| The effect of temperature and moisture on the fatigue properties of AS/3501-6 composite was explored. This includes the design of a fatigue specimen, its fabrication procedure, displacement and temperature monitoring technique, and analysis/data correlation. The specimens used were of layup [90] ₂₀ and [±45] ₂₀ . The fatigue load ratio was set at 0.1 and the cyclic frequency was set at three hertz. No appreciable heat was generated in the 90° specimen during fatigue. The ±45 specimens experienced appreciable | | |

temperature increases at various environments. Test data from a fatigue tension test was generated to supplement the analysis of predicting the temperature distribution in the specimen due to continuous heat generation experienced by the ~~45~~ specimen. A probabilistic fatigue failure model derived from the concept of crack propagation in viscoelastic material was used for the data analysis. The temperature effect and moisture effect was accounted for by this analysis model.

FOREWORD

This study for the Phase II program entitled "The Effect of Environment on Mechanical Behavior of AS/3501-6 Graphite/Epoxy Material" was conducted by Vought Corporation Advanced Technology Center and was sponsored by the Naval Air Systems Command under Contract Number N00019-78-C-0599.

Mr. M. Stander was the Navy Project Manager and Dr. W. J. Renton was the Vought Program Manager. Other key personnel are Dr. T. Ho, Principal Investigator, Dr. D. H. Petersen, Technical Coordinator, and Dr. R. A. Schapery, Technical Consultant.

This study was conducted from September 1978 through August 1979.

1.0 INTRODUCTION

Wide usage of advanced composite materials in aerospace systems is projected to become a reality over the next ten years. A V/STOL fighter aircraft is one of several Navy articles projected to be increasingly dependent on composite materials for primary and secondary structural components.

Presently, it is known that many realistic service loads and environments have a significant adverse effect on the performance of advanced composite materials. The material's response characterization procedures in severe environments and related fatigue lifetime prediction methods are presently insufficient. This complete research program will assist in resolving this deficiency in the technology base. This in turn will help to ensure that confident usage of advanced composite materials by the stress analyst and designer can be attained in the near future.

The overall objectives of this research program are:

- 0 To ascertain if the mechanical response of AS/3501-6 graphite/epoxy composite material, subject to various time, temperature and moisture effects, can be characterized using traditional viscoelastic shift factors, and to formulate a master curve of material property dependence on time, temperature and humidity.
- 0 To ascertain the feasibility of predicting fatigue failure of a composite material by accounting for the linear viscoelastic behavior of the resin in various temperature and humidity environments.
- 0 To determine if a specific thermal conditioning environment can be directly substituted for a specific moisture conditioning environment over a prescribed temperature vs. humidity range for AS/3501-6 graphite/epoxy material, and obtain an equivalent moisture effect on mechanical and fatigue properties. If this can be shown, a substantial cost and time savings in moisture conditioning of the test specimen can be achieved and possibly extended to other composite specimens.

During the first phase of this program, the basic static properties of AS/3501-6 graphite/epoxy composite material, subjected to various temperature and humidity environments, was characterized through linear viscoelastic theory. The first and third objectives were achieved, at least for the environments investigated. This report covers exploratory research to study the second objective, which calls for the fatigue characterization of composite material in various temperature and humidity environments. Tests of fatigue specimens with basic laminate layups of 90° and $\pm 45^\circ$ were successfully conducted within several severe environments. Internal damping of the $\pm 45^\circ$ specimens created a considerable temperature rise in the course of fatigue cycling.

An analytical study of fatigue failure prediction methodology based on the fatigue test results was begun in Phase II and will be pursued during the Phase III segment of this program, and thereby initially determine the extent to which viscoelastic behavior is a necessary factor in predicting the fatigue failure of composite materials.

2.0 SPECIMEN FABRICATION AND CONDITIONING

2.1 SPECIMEN FABRICATION AND QUALITY ANALYSIS

Hercules AS/3501-6 prepreg tape was used to prepare the specimens for this program. Four composite panels, as shown in Table 1, were fabricated by Vought's Manufacturing Research and Development Division per the fabrication procedure in Table 2 recommended by Hercules. Panels A and B of Table 1 were for 90° specimens and panels C and D were for $\pm 45^{\circ}$ specimens. Each panel was inspected with ultrasonic C-scan by a 5-MHz transducer (40 dB level for 90° panels and 45 dB level for $\pm 45^{\circ}$ panels). Only panel A was shown to possess a defect area. A process control panel was separately made to evaluate the quality of the panels. The mechanical properties of the specimens from the process control panel are summarized in Table 3. The flexural strength, flexural modulus and short beam shear results indicate that our panels yield acceptable properties as compared with vendor published values for AS/3501-6 composite.

