1.0 INTRODUCTION

The work reported herein was sponsored by the Arnold Engineering Development Center (AEDC), Air Force Systems Command (AFSC), Arnold Air Force Station, Tennessee, under Program Element 65807F, and Control Number 9R02-00-9. The results were obtained by ARO, Inc., AEDC Division (a Sverdrup Corporation Company), operating contractor for the AEDC. The test was conducted in the Propulsion Wind Tunnel Facility (PWT), Aerodynamic Wind Tunnel (4T) under ARO Project No. P41C-A9 from September 26 to October 3, 1979. This test provided data in support of the research project "AEDC Dynamic Stability Research," ARO Project Number V32F-09. The AEDC Research Monitor was Mr. Alexander F. Money, and the Test Project Monitor was Mr. Bob L. Uselton of ARO, Inc. This work is a continuation of the work reported in Refs. 1 and 2.

The objective of the test was to determine sting-support interference effects on the measurements of static and dynamic stability derivatives and base pressure. This included: (1) defining critical sting length by the measurement of pitch-damping derivatives for two frequencies of oscillation, (2) investigating the effect of sting length on yaw-damping derivatives as a function of angle of attack, and (3) investigating the effect of splitter plates, located behind the model, on pitch damping derivatives.

The model was a 15 percent spherically blunt 7 deg cone. Data were obtained at a constant model oscillation amplitude of \pm 1 deg, using the VKF (von Karman Facility) 1.C Forced Oscillation Test Mechanism. Two frequencies of oscillation, nominally 5.6 Hz and 3.1 Hz, were tested. At the high frequency, both pitch-damping and yaw-damping data were obtained as a function of angle of attack (0 to 28 deg) at Mach numbers 0.2 to 1.3. At the low frequency, pitch-damping data were obtained at angles of attack of 0 to 20 deg at Mach numbers 0.2 to 0.9. The effective sting length was varied from 1 to 3.4 model diameters by extending a conical flare to various stations along the sting. Two model wake splitter plates were also investigated. The Reynolds number based on model diameter ranged from 0.2 x 10⁶ to 3.6 x 10⁶ and the reduced frequency parameter varied from 0.006 to 0.049.

A microfilm copy of the final data has been retained in the PWT at AEDC. Inquiries to obtain copies of the test data should be addressed to AEDC/DOT, Arnold Air Force Station, Tennessee 37389.

2.0 APPARATUS

2.1 TEST FACILITY

The Aerodynamic Wind Tunnel (4T) is a closed-loop, continuous flow, variable-density tunnel in which the Mach number can be varied from 0.1 to 1.3 and can be set at discrete Mach numbers of 1.6 and 2.0 by placing nozzle inserts over the permanent sonic nozzle. At all Mach numbers, the stagnation pressure can be varied from 400 to 3400 psfa. The test section is 4-ft square and 12.5 ft long with perforated, variable porosity

(0.5- to 10-percent open) walls. It is completely enclosed in a plenum chamber from which the air can be evacuated, allowing part of the tunnel airflow to be removed through the perforated walls of the test section. The model support system consists of a sector and boom attachment which has a pitch angle capability of -7.5 to 28 deg with respect to the tunnel centerline and a roll capability of -180 to 180 deg about the sting centerline. A more complete description of the tunnel may be found in Ref. 3.

2.2 TEST ARTICLE

The model was a flat base 7-deg half angle cone with a nose bluntness ratio (nose diameter to base diameter) of 15 percent. The moment reference axis was located on the model pivot axis at 60.9 percent of the model length aft of the model nose. The model was constructed of stainless steel and had a total weight of 30.4 lbs and a moment of inertia about the pivot axis of 0.408 slug-ft². A sketch of the model and external dimensions is shown in Fig. 1.

Rings of stainless steel coated with carborundum grit were used as boundary layer trips at some of the test conditions. These trip rings were spotwelded to the model just behind the model nose. Trip details and the location on the model are shown in Fig. 2.

The model, when mounted to the Test Mechanism (described in Section 2.3 below), had an effective sting length of 3.4 model diameters and an effective sting-to-model diameter ratio at the model base of 0.22. The effective sting length was shortened by positioning a conical flare (Fig. 3) at 3.3, 3.0, 2.5, 2.0, 1.5, or 1.0 model diameters to the rear of the model base. The flare was mounted to the motor housing such that it did not touch the sting forward of the motor housing. This eliminated the possibility of the flare's changing the sting frequency characteristics or model tare damping. This sting configuration and the associated conical flare components were designed and bulit at AEDC by the VKF, and were also used during the Ref. 1 and 2 tests.

