of a real world. The only application that seems to be reproducible and meaningful is where the ratio refers to the bik water-rock ratio in a whole geothermal system, av raged over all of it. The changes in formulat in suggested by Spooner and Fyfe (1973), while giving a better feel for the quantity of water seen by parts of the system, has the defect of being dependent on the unit of length used for met.urement, since as formulated it is not a dim-nsionless ratio. The results of both isotopic and experimental approaches suggest bulk water-rock ratics of about 1-10, but with considerable variation, and with much larger effective ratios in the more permeable parts of the system.

Elder (1965) introduced another distinction, between open hydrothermal systems (single pass systems), which draw in cold sea water, and vent hot hydrothermal fluids into the ocean, and sealed systems (multi-pass systems) where circulation is sealed beneath a sedimentary cover, and the same water circulates repeatedly. Sealed hydrothermal fluids ar. likely to be better agents of metamorphism than open system fluids, primarily because the mean temperature of the circulating system is higher, but also because of the lower water-rock ratio and the more reducing conditions.

Observations on ophiolites provide further constraints, thour\_ this evidence is not easy to interpret, because of the uncertainty of how far ophiolites represent oceanic crust. However, on Troodos, hydrothermal circulation produced at times massive sulphide deposits above the outvelling limbs of the systems. These deposits were formed close enough to the axis of spreading to be covered by later lavas flows (Gass and Smewing, 1973; Spooner, 1977; Kidd, 1977), probably within 1-2 km, and thus very early in the life of the crust. It is not clear, as I said earlier, how far the metamorphic structure of ophiolites can te extrapolated to the ocean crust, especially in view of the drilling results, and this information will not be used as a constraint.

Some of the evidence from the ocean crust itself is direct, other indirect. Dredging has recovered metamorphic rock from the walls of the median valley in the Mid-Atlantic Ridge (Aumento et al., 1971; Melson et al., 1968; Bonatti et al., 1975), showing that metamorphism occurs very soon after the formation of the crust, as suggested by the evidence from the ophiolitic sulphide deposits. Confirmation of this comes from the very high geothermal gradient at the Lime of metamorphism shown by the telescoping of metamorphic facies covering several hundred legrees within the upper

half of the oceanic crust (Cann, 1968, 1974), the gradational transition from magmatic to metamorphic mineralogy in the ocean floor gabbros (see above), and the observation of hot water emerging very close to the ridge crest at the Galapagos spreading centre (Weiss et al., 1977).

The connexior of the ridge-crest-parallel faults with metamorphism suggested circumstantially in the discussion of permeability above, receives strong support from observations in the mounds area just south of the Galapagos Spreading Centre. The mounds are composed of hydrothermally deposited manganese oxides and clay minerals (Corliss et al., 1978) and clearly represent the vents of hydrothermal systems, perhaps extinct, perhaps intermittently active. They form clusters, aligned along faults of this kind, identified by deep-tow survey (Klitgord and Mudie, 1974), and the hydrothermal circulation that gives rise to them must be associated with the faults.

Very similar faults have been extensively studied by Whitmarsh and Laughton (1976) and Searle and Laughton (1977) in the Atlantic at several places using GLORIA, a long-range side-scan sonar. Their deta suggest that the faults initiate within the median valley, about 1 km from the median line, are active during the rift valley faulting phase, but become inactive after the crust passes the upper rim of the median valley. The mean spacing between these faults is about 1.5 km and individual faults may stretch for as far as 20 km parallel to the ridge crest. A very similar spacing and continuity can be seen in maps of the Galapagos Spreading Centre (Klitgord and Mudie, 1974). How such faults form is controversial, but this is not important here: they appear to be a constant feature of the spreading process, whether the crust becomes rifted eventually or not.

With this basis, it is possible to discuss the metamorphic process relatively exactly. As the ocean crust forms, by some such injection -effusion mechanism as proposed by Kidd (1977), it is at first unmetamorphosed, and hot. Beneath the crust as it forms is a source of magna - perhaps a small isolated magma chamber at slow spreading rates, perhaps a continuous one at higher rates. After about 1 km of spreading the crust fractures with the first ridge-crest-parallel fault. This fracturing terminates downwards in the plastic, nearly molten cap to the magma chamber. Within the fault plane, highly permeable and very hot, intense hydrothermal circulation is initiatec, cooling the crust and producing the main metamorphic effect. This is most complete near to the fault, where the availability of water is greatest, and is much less well-developed in the centres of the blocks, which are relatively impermeable and from which the heat is most easily extracted by conduction. Local waterrock ratios vary from very low at the centres of the blocks to very high near the faults in which the convection is most active.