A typical fatigue specimen 7.0" long by .75" wide is shown in Figure 1. A specimen fabrication procedure that is capable of minimizing the edge defects was developed as shown in Figure 2. A comparison of the composite's finished cut surfaces as obtained from using different cutting techniques is shown in Figure 3. Upon inspection of the 40X photomicrograph, it becomes apparent that a wafering diamond cutter produces a better surface finish than those produced by a carbide bandsaw, radial diamond saw, or 400 grit fine sandpaper. Most machining defects seem to have disappeared on the wafering cut surface, including the edge area. Approximately 130 90° -specimens and 130 $\pm 45^{\circ}$ -specimens were subsequently fabricated according to Figure 2 and used for testing in this program.

The finished thickness of the 90° -specimen is approximately 0.10 inches (20 plies) which is considered to be thick enough to avoid normal handling damage of 90° -specimens. The thickness of the $\pm 45^{\circ}$ -specimens is around 0.04 inches (8 plies) which is designed to be thinner than that of the 90° -specimens in order to transfer sufficient load through the bonded tab area without inducing a bond tab failure during the fatigue test.

TABLE 1. COMPOSITE PANELS FOR THE PROGRAM

| PANEL NO. | LAYUP ORIENTATION | DIMENSION | C-SCAN READING |
|-----------|-----------------------|------------------|-----------------------------------|
| A | $[90^\circ]_{20}$ | 48" x 16" x .1" | One Defect Area With Size 5" x 1" |
| B | $[90^\circ]_{20}$ | 20" x 16" x .1" | No Defect |
| C | $[\pm 45^\circ]_{2S}$ | 48" x 16" x .04" | No Defect |
| D | $[\pm 45^\circ]_{2S}$ | 20" x 16" x .04" | No Defect |

TABLE 2. THE LAYUP PROCEDURE AND CURE CYCLE FOR AS/3501-6

The layup procedure was:

- o Clean all tooling
- o Apply a mold release agent to the tooling
- o Cover both surfaces of the layup with peel ply
- o Cover both surfaces of the layup with TX-1040
- o Position the layup on the tool
- o Apply the cork dam and 6 bleeder plies
- o Cover the layup with nylon film
- o Cover the layup with two plies of fiberglass bleeder cloth
- o Install the layup in a vacuum bag and place in an autoclave

The cure cycle was:

- o Apply 25" Hg minimum vacuum
- o Apply 10 psi autoclave pressure
- o Heat to $350 \pm 5^\circ\text{F}$ (5-10°F/min rate)
- o Apply 90 ± 5 psi autoclave pressure when the panel reaches $275 \pm 5^\circ\text{F}$ (DO NOT VENT)
- o Maintain the laminate at $350 \pm 5^\circ\text{F}$ for 120 ± 5 minutes
- o Cool slowly to below 150°F (Cool no faster than 5°F per minute - Cool down should take approximately 45 minutes)

FIGURE 3. SPECIMEN EDGE SURFACE FINISHES OBTAINED THROUGH
VARIOUS KINDS OF CUTTING TECHNIQUES.

Each individual specimen was examined under a microscope (16X or 25X magnification) to ascertain the presence of porosity and/or possible machining defects. The texture of the edge of a typical specimen is shown in Figure 4. Those surfaces were prepared using a wafering cutter. Most specimens were of high quality. This is a good indication that machining defects have been minimized in the preparation of the current batch of specimens and that the scatter of data would also be more confined.

Although care was taken in specimen preparation, certain defects still existed in some specimens, especially 90°-specimens. Those defects are classified as porosity, carbide cut and surface peel and are shown in Figures 5 and 6 respectively. All three types of defects represent flaws or notches that may have a bearing on the crack propagation in the fatigue specimens. The surface peel defects result from removing the peel ply from the surface of the cured panels. Surface peel defects were found in only two incidents. The average void content in the 90°-specimens was 1.3% based on the photomicrograph pictures. Porosity defects are normally found in only those specimens that have void content in excess of roughly 2.5%. Porosity defects were not found in the $\pm 45^\circ$ specimens. Carbide cut defects were created by accidentally touching the carbide bandsaw to the edge of the specimen during the cutting of the tabs. Both the carbide cut defect and surface peel defect will be called machine defect in the future quality analysis discussion.

Carbide cut defects on 90°-specimens were removed by sanding the defect surface using 400 grid sandpaper. Porosity defects and surface peel defects were left untreated. The purpose of the above defect observations was to understand the specimen quality and to identify the parameters that might cause a relatively large fatigue data scatter.