Two types of model wake splitter plates, which attached to the conical flare, were also investigated. A circular clamp was attached to the long plates (No. 8 Plates) to minimize vibration at the forward end of the plates. Neither the clamp or the plates touched the sting. Plate details are shown in Fig. 4, and plate installation details are shown in Figs. 5 and 6.

A sketch of the model installation is presented in Fig. 7. A photograph showing a typical model-sting configuration in the test section is shown in Fig. 8.

2.3 TEST MECHANISM

The VKF 1.C Forced Oscillation Test Mechanism (Figs. 9 and 10) utilizes a cross flexure pivot, an electric shaker motor and a onecomponent moment beam which is instrumented with strain gages to measure the forcing moment of the shaker motor. The motor is coupled to the moment beam by means of a connecting rod and flexural linkage which convert the translational force to a moment to oscillate the model at amplitudes up to ±3 deg (depending on flexure balance) and frequencies from 2 to 8 Hz. The cross flexures, which are instrumented to measure the pitch/yaw displacement, support the model loads and provide the restoring moment to cancel the inertia moment when the system is operating at its natural frequency. The moment beam is not subjected to the static loads, and can be made as sensitive as required for the dynamic measurements.

Two different sets of cross flexure pivots were used to obtain data at the high and low oscillation frequencies. The high frequency (\approx 5.6 Hz) was obtained with the 0.150 in. thick cross flexures, having a stiffness of 466 ft-lb/rad. These were used for Runs 4 to 199, inclusive. The low frequency (\approx 3.1 Hz) was obtained with the 0.100 in. thick cross flexures, having a stiffness of 141 ft-lb/rad. These were used for Runs 200 to 270, inclusive. The same moment beam was used throughout the entire test. It has a thickness of 0.046 in., and is capable of measuring a total moment of 9.8 inch-lbs.

The cross flexure pivot, moment beam, and flexural linkage assembly, which is referred to as the Balance Assembly (Fig. 10b), is supported by a long, slender cylindrical sting with a 1 deg taper. The sting is instrumented with strain gages to measure the static and oscillatory deflections of the sting in both the pitch and yaw planes.

A penumatic- and spring-operated locking device is provided on the balance to hold the model during tunnel start-up and shut-down. More detailed information regarding the VKF 1.C Forced Oscillation Test Mechanism may be found in Ref. 2.

2.4 TEST INSTRUMENTATION

2.4.1 Forced Oscillation Instrumentation

The forced-oscillation instrumentation (Ref. 4) utilizes an electronic analog system with precision electronics. The control, monitor, and data acquisition instrumentation are contained in a portable console that can be easily interfaced with the instrumentation of the various wind tunnels at AEDC.

The control instrumentation provides a system which can vary the oscillation amplitude of the model within the flexure limits. The oscillation amplitude is controlled by an electronic feedback loop which permits testing of both dynamically stable and unstable configurations.

Data are normally obtained at or near the natural frequency of the model flexure system; however, the electronic resolvers permit data to

be obtained off resonance. All gages are excited by d-c voltages, and outputs are increased to optimum values by d-c amplifiers. Typical balance outputs from an oscillating model are composed of oscillatory components (OC) superimposed on static components (SC). These components are separated by bandpass and lowpass filters. The SC outputs are used to calculate the static moment coefficients and static sting deflections. The OC outputs are input to the resolver instrumentation and precise frequency measuring instrumentation. The resolvers utilize very accurate analog electronic devices to process the OC signals and output d-c voltages. The output d-c voltages are porportional to the amplitude squared, the in-phase and quadrature (90 deg out-of-phase) balance components (forcing torque), and the in-phase and quadrature sting components. An analog-to-digital (A/D) converter converts these outputs to digital signals. The data are recorded for a period of time selected from approximately 2 to 60 sec at a sample rate appropriate for the type test and wind tunnel.

2.4.1 Model Base Pressure Instrumentation

Model base pressures were measured with 2 Sunstrand (Kistler) 314D Servo pressure:transducers located on the tunnel plenum chamber wall. The locations of the orifices with respect to the model and sting are shown in Fig. 11.

3.0 TEST DESCRIPTION

3.1 TEST CONDITIONS AND PROCEDURES

3.1.1 General

A summary of the nominal test conditions at each Mach number is listed below.

<u>M</u>	PT, psfa	TT, deg R	Q, psf	P, psf	V, ft/sec	<u>REx10⁻⁶,ft⁻¹</u>	REDx 10 ⁻⁶

*Primary Test Conditions

The reduced frequency parameter at the high oscillation frequency (\approx 5.6 Hz) ranged from 0.008 radians at Mach number 1.3, to 0.049 radians at Mach number 0.2. At the low oscillation frequency (\approx 3.1 Hz), it ranged from 0.006 radians at Mach number 0.9, to 0.027 radians at Mach number 0.2.