After this initial very rapid convective

overturn, there is a pause while conductive equilibrium is re-established, and during this time the brittle zone is extended into the mantle. Then, renewed convection is possible, leading to little change in the initial mineral assemblage, but to serpentinisation of the upper part of the mantle followed, very often, by diapiric intrusion of serpentinite to high levels in the crust, especially along faults (Barrett and Aumento, 1970; Cann and Funnell, 1967). Further episodes of convection are milder. They are active in transporting heat out of the crust, and extend the low temperature metamorphic effects into the centres of the less permeable blocks, producing brownstone or zeolite facies alteration there. This low temperature alteration is a slow business, however, and does not become complete for tens of millions of years.

On such a model, the high temperature metamorphic imprint is imposed on the crust very rapidly early in its history, but is largely limited to the edges of crustal blocks, especially along the ridge-crest-parallel faults. Such a picture can help to reconcile the apparently contradictory results of dredging and drilling, since dredging by its nature selectively samples the edges of blocks and the more highly fractured, more permeable rocks, while drilling selectively recovers the massive flow units and less permeable horizons, losing brecciated rock as cuttings that do not enter the core barrel. This picture receives some support from the observations of the unusually complete recovery at sites 417 and 418 in 105 m.y. old Atlantic crust. Here brecciated zones had become cemented and softened, and could be recovered, and from these zones Pritchard (in press) has reported the presence of chlorite, indicating a higher temperature alteration than any seen previously on the Deep Sea Drilling Project.

TECTONIC AND IGNEOUS EMPLACEMENT OF CRUST IN OCEANIC TRANSFORM ZONES

## Enrico Bonatti

Lamont-Doherty Seological Observatory of Columbia University, Palisades, New York 10964

Andy Chermak and Jose Honnorez

Rosenstiel School of Marine and Atmospheric Science, University of Miami, Miami, Florida 33149

Abstract. The following questions are briefly reviewed: (1) Does tectonic emplacement of crust occur in the large oceanic fracture zones? (2) Does igneous emplacement of crust occur in the same? (3) Can fracture zones expose thick sections of oceanic crust?

t i n

es.

tion

NA STAR SALS

On the basis of copographic, geophysical and lithological data, a "secondary tectonized domain" is defined for the large fracture zones. This domain, located on one or both sides of the "main transform domain" (deeper part of the main transform valley), consists of a zone of faulted blocks with intense vertical tectonism which might be related to convergent wrenching in the transform zone. Tectonic emplacement of crust, incorporating also slivers of mantle-derived material, occurs in the secondary tectonized domain. Basaltic rocks with alkaline affinities, found at the St. Paul, Romanche and Owen Fracture Zones may represent examples of igneous emplacement of crust in fracture zones, related mainly to divergent wrenching. The possibility that relatively undisturbed sections of oceanic crust are exposed in some fracture zones is discussed. Possible examples of such sections are given from the Romanche and the Owen fracture zones.

#### Introduction

Among the transform faults which intersect the ocean ridge system a distinction has been made between (a) "boundary" or "initial" transforms, i.e., transforms with long (>100 kms) offset and which constitute an important, permanent or semi-permanent boundary between lithosphere of different age, and (b) small, second generation transforms constituting transient features affecting young, hot lithosphere and probably related only to the geometry of crustal spreading (Gilliland and Meyer, 1976). Small (<50 km) type (b) offsets have been estimated to occur on the average every 50 kms or less along the Mid-Atlantic Ridge (Fox <u>et al</u>., 1976) while the large "boundary" fracture zones are spaced at irregular intervals generally of several hundred kms or more.