2.2 MOISTURE ABSORPTION STUDY AND SPECIMEN CONDITIONING

In the process of conditioning the specimens at elevated temperatures and humidities, microcracks may be created in the specimen. Since this program is primarily a fatigue life study, it is important to not introduce any significant damage from conditioning. Several specimens were examined after they had been conditioned to moisture saturation at 200°F. As shown in Figure 7, cracks

(b) Cracks in $\pm 45^\circ$ Specimen (590X)

FIGURE 7. CRACKS IN SPECIMENS THAT WERE CONDITIONED
IN 200°F/95% R.H. ENVIRONMENT.

were observed in both the $\pm 45^\circ$ and 90° specimens conditioned in the $200^\circ\text{F}/95\%$ R.H. environment. Cracks were not observed in specimens from Phase I program that were conditioned in the $200^\circ\text{F}/71\%$ R.H. environment or room temperature environment. Thus, specimens designated for testing at various temperatures in a 50% and 95% R.H. environments were conditioned for moisture absorption in a 170°F .

An enclosed glass chamber and a forced air oven were used to environmentally condition the specimens to the desired moisture level. A saturated aqueous solution of Sodium Bromide (NaBr) in contact with a solid phase of the salt at 170°F temperature was used to generate the 50% relative humidity level and that of Sodium Fluoride (NaF) was used to generate the 95% relative humidity level. The length of time required to attain 95% saturation was determined by moisture absorption tests. Two square samples with dimensions $0.75'' \times 0.75'' \times 0.1''$ were placed in the $170^\circ\text{F}/95\%$ R.H. environment for conditioning. The moisture absorption result is shown in Figure 8. It is apparent that 85 days of conditioning is necessary to insure that the specimens with a $0.10''$ thickness attain at least 95% saturation at the 170°F temperature environment. Based on results from Shen and Springer², eighty-five days of conditioning for a specimen with a $0.10''$ thickness will translate to fifteen days of conditioning for $\pm 45^\circ$ specimens which have a $0.04''$ thickness. Thus the 90° -specimens were conditioned for at least 85 days and the $\pm 45^\circ$ specimens for a minimum of 15 days in the 170°F environments (either 95% R.H. or 50% R.H.) before initiating the physical tests.

During the environmental conditioning, fatigue specimens were positioned in three-level steel racks in the glass chamber. The three-level steel racks can house up to forty-eight specimens and were designed for ease of specimen tracking and handling. Before conditioning, tab areas of all the specimens were coated with Ecco-coat VE on top of the scotch tape to prevent adhesive degradation by moisture ingress so that the bonding strength of the adhesive in the tab area could be maintained at the desired level (around 5000 psi for the bonding adhesive) during the fatigue test.

FIGURE 8. MOISTURE ABSORPTION OF 90°-SPECIMEN UNDER 170°F/95% R.H. ENVIRONMENT

3.0 MECHANICAL TESTS

3.1 TEST MATRIX AND TEST INSTRUMENTATION

Specific tests that were conducted in this program are shown in the test matrix, Table 4. Baseline data on the fatigue load levels employed in test Item C, were determined by static strength tests from ITEM A of the test matrix. Hysteresis tests (Item B) were conducted at various stress levels and frequencies within various environments to evaluate the temperature rise due to heat generation. Fatigue tests (Item C) were conducted at various environments by keeping the mean stress level and environment unchanged during the cycling. Creep-recovery tests (Item D) were conducted to verify that the long term creep-recovery results are predictable from previous obtained short-term data.

Half of the fatigue specimens had their displacement monitored continuously during testing with the environmental extensometer which Vought developed for the Phase I program. Each extensometer was conditioned in a 180°F dry environment for two weeks to study the long term exposure effect on its data gathering accuracy. As shown in Figure 9, the calibration of the LVDT after the conditioning duplicates its calibration before the conditioning. Thus, extensometer readings were assumed to remain stable throughout the test program. Two sets of extensometers were used alternately. All the $+45^{\circ}$ -specimens and selected 90° -specimens had one resistor type temperature sensor (ETG-50B from Micro-Measurements) to monitor the continuous temperature reading of the specimen during fatigue cycling. The temperature sensor was encapsulated between two pieces of $0.5'' \times 0.5'' \times 0.004''$ stainless steel plates, as shown in Figure 10, and is attached to one side of the specimen by using a small U-shape steel spring clamp.