The variables for each configuration are listed in Table 1. The Test Summaries, which contain all configurations tested and the variables for each, are shown in Tables 2 and 3. Table 2 contains the summary of the model boundary layer and trip effectiveness investigation (Runs 26 to 46), and Table 3 contains the summary of the support interference investigation (Runs 49 to 269).

Testing procedures in the yaw oscillation plane were identical to those in the pitch plane, except that the entire forced oscillation mechanism was rolled +90 deg (PHIB = 90).

3.1.2 Data Acquisition

After establishing tunnel conditions and model attitude, the model was unlocked, and brought to a constant oscillation amplitude of ±1 deg by using the Forced Oscillation Control System. The system was allowed to stabilize at the system resonant frequency before data were recorded. At each angle of attack, generally two data points were taken. Data were obtained over a 60 second time interval at each data point. The balance and sting gage outputs and frequency instrumentation were read from the forced oscillation instrumentation console by a Digital Data Acquisition System (DDAS), at a rate of approximately 54 samples per second.

The Automatic Model Attitude Positioning System (AMAPS) was used to control the model position. A list of model angle of attack requirements were programmed into the AMAPS prior to the test. After data were obtained at a given angle of attack, the AMAPS was manually activated, and the model was automatically pitched to the next angle of attack on the AMAPS list.

3.2 DATA REDUCTION

Data from the DDAS were combined with tunnel model attitude and base pressure instrumentation data and sent directly to a DEC-10 System Computer. Average values of the balance and sting gage outputs were calculated by the computer, and used in conjunction with the remaining DDAS outputs to calculate the dynamic derivatives. Both the SC and OC sting gage outputs were used to correct the data for sting bending effects. The method used to reduce the data is given in Refs. 4 and 5.

A print-out of each reduced data point was obtained approximately 2 minutes (Real Time) after the DDAS sent the unreduced data to the computer. Summary data were printed-out at the conclusion of each angle of attack sweep. Reduced data were also plotted during the test, using the IBM-370 computer Interactive Graphics System, which received the reduced data from the DEC-10. Usually, the data were available for plotting on the IBM-370 Graphics System within the same amount of time (2 minutes Real Time) as the reduced data print-out. This enabled close monitoring of the data during the angle of attack sweep, and allowed cross plots (cross checks) to be made with similar configurations obtained earlier in the test.

3.3 UNCERTAINTY OF MEASUREMENTS

In general, instrumentation calibrations and data uncertainty estimates were made using methods recognized by the National Bureau of Standards. Measurement uncertainty is a combination of bias and precision errors defined as:

$$U = \pm (B + t_{q5}S)$$

where B is the bias limit, S is the sample standard deviation, and t_{95} is the 95th percentile point for the two-tailed Student's "t" distribution, which for degrees of freedom greater than 30 is equal to 2.

Estimates of the measured data uncertainties for this test are given in Table 4a. With the exception of the Test Mechanism, data uncertainties are determined from in-place calibrations through the data recording system. Static load hangings on the Forced Oscillation Mechanism simulated the range of loads and deflections anticipated during the test, and measurement errors are based on differences between applied loads and deflections and corresponding values calculated from the mechanism calibration. Load hangings to verify the sting and balance calibrations are made in the tunnel prior to testing using a special calibration model.

Propagation of the bias and precision errors of measured data through the calculated data were made in accordance with Ref. 6. Uncertainties in the calculated tunnel parameters are given in Table 4b, and uncertainties in the dynamic parameters are given in Table 4c.

The quoted uncertainties are based upon steady-state operation and do not reflect the effects of the wind tunnel environment. In some instances the damping data (CLMQ) will show slightly larger scatter in the repeatability, usually on the order of about 5-10 percent. Also, the large quoted uncertainties for CLMA are the result of the small magnitude of the measurement and the fact that the wind-on measurement level is about the same level as the wind-off measurement (particularly at lower angles of attack).

4.0 DATA PACKAGE PRESENTATION

The Data Package includes tabulated and plotted data, data notes, run logs, and nomenclature. The tabulated data includes summary data, point-by-point data, wind-off tare data. and torque calibration data. Plotted data include (1) individual plots of CLMQ, CLMA, CLMT, and PB2 as functions of angle of attack, and (2) comparison plots which depict sting length ratio (LS/D), Reynolds number, frequency, and splitter plates effects. A sample of the Tabulated Data and Plotted Data is presented in Appendix III.

Verification plots of the pitch-damping data and base pressure ratio data are shown in Fig. 12. The plots indicate good agreement between the extrapolation of the present results $(0.2 \le M \le 1.3)$ and the previous supersonic-hypersonic results $(2.0 \le M \le 8)$ reported in Refs. 1 and 2.