Some of the sharpest topographic relief of the ocean floor is associated with the large "boundary" fracture zones. For instance, at the Romanche Fracture Zone (F.Z.) between 18° and 16°W the depth changes within a few tens of km from greater than 7 km below sea level (bottom of the main fracture valley) to less than 1 km below sea level (summit of the transverse ridge on the north side of the fracture valley), with a vertical relief of over 6 km. Thus, thick crustal sections are exposed along the large oceanic fracture zones. The following two questions pertaining to the geology of fracture zones are reviewed briefly in this paper:

1. Do the large oceanic fracture zones expose sections of "normal" oceanic crust [where by "normal" crust we mean crust generated at an accretionary plate boundary (mid ocean ridge)], thereby exposing lower crust? Our direct knowledge of the composition of the lower crust is presently very scant, since drilling has been achieved only through the top few hundred meters of the igneous crust beneath the ocean.

2. Is new crust emplaced along the large oceanic fracture zones by tectonic or igneous processes? This question is related to the first because, if processes of crustal generation are ubiquitous along fracture zones, the probability of their exposing "normal" oceanic crust is low. Moreover, if, in addition to accretionary plate boundaries, crust is generated also along fracture zones, it is of interest to understand the mechanisms and the products of such crustal generation.

## <u>Tectonic Emplacement of Crust in Oceanic</u> <u>Fracture Zones</u>

The ridges commonly found parallel and adjacent to one or both sides of fracture zone valleys (transverse ridges) are clearly caused

Fig. 1. Basement morphology in the Romanche F.Z. region. Location of profiles discussed in this paper is shown: a = profile of figure 4; b = profile of figure 7; c = profile of figure 2. Triangles indicate locations where basaltic rocks with alkaline affinity were recovered.

by tracture zone-related processes, i.e., either tectonic activity or igneous activity or both.

Geophysical data and de\_ailed sampling of sections exposed across some of the large Atlantic and Indian Ocean fracture zones indicate that the fracture zone transverse ridges are generally uplifted blocks of oceanic crust and/or uplifted blocks of oceanic upper mantle.

(a) <u>Uplifted Oceanic Crust</u>. Two examples are shown in Figures 1, 2 and 3, one at the Romanche F.Z. (equatorial Atlantic) and one at the Owen F.Z. (western Indian Ocean).

The north-south section of Figure 2 shows locations where samples were obtained on the transverse ridge on the north side of the Romanche fracture valley at about 17°W. The summit of the transverse ridge is over 2 km above the level of "normal" crust, presumably of the same age, immediately to the north. Rocks obtained on the lower level of the ridge were described by Melson and Thompson (1970) and interpreted as part of a gabbro-ultramafic basic layered complex. These rocks are identical to what generally accepted models predict for constituents of the lower oceanic crust. Basalt, of a type normally encountered in the upper part of the oceanic crust, is the prevalent material recovered at about half-slope on the transverse ridge. Limestones were recovered on, and close to, the summit of the ridge. These limestones, described in Bonatti et al. (1977), were deposited at sea level about 5 million years before the present. It appears,

therefore, that the Romanche F.Z. transverse ridge is in this area a block of crust which has been subjected to intense vertical motion, having reached sea level 5 million years ago and having subsided since at an average rate about one order of magnitude faster than that of crust of equivalent age (Bonatti <u>et al.</u>, 1977).

A subbottom reflection is visible about 100 meters below the summit of the transverse ridge in a seismic reflection profile taken where the limestones were dredged. This reflection has been interpreted as marking the base of the limestone cap (Chermak, 1978). Similar reflections appear in profiles taken across the summit of the transverse ridge about 60 km to the east and 40 km to the west of the profile taken where the limestones were dredged. It is possible, therefore, that the vertical motions documented at the section of figure 2 have affected the transverse ridge for considerable distance.

Figure 3 shows a section across the Owen F.Z., where the transverse ridge on the western side of the sediment-filled fracture valley exposes prevalently lower crustal metagabbroic rocks overlain by upper crustal basalts. This lithology is consistent with the hypothesis that the Owen transverse ridge along this profile constitutes an uplifted block of oceanic crust.

(b) <u>Uplifted Oceanic Mantle</u>. In some sections across the large oceanic fracture zones the transverse ridges have been shown to expose exclusively ultramafic rocks. A spectacular example is at the Romanche F.Z. on the southern wall of the fracture valley between 18°W and

Pig. 2. Seismic reflection profile across the Romanche F.Z. at about 16°45'W (profile C in figure 1). Rock types recovered along this section are indicated.