3.2 CREEP-RECOVERY TESTS

Numerous creep-recovery tests were conducted in the Phase I program to study the effect of environment on the mechanical behavior of AS/3501-6 composite material. Those creep-recovery tests were all one hour in duration - 15 minutes loading and 45 minutes unloading. In order to validate the applicability of the test results from a one-hour test to the accurate prediction of long term composite material properties, creep-recovery tests with a one-day loaded and three days unloaded profile, were conducted at the 176°F/50% R.H. environment which is one of the environments used in the Phase I program. The specimen used was a $+45^{\circ}$

FIGURE 10. TEMPERATURE SENSOR MOUNTED ON SPECIMEN IN THE ENVIRONMENTAL TEST CHAMBER.

specimen which had been cycled in creep-recovery several times in short duration (two cycles per minutes). The creep-recovery test setup is shown in Figure 11. Due to the capability of the test equipment, two creep-recovery cycles were completed. The 8-day creep-recovery test result is shown in Figure 12. The second cycle is used for data analysis. Based on the discussion in the Phase I program, (section 6.0 of Reference 1) the creep compliance, ϵ/σ , of AS/3501-6 composite material can be represented by the power law equation:

$$D = D(t, T, H) = D_0 + D_1 t^n = D_0 + D_1 \left(\frac{t}{a_T a_H} \right)^n$$

By plotting the creep data vs. various values of n , we were able to find, from the compliance D vs. t^n plots in Figure 13, that $n = 0.18$ gives the best straight line data fit based on creep-recovery data of the second cycle in Figure 12. That is, 0.18 is the best value for the exponent in the power law equation (1) at 176°F/50% R.H. environment. The exponent value, 0.18 was also the result from short term creep-recovery test data developed in the Phase I program and it is a value that is appropriate for the environments studied (there are small fluctuations of n value at different environments). By using equation (1) and Figure 13, one can obtain values of initial compliance D_0 and transient compliance D_1 . Together with the data from the Phase I program, the power law constants presently obtained are shown in Figure 13. If the creep-recovery test had been continued into the third or fourth cycle, the values of D_0 and D_1 may have been closer to those found previously. But, as noted below, there is a difference in conditioning environments for the earlier and current tests, which could account for at least some of the difference in the values of D_0 and D_1 .

3.3 STATIC TESTS

Since a new procedure was used to fabricate the Phase II specimens and the specimens were conditioned in the 170°F wet environment instead of the 200°F wet environment used in Phase I, new static tests in tension were conducted. The load rate for the static tests was set at 250 lb/min and the displacement in the gage section of the specimen was monitored by using the extensometer system that was developed in Phase I. Before testing, specimens were moisture saturated to their

respective moisture level in the 170°F wet environment for at least eighty-five days for 90°-specimens and at least fifteen days for $\pm 45^\circ$ -specimens to attain at least a 95% moisture saturation level. The test results for the 90°-specimens and $\pm 45^\circ$ -specimens are listed in Tables 5 and 6. The static results from reference 1 are also listed for comparison. The specimens which were tested in the "AS FAB" condition were specimens that were kept and tested within the test laboratory environment within one month after fabrication.

Three distinct types of failure modes, namely edge, gage and hole, were used to describe the failure location within the 90°-specimen. They are described by the pictures in Figure 14. The strength of the 90°-specimens was improved roughly 4% through use of the new fabrication procedure. Its typical stress-strain curves are shown in Figure 15. The material response gradually becomes non-linear when it approaches the failure point. From Table 5, the secant stiffness of the 90°-specimen (secant modulus at 2000 $\mu\text{in/in}$) decreases as the temperature and relative humidity becomes more severe. Ultimate strength and ultimate strain of the material in Figures 16 and 17 reflect an effect of residual stress (inherited from 350°F curing).

Failure modes of gage type and edge type were observed on $\pm 45^\circ$ -specimens under static load (Figure 18). A gage type failure mode is one where the failure area is confined between two end tabs. An edge type of failure means that the tab end of the specimen is adjacent to the failure location. Edge delamination was observed to start forming around 65% of the ultimate load level for "AS FAB" specimens. The failure location and the worst delamination area do not necessarily coincide.

Typical stress-strain curves for $\pm 45^\circ$ specimens within three environments are shown in Figure 19. Material behavior is highly nonlinear after approximately a 7500 psi stress level is attained. The sample can sometimes be stretched to 90,000 $\mu\text{in/in}$ before failure and creates a necked-down shape over the gage section of the specimen. Secant moduli at various environments are calculated at a 5000 $\mu\text{in/in}$ strain level and are also shown in Table 6. The strain level, 5000 $\mu\text{in/in}$, is an upper strain region for comfortable design application. Based on the results of Table 6, static failure of $\pm 45^\circ$ specimens tended to be gage failures. This phenomenon is probably due to the tab constraining the surface from peeling in the tab area and the necking of the gage section. The static results indicate that specimens made by using a wafering cutter technique did not improve properties significantly over those specimens that were made by using

a carbide bandsaw technique. This is because the machine defects or cracks as caused by higher temperature conditioning of the specimen will effect the crack propagation mechanism most in fatigue loading mode. The effect of environment on the ultimate strength and ultimate strain are shown in Figures 20 and 21 respectively.