19°W (figure 4). Here ultramafic rocks were recovered almost exclusively, suggesting they outcrop for a vertical thickness of over 4 km (Bonatti and Honnorez, 1976).

ge

he

nit

st

ed

ere

Another example is provided by the St. Peter Paul Rocks at the St. Paul F.Z., also in the equatorial Atlantic, which constitutes the subaerial summit of a prevalently ultramafic block (Melson <u>et al.</u>, 1972).

An additional example is at the Owen F.Z., close to its intersection with the Mid-Indian (Sheba) axis of spreading (figure 5), where ultramafic rocks, mainly spinel lherzolites, have been shown to be the only material outcropping from the base to the summit of the transverse ridge for a thickness of over 2 km (Bonatti and Hamlyn, 1978).

In the three cases cited above the ultramafic massifs can be interpreted as blocks of uplifted upper mantle. The large size of these bodies makes a lower crustal origin for them unlikely because ultramafic rocks are considered to comprise only a minor constituent of the lower crust. In addition, the texture of the rocks and pressure/temperature estimates based on pyroxenes compositions indicate a mantle derivation in all three cases (Printz et al., 1976; Melson et al., 1971; Bonatti and Hamlyn, 1978). The Owen F.Z. ultramafic protrusion occurs in very young crust (only about 40 km from the axis of accretion). Its rate of ascent in the fracture zone has been estimated at being of the order of 1 mm/year (Bonatti and Hamlyn, 1978).

### Igneous Emplacement of Crust in Oceanic Fracture Zones

Basalts and gabbros have been recovered abundantly from the scarps of fracture zone valleys. These rocks generally have a composition similar to that of basalts from accretionary plate boundaries (ocean ridges). They can be interpreted as having originated at the ocean ridge axis, close to its intersection with the Liansform zone, and having subsequently become exposed on the scarps of the fracture valley during the process of crustal spreading at the edge of the transform zone. The northern side of the Vema fracture valley (Atlantic at 11°N) provides an example of this situation: basalts sampled along the fracture valley scarp at various distances from the axis of spreading show some indication of increase in age with distance from the axis of spreading, and are chemically and mineralogically very similar to samples collected from the axis of spreading, except that they tend to be more altered (Bonatti and Honnorez, 1976; Bonatti et al., 1977).

However, at several sites along some of the

Fig. 4. Seismic reflection profile across the Romanche F.2. at about 18°45'W (profile a in figure 1). Rock types recovered along this section are indicated.

large oceanic fracture zones ignoeus rocks have been recovered with a different petrochemistry from that of basalts from oceanic accretionary plate boundaries. Basalt with alkali affinities and with a light rare earth elements (REE) enriched pattern was collected at the St. Paul F.Z., close to the St. Peter-Paul ultramafic massif (Melson <u>et al</u>., 1967; Frey, 1970). An alkali gabbro with modal nepheline was described from the Romanche F.Z. (Honnorez and Bonatti, 1970).

Similar basalts with alkaline affinities have been recovered at several sites in the Romanche F.2. (figure 1) and the Owen F.Z. They are characterized by: (a) a normative composition which is displaced into or close to the nepheline-normative field relative to the population of ridge-axis basalts which are olivine tholeiites; (b) a clinopyroxene composition different from that of the population of ridgeaxis baselts; for instance, a higher Ti/Al ratio (figure 6); (c) a concentration of several lithophile elements (such as Ba, Sr and Zr) substantially higher than in ridge-axis basalts; (d) a flat or light REE enriched pattern (chondrite-normalized) in contrast to ridge axis basalts which generally display a light REE depleted pattern.

These data, as yet unpublished, suggest that a magma source, different from that which produces oceanic crust at accretionary plate boundaries, is active in the large oceanic transform zones. Thus, igneous emplacement of crust probably does occur in the large fracture zones, even though the volume of crust produced by this process is minor relative to that produced along accretionary boundaries.

## Structure of Oceanic Fracture Zones

Several authors have pointed out that the large oceanic transforms are more complex than just two crustal blocks sliding passively by each other. Dewey (1975) stressed the fact that the large transform faults constitute major plate boundaries, where compressional and tensional stresses of the upper part of the lithosphere may be relieved. Bonatti (1978)

Fig. 3. Seismic reflection profile across the Owen F.Z. (profile b). Location of profile is shown in figure 5. Rock types recovered along this section are indicated.

Fig. 6. Al203/TiO2 ratio in clinopyroxene crystals from basaltic rocks of alkaline affinity from the Romanche F.Z. (see figure 1) and from the Owen F.Z. Shown for comparison is the field for pyroxenes from basalts of oceanic axial zones of spreading and DSDP sites, the bulk of which falls in the shaded area.

discussed the occurrence of anomalous topographic highs (transverse ridges) along many of the large oceanic fracture zones, and the factors determining intense vertical tectonism on these structures. Recent detailed topographic and seismic reflection surveys of large fracture zones such as the Charlie-Gibbs F.Z. (Searle, 1978) and Romanche F.Z. (Chermak, 1978) have shown that these features have a complicated structure with a highly tectonized zone extending for considerable distance on one or both sides of the main transform boundary.

The detailed topographic coverage made possible by the "Gloria" side-scan sonar system allowed Searle (1978) to detect, among other features, sets of oblique faults, striking about 45° from the transform direction, on the margins of the Charlie-Gibbs main transform fault boundary. Searle (1978) pointed out the similarity of these oblique structures to normal faults and tension fractures commonly associated with the early stages of crustal shearing (Wilcox et al., 1973). In fact, Searle (1978) stressed that the topography and structural framework of a longoffset oceanic fracture zone such as the Charlie-Gibbs F.Z. are similar to those of large continental strike-slip fault zones.

Chermak (1978), on the basis of topographic data and of conventional seismic reflection data, also stressed the similarity of the eastern portion of the Romanche F.Z. to large continental strike-slip shear zones such as the San Andreas fault system. Chermak has shown that the transverse ridge on the north side of

the Romanche F.Z. main transform fault boundary (corresponding to the deepest part of the Romanche F.Z. valley) has a complicated structure, with a complex system of faults, some subparallel to the main transform fault direction, some trending obliquely to that direction. This system of faults includes high-angle normal faulting on the summit and southern, internal (i.e., facing toward the deep valley) flank of the transverse ridge, reverse and thrust faulting on its northern, external flank. Both Searle (1978) and Chermak (1978) interpret the complicated structures associated with the large oceanic fracture zones in terms of the concepts of "wrench tectonics" as derived from laboratory experimental models and from observation of large continental shear zones (Moody and Hill, 1956; Wilcox et al., 1963). In their interpretation, the fracture zone transverse ridges consist of a mosaic of faulted blocks created in response to compressional and tensional stresses resulting from the shear motion at the transform boundary. A model on the evolution of the Romanche F.Z. based on the concepts of wrench tectonics has been discussed by Chermak (1978).

The strong vertical tectonic motions documented for fracture zones (see Bonatti et al., 1977) were ascribed by Bonatti (1978) to several factors, the principal being compressional and tensional stresses related mainly to small changes in the spreading direction of the crust adjacent to the transform boundary. This interpretation can be combined with the "wrench tectonics" interpretation of Chermak (1978). In fact, Wilcox et al. (1973) and Emmons (1969) discuss cases of convergent and divergent wrenching on the basis both of clay model experiments and field occurrences. Convergence or divergence can develop locally within a wrench fault where the direction of motion of adjacent blocks is parallel on a regional scale; or they can occur due to non-parallel displacements of adjacent crustal blocks on a regional scale. Both cases are probably common in large oceanic transforms, the latter case resulting from small changes in spreading direction. Convergent wrenching on whatever scale enhances compressive structures, including folding, reverse faulting and thrusting, while divergent wrenching enhances tensional structures, mainly normal faults (Wilcox et al., 1973). Experiments on clay models suggest that even with a small, 2° convergence, important secondary structures are created (Wilcox et al., 1973). Thus, convergent wrenching is probably most effective in causing vertical motions related to the formation of fracture zone transverse ridges.

These considerations lead to a model of the

Fig. 5. Seismic reflection profile across the Owen F.Z. (profile a). Rock types recovered along this section are indicated. Profile b is shown in figure 3.