3.4 FATIGUE TESTS

All the fatigue specimens were tested using a pin-load type loading fixture within the Shore Western Environmental Test Machine. They had 0.25" holes drilled through the two end tabs before they were put into the controlled environments for moisture absorption.

The fatigue test frequency was set at 3 Hertz with the load ratio being .1. Two specimens were tested at the same time. Specimens tested at one hydraulic station had a temperature sensor attached to it. The specimen tested at the other hydraulic station had both a temperature sensor and an extensometer attached to it. Diagrams depicting the fatigue test set-up are shown in Figures 22 and 23. The displacement in each specimen is measured by the extensometer. The LVDT signals in the extensometer are recorded on the strip chart recorder. The temperature in the specimen is monitored by the temperature sensor (ETG-50B from Micro-Measurements) and is recorded on the strip chart through the Vishay 2120 amplifier. Maximum fatigue stress levels were 70%, 60%, and 45% of the ultimate tensile strength and the environments were 75°F/50% R.H., 132°F/50% R.H., 132°F/95% R.H., 170°F/50% R.H. and 170°F/95% R.H.,. The selected stress levels produced fatigue tests of adequate duration.

A typical displacement history for a 90° specimen during fatigue testing is shown in Figure 24 (reproduced from Reference 1). The two black lines are LVDT traces and their average is the displacement of the two inch gage section of the specimen. Typical load and displacement curves for a ± 45° specimen are shown in Figure 25. The creep of displacement under combined mean and oscillating load is obvious for the ± 45° specimen. It demonstrates essentially the viscoelastic shear response of the composite under axial tensile load.

FIGURE 25. TYPICAL STRIP CHART RECORDING OF LOAD AND DISPLACEMENTS FOR $\pm 45^\circ$ -SPECIMEN DURING FATIGUE.

A summary of the fatigue test results is tabulated in Tables 7 to 16. The failure mode definition for fatigue is identical to that for the static specimens shown in Figures 14 and 18. Residual strength tests of unfailed fatigue specimens were conducted only if unusual circumstances happened in the test laboratory (such as equipment malfunction or electric power disruption). Most fatigue failed specimens were compared for defects vs. those defects observed while they were in their as-fabricated state as discussed in Section 2.1

The defect analysis of the as-fabricated specimens, such as high porosity obtained from C-scan results or photomicrographs and machining defects observed in microscope examination, is described in Tables 7 to 16 in the specimen quality column. By excluding the data obtained from the defective specimens, specimens that failed in the hole area and specimens that failed by laboratory incidences, the conventional S-N curves based on data in Tables 7 to 16 is shown in Figures 26 and 27.

3.5 HYSTERESIS TESTS

Under a cyclic driving force, the internal damping of a viscoelastic material will cause a hysteresis loop in the stress-strain curve. This hysteresis is associated with a heat buildup in the test specimen. The $\pm 45^\circ$ -specimen fatigue test results indicated that a significant heat buildup had been generated in the form of a temperature rise at the various test environments. To study this thermal behavior of the composite, hysteresis tests were conducted using the Shorewestern Test Machine at various environments and stress levels as shown in the hysteresis test matrix, Table 17. Frequencies were set at 0.1 Hz, 0.5 Hz and 1.0 Hz at various environments and stress levels. The effect of a one-hour fatigue test at a 60% ultimate strength level at 3 Hz was also investigated. The Hewlett-Packard 3300A function generator was used to generate the sine wave load. The instrumentation for load and displacement in hysteresis tests was the same as that for fatigue test (see Figure 23). Additionally, two X-Y plotters, one for each LVDT, were used to record the actual hysteresis loop for the load-displacement relation. A typical wave generated by the H-P function generator is of the trapezoidal shape shown in Figure 28 along with the corresponding displacement curves from the two LVDT's.

FIGURE 27. THE S-N CURVE OF ±45°-SPECIMENS AT VARIOUS ENVIRONMENTS.

TABLE 17. HYSTERESIS TEST MATRIX.

| LOAD LEVEL FREQUENCY (HZ) | 20% F_{tu} | 45% F_{tu} | 60% F_{tu} |
|---------------------------------|--------------|--------------|--------------|
| 0.1 | X | X | X |
| 0.5 | X | X | X |
| 1.0 | X | X | X |
| (After One 1.0 Hour Fatigue) | --- | --- | X |

- NOTE: a. The environments for the above hysteresis matrix are AS-FAB; 75°F/50% R.H., 132°F/50% R.H., 132°F/95% R.H., 170° F/50% RH, 170° F/95% RH.
- b. The ultimate tensile strength (F_{tu}) of the cyclic load level is based on the following table with units in psi:

| ENVIRONMENT SPECIMENS | 75/DRY | 75/50 | 132/50 | 132/95 | 170/50 | 170/95 |
|--------------------------|--------|--------|--------|--------|--------|--------|
| + 45° | 29,800 | 28,300 | 29,300 | 26,000 | 26,700 | 25,900 |
| 90° | 6,970 | 4,580 | 4,780 | 3,330 | 5,330 | 3,470 |

FIGURE 28. STRIP CHART RECORDING OF LOAD AND DISPLACEMENT OF $\pm 45^\circ$ -SPECIMEN DURING HYSTERESIS TEST AT $170^\circ\text{F}/50\%$ R.H. ENVIRONMENT AND 60% OF ULTIMATE STRENGTH.

Based on the results in Figure 28, a gradual distortion on the flat section of the trapezoidal wave at 0.5 Hz frequency which became more severe at 1.0 Hz is probably due to the inertia effect of the hydraulic loading system. Hence, subsequent data analysis was confined to 0.1 Hz frequency results. Typical hysteresis curves at 0.1 Hz, recorded by the X-Y plotters, are shown in Figure 29. The creep in displacement under mean cyclic load from cycle to cycle is apparent at the 170°F/95% R.H. environment for a $\pm 45^\circ$ specimen. For data analysis purposes, those hysteresis curves can be idealized to the shape shown in Figure 30 together with the dimensions that characterize the hysteresis. Table 18 gives a list of dimensions of hysteresis loops at various environments and stress levels. The dynamic modulus is defined in the last cyclic loading. Both 90° and $\pm 45^\circ$ specimens became stiffer after being fatigue loaded for one hour at 60% Ft_u and 3 Hz frequency.

4.0 ANALYSIS OF TEST RESULTS

4.1 THERMAL ANALYSIS

Based on the temperature results in Tables 7 through 16, a significant temperature rise in the $\pm 45^\circ$ -specimen was recorded during fatigue testing at various environments. The 90° specimens experienced at most a 2°F temperature increase. This temperature rise is important in data analysis for viscoelastic material where the temperature shift factor is effected. To explore this phenomenon, temperature profile tests for $\pm 45^\circ$ -specimens were conducted by attaching four temperature sensors to the specimen in the arrangements shown in Figure 31 with three configurations. The temperature profile test results are shown in Table 19. Unless the sensor was close to the failure location of the specimen, temperature variations on the surface of the specimens may be due to free edge effects and the inhomogeneity in the specimen and between specimens. The temperature field on the surface can be considered uniform during fatigue cycling for reasons to be discussed below.

Definition of the exact temperature variation across the thickness of a specimen is difficult. Therefore, the heat conduction equation for a cycle-average temperature field was used (e.g. Schapery³):

$$\frac{\partial^2 T}{\partial x^2} = \frac{c}{K} \frac{\partial T}{\partial t} - \frac{\sigma_o^2 \omega^2 D''}{2K} \quad (2)$$

where T is the temperature at location x ($^\circ\text{F}$)
 c is the specific heat ($\text{In-Lb/In}^3\text{-}^\circ\text{F}$)
 K is the transverse thermal conductivity ($\text{In-Lb/In-Sec-}^\circ\text{F}$)
 σ_o is the amplitude of the applied cyclic stress (psi)
 ω is the cyclic frequency (radian/sec); stress is assumed sinusoidal
 D'' is the imaginary part of the dynamic compliance $D^* = D' + i D''$
 t is the time

By assuming steady state thermal conduction, equation (2) can be solved without the time dependent term. Thus, the maximum temperature difference in the specimen with thickness $2h$ is between the center of the specimen and its surface or

$$\theta_{\max} = T_c - T_s = \frac{\sigma_o^2 \omega^2 D''}{4K} \quad (3)$$

where D'' is related to the energy dissipation \bar{W} (in-lb/in³) by

$$D'' = \frac{\bar{W}}{\pi \sigma_o^2} \quad (4)$$

By using Figure 29a, the energy that is converted to heat per cycle is calculated as 12.361 in-lb/in³. When values of parameters

$$K = 0.1684 \text{ in-lb/In-Sec-}^\circ\text{F}$$

$$c = 2240 \text{ in-lb/lb}^\circ\text{F}$$

$$a_T = a_H = 1 \text{ (for } 75^\circ\text{F/50\% R.H. environment)}$$

$$\sigma_o = 7278 \text{ Psi}$$

$$\omega = 0.1 \times 2\pi \text{ Rad/Sec}$$

are substituted into equations (4) and (3), the maximum temperature difference in the $\pm 45^\circ$ specimen is approximately 0.001°F . To justify the steady state assumption in the above arguments, we find that the time required to attain 95% of the steady state condition, according to Schneider⁵ and Equation (2), is

$$t = \frac{12h^2c}{\pi^2K} \quad (5)$$

and is 6.47 seconds for the $\pm 45^\circ$ specimen. The short duration to reach a steady state condition and the small difference in temperature between center and surface of the specimen indicates that the temperature field through the thickness of the specimen can be assumed essentially uniform throughout its fatigue life.

The specimen's surface temperature was monitored continuously by temperature sensors and the results for $\pm 45^\circ$ specimens at various environments and approximate stress levels are shown in Figures 32 through 36. Steady state temperature was reached in only a few cases. Temperature data scatter from specimen to specimen at each environment is typical. Several factors contributed to the scatter.

- a. The temperature sensor location during testing was not always in the area where the specimen failed. Usually a 3°F or more temperature jump was observed seconds before failing at the failure location.

- b. Edge effects and the cross sectional area difference between specimens made the applied fatigue stress field different.
- c. The probabilistic nature of microcrack distribution between specimens creates various fatigue failure processes at various locations within the specimens.

4.2 FATIGUE ANALYSIS

The initiation of the failure process was not observable as the test assembly was enclosed in the metal encased environmental test chamber. The fatigue failure surface of 90° specimens usually yields a clean cut edge appearance such as those shown in Figure 14. The correlation between failure surface and specimen quality can be readily established. Typical failure edges of quality 90° specimens are shown in Figure 37. Porosity and machine defects have an effect on the specimen's low fatigue life as seen by comparing Figures 38 and 39 with test results in 90° specimen fatigue (Tables 7-11). Especially subpanels A9 and A18 were in the neighborhood of the C-scan void area of the original big A-panel of Table 1. Also, by comparing the fatigue tables of 90° specimens, specimens from panel A show reduced fatigue life. Specimens made from subpanels NA suffered a lot of carbide cut defects and rendered only minimum fatigue life. These are indications that the fatigue behavior of 90° specimens is highly sensitive to its fabricated quality.

The surface appearance of ± 45° specimens that failed in fatigue, shown in Figure 18, were similar to those of the static failure specimens. The static failure process for ± 45° specimens seem to be initiated from the edge area with the peeling of surface layers along a 45° direction. Final failure ran along the worst peeled area. The fatigue failure process is believed to start by microcrack growth throughout the specimen including the edge area. Final rupture occurred after the crack grew to an unstable size. The similarity of failure appearance between static and fatigue ± 45° specimens is to be noted. The ± 45° panels of Table 1 did not show either the C-scan voids or visual type porosity (under 25X microscope inspection). The fatigue life of ± 45° specimens showed significantly less scatter than that of the 90° specimens.

FIGURE 39 (Continued). MACHINE DEFECTS THAT INVOLVED THE FATIGUE FAILURE OF 90° SPECIMEN.

Since the effect of temperature and humidity on the mechanical properties of Gr/Ep can not be ignored¹, a fatigue theory, proposed by Schapery⁶, that incorporates the viscoelastic effect will be adopted here to study the fatigue crack growth response of the composite. In its simplest form, this fatigue theory involves the application of the power law for opening-mode crack growth,

$$\frac{da}{dN} = c(\Delta K_I)^q, \quad (6)$$

to a so-called dominant flaw or crack. Here, N is the number of cycles, a is the crack size and q is a positive constant. The coefficient c can be expected to depend on frequency, temperature, humidity, R -value and probably other parameters, such as mean strain. The amplitude of stress intensity factor, ΔK_I , is related to the amplitude of stress level $\Delta\sigma$ by

$$\Delta K_I = k \sqrt{a} \Delta\sigma \quad (7)$$

where k is a crack geometry parameter.

We now consider a set of specimens which are identical except for their distribution of initial dominant flaws. Allowing for variation of the c and k values from specimen to specimen, the dominant crack in the i th specimen will have

$$\begin{aligned} c_i &= c_{oi} C \\ k_i &= k_{oi} K \end{aligned} \quad (8)$$

where subscripts "o" and "i" indicate quantities for the initial value and for the i th specimen respectively. If the specimen fails at $N = N_{fi}$ as defined by $a \rightarrow \infty$, we predict, from equations (6), (7), and (8),

$$\int_0^{N_{fi}} c_i k_i^q (\Delta\sigma)^q dN = e^i \quad (9)$$

By definition,

$$e^i \equiv (p s_{oi}^p c_{oi} k_{oi}^q)^{-1}, \quad p \equiv \frac{q}{2} - 1 \quad (10)$$

It is seen that the effect of separate statistical distributions of a_0 , c_0 , and k_0 on failure is through a single statistical distribution parameter, F which is

$$F = \log \left[\int_0^N C' K^q (\Delta \sigma)^q \frac{dN}{a_{TH}} \right], \quad C = C' / a_{TH} \quad (11)$$

The temperature and humidity effects are introduced through the time-shift factor a_{TH} . If the values c and k are assumed constant during the constant amplitude fatigue tests, equation (11) becomes

$$\log N + q \log \Delta \sigma = F + \log a_{TH} \quad (12)$$

At each temperature and humidity, the quantity, $F + \log a_{TH}$ is a statistical quantity. Equation (12) is a good starting point for fatigue data analysis. By looking for the proper q value that will minimize the square error of quantities $F_i + \log a_{TH}$ from the statistical mean value $F + \log a_{TH}$, equation (12) can be analyzed by linear regression techniques. Thus, the fatigue data in Tables 7 through 16 were analyzed by equation (12) and results are listed in Table 20. The sequence of environmental severity is defined by the corresponding $\log a_{TH}$ value. The value of the quantities $\log N$ and $\log a_{TH}$ are in the order of 1 - 5 and that of $q \log \Delta \sigma$ and F are in the order of 20 - 50. It is obvious that the balance of equation (7) is dominated by the exponent q and $\log \Delta \sigma$. The exponent q , the unknown quantity, can be determined from the slope of the $\log N$ vs. $\log \Delta \sigma$ curve.

5.0 DISCUSSIONS AND CONCLUSIONS

The basic mechanical properties of AS/3501-6 Gr/Ep composite under combined temperature and humidity environments has been characterized in Reference 1 based on the creep-recovery tests and viscoelastic theory. Under the combined effects of temperature and humidity, short term results from Reference 1 can be used to predict the long term behavior of AS/3501-6. Their validity to long term behavior prediction has been verified by conducting a creep-recovery test with four days per cycle.

The main objective of this Phase II program was to investigate fatigue response of the basic laminates $(90^\circ)_{20}$ and $(\pm 45^\circ)_{25}$ and relate it to realistic laminate prediction through viscoelastic analysis. In order to minimize the variables that might effect the fatigue result, the specimen quality and its condition before testing were of vital importance to the final data analysis. Microcracks might be created during the moisture soaking process. But by conditioning the specimens in a 170°F environment as described in Section 2.1, rather than at a higher temperature, no apparent flaws were produced. Defects that might be created by improper machining of the specimen were eliminated by using a new specimen fabrication procedure. Porosities in the specimen were also studied under the microscope and the results were related to the fatigue test data in the fatigue tables.

Fatigue data has been generated for laminates $(90^\circ)_{20}$ and $(\pm 45^\circ)_{25}$ at various environments and stress levels. In the process of fatigue testing, a significant temperature rise in the $\pm 45^\circ$ specimens was observed. Temperature profile tests were subsequently conducted to investigate the transient temperature state within the specimen and the homogeneity of the temperature field. The test data together with the analysis method indicate that the temperature distribution in the fatigue specimens can be considered uniform through the specimen. The continuous rate change of temperature rise on most of the specimen indicates that thermal equilibrium between specimen and environment was not reached during fatigue testing.

Hysteresis tests were conducted at various environments and stress levels to study the energy dissipation associated with each fatigue load-unload cycle. Hysteresis data for the 90° specimen agrees with the temperature prediction of negligible increase. The amount of energy loss in $\pm 45^\circ$ specimens increased as the stress level and/or temperature level became severe. The dynamic modulus increased in magnitude after one hour of fatigue testing.

From preliminary analysis of the fatigue data, it seems that heating may have a strong bearing on composite's failure mechanism. This fact seems to fit in explaining the temperature rise phenomenon of 90° and $\pm 45^\circ$ specimens. For 90° specimens, there was always a dominant flaw among a distribution of cracks and voids. This dominant flaw suffered continuous crack tip heat build-up due to the fatigue cycling. This heat build-up was confined locally to the low thermal conductivity of polymer. On the other hand, the $\pm 45^\circ$ specimen was under cyclic in-plane and interlaminar shearing load during the uniaxial fatigue testing. The cross-ply layup of $\pm 45^\circ$ specimen tends to constrain any single dominant flaw to grow to unstable state. As a result of this constraining action, less dominant flaws gradually grew to become large flaws one by one. Final fatigue failure happened from the coalescence of those large flaws. As the population of large flaws grew, more local heating area were exposed to the surface area. This explains the temperature rise phenomenon detected by temperature sensor on $\pm 45^\circ$ specimen.

Also, from preliminary fatigue analysis, the parameter q of equation (6) is probably the dominant factor in introducing the effect of temperature and humidity on fatigue behavior of Gr/Ep composite, together with the time shift factor a_{TH} . The proper fatigue analysis technique hinges on a clear understanding of q . The parameter c of equation (6) will also be investigated for its possible role in our crack propagation model.