Fig. 7. Structural scheme of large oceanic fracture zones, based on a section across the Romanche F.Z. at about  $13^{\circ}10^{\circ}W$  (section b in figure 1). For explanation see text.

structure of the large oceanic fracture zones, as shown in figure 7. The main strike-slip fault ("main transform domain") corresponds to the axial, deeper zone of the main fracture valley. On one or both sides of the main frac-ture valley a "secondary tectonized domain" exists, corresponding generally to the transverse ridges, and consisting of a mosaic of faulted blocks subjected not only to strikeslip motions but to considerable vertical motions. The width of the secondary tectonized domain appears to be, very roughly, related to the age of the plate, i.e., its maximum width in a given transform zone is roughly proportional to the length of the transform offset. However, in some cases the secondary tectonized domain appears to be well developed in very young crust (i.e., see section of figure 4 at the Owen F.Z.). In other cases the secondary tectonized domain is well developed on one side of the main transform valley (i.e., south side of the Vema F.Z.) but is absent on the other side (i.e., north side of the Vema F.Z.).

Selates Selector

#### Conclusions

On the basis of the considerations of the structure of oceanic fracture zones outlined in the previous section, and of the lithology of samples recovered from them, some partial answers to the questions posed in the introduction of this paper can be attempted. 246 BONATTI

The "secondary tectonized domain" is interpreted by us essentially as produced by tectonic explacement of crust (incorporating also upper mantle blocks), involving considerable vertical motions. Compression related to convergent wrenching in the transform zone is probably a major cause of this vertical tectonism. The reasons for mantle-derived altramafics to frequently reach high levels in this domain relative to other rock types have been discussed by Bonatti and Honnorez (1976), Bonatti (1976), Francheteau et al. (1976) and Bonatti and Hamlya (1978).

#### Igneous Emplacement of Crust in Fracture Zones

Divergent wienching on a regional scale along a transform zone may lead to extension in a direction perpendicular to the strike of the transform zone (as in the concept of "leaky" transform faults of Van Andel <u>et al.</u> (1971) and Thompson and Melson (1972)), is well as to enhanced tensional structures in the secondary tectonized domain. Igneous activity may occur in zones of extension, preferentially along the main transform fault which probably extends deeper in the lithosphere than the tensional features in the secondary tectonized domain. The alkaline affinity of the basaltic magmas emplaced along the fracture zones may reflect a small degree of partial melting in the source due to limited upwelling, and differentiation during the relatively slow ascent of the acquid.

Both convergent and divergent wrenching can occur commonly along any one long-offset transform, one or the other being prevalent at different times or in different areas. Thus, both tectonic emplacement of crust (favored by convergent wrenching) and igneous emplacement of crust (favored by divergent wrenching) can occur in the same fracture zone at different times and/or locations.

## Sections of Oceanic Crust in Fracture Zones

Whether or not relatively thick sections of "normal" oceanic crust can become exposed in the large fracture zones has been discussed by Bonatti and Honnorez (1976) and Francheteau <u>et</u> al. (1976). Two situations can be envisaged where relatively thick sections of oceanic crust might be exposed in fracture zones.

(1) If the secondary tectonized domain is absent on one side of a transform valley due, for instance, to reduced shear related to slight divergence of the plates on opposite sides of the transform boundary, windows exposing relatively untectonized crust might exist. The north side of the Vema F.Z. might provide a case of this situation, as discussed by Bonatti and Honnorez (1976). Francheteau et al. (1976) argue that the walls of transform valleys consist of many faults each with small vertical offsets, which would allow exposure only of thin sections of the upper crust. This is probably true in transforms with small offset, such as fracture zone A in the FAMOUS area. However, single scarps over several hundred meters high have been observed at the Vema F.Z. by sidesonar methods in a recent cruise of the French vessel Charcot, and by submersible observation in the Cayman Trough area (De Long et al., 1978). In addition, it has been suggested that layer 2 may be thinner than normal in the vicinity of fracture zones because a smaller quantity of basaltic lava is injected at an axis of spreading close to a cold transform boundary. If so, the chemical composition of these basalts could be expected to differ from that of basalts from the axis of spreading away from the fracture zone. However, the composition of basalts from the north side of the Vema F.Z. is idential to that of basalts from the axis of spreading at various distances from the fracture zone (Bonatti et al., 1977), suggesting a normal thickness of layer 2 on the north side of this fracture zone.

(2) If the secondary tectonized domain is cell developed in a fracture zone, it is possible that slivers of crust might be uplifted which preserve, more or less, their original stratigraphy. Possible examples of such uplifted cruatal blocks are the section of figure 2 from the northern side of the Romanche main transform valley, and the section of figure 3 from the Owen F.Z. Detailed field work in these promising areas is required to test this interpretation.

BASALTIC GLASS ERUPTED ALONG THE MID-ATLANTIC RIDGE BETWEEN 0-37°N: RELATIONSHIPS BETWEEN COMPOSITION AND LATITUDE

William G. Melson and Timothy O'Hearn

Department of Mineral Sciences, Smithsonian Institution, Washington, D. C. 20560

Abstract. The basaltic rocks from the upper part of the basement of the Atlantic between the Equator and 37°N have major and minor element signatures which correlate with large latitude intervals. 204 compositional basalt types "ased on electron microprobe analyses of the gla. rinds of pillow lavas fall mainly into two g ups of Recent to Eocene age: a  $0-29^{\circ}N$  group characterized by higher  $10_2$ ,  $Na_20$ ,  $P_205/K_20$ , and lower Ca0 than a  $36-37^{\circ}N$  group Basalt cores from Cretaceous and Jurassic DSDP drill sites suggest migration of the 0-29°N group to the north through time. The higher K20 contents of the 36-37°N ;roup may reflect the influence of a southward longitudinal migration of the postulated Azore's 'thermal plume' magmas. If so, the migration is dammed by the Oceanographer Fracture Zone, which marks the southern limit of this group. High K20 lavas reappear in the vicinity of the Equator, perhaps reflecting on-going activity of the proposed Sierra Leone or St. Paul's Rocks 'thermal plume'.

#### Introduction

Studies of the Mid-Atlantic Ridge are in part aimed at a clear understanding of the process of lithospheric formation at a slowly accreting plate margin. This paper focuses on submarine volcanism, and on but one facet of it; the variation in space and time of the major and minor element composition of the glassy rinds of pillow lavas. It is restricted to the publication and preliminary interpretation of results on samples dredged, drilled, or collected by submersibles between the Equator and 37°N. Samples range in age from Recent to about 150 m.y. (late urassic). The data, in particular, are examined ithin the context of the evolution of the proosed Azores and St. Paul's Rocks 'thermal lumes' during the on-going opening of the lantic Ocean Basin. Sample ages and regional stribution present a long sought opportunity examine these and the many other problems dressed in this volume and so appropriately dicated to Maurice Ewing.

Analyses of glassy pillow rinds are rapidly

and accurately done using the electron microprobe. Numerous investigators are now routinely using such analyses in studies of volcanic glasses from land and beneath the sea. The glass analyses reported here are an extension of work reported previously (Melson, 1973; Melson et al., 1976; Byerly et al., 1977; Melson et al., 19/7). The analyses are for Si, Al, Fe, Mg, Ca, Na, K, Ti and P. Table 1 gives the results for Atlantic abyssal basalts between 37°N latitude and the Equator.

## Comparison of Field Sampling Methods

The analyzed samples come from dredges, drill cores and supmersibles. Each method involves a different sampling capability and are complementary. Dredging involves least control on where samples are precisely collected and least knowledge of the geometric relationships of rock units. Nonetheless, dredging is the least expensive way of obtaining exposed deep sea basement rocks and remains useful in reconnaissance sampling. Also, as shown here, basalt from extensive regions of the Mid-Atlantic Ridge have 'chemical signatures' which were revealed by dredge samples and later substantiated by drill cores and samples obtained by submarines. In and very near the median valley a single dredge has yielded up to 5 compositional basalt types (Nocality A25.40N, table 1) which are probably derived from 5 separate flows. Normally, though, 1 to 2 types of basalt are recovered in a single dredge haul.

Submarines give samples carefully selected in regard to field relationships. Flows of different ages are recognizable and there is excellent control in regard to bottom morphologic features (Heirtzler and Van Andel, 1977). Except in fissures and along fault scarps, the sampling is essentially two-dimensional.

Core drilling of the Deep Sea Drilling Project gives vertical sequences and can provide basement sequences beneath thick sedimentary sections, a capability essential in verifying current plate tectonic theory in regard to sea-floor spreading. Ar present, drilling requires about 40 meters or more of sediment to spud in, a severe limitation

                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                         |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |
