FOREWORD

This report was prepared for the U.S. Department of the Air Force, Ballistic Missile Office (BMO), in compliance with Contract No. F04704-80-C-0006, CDRL Item 004A2. It represents the results of Ertec Western, Inc.'s (formerly Fugro National, Inc.) investigations of the water resources at three of the candidate Operational Base (OB) sites in the Utah and Nevada MX deployment area.

The report has been divided into two discrete volumes. Each volume discusses the hydrologic information which is pertinent to the valley in which the candidate OB sites are located and is summarized below.

- Volume I - Includes the results of Ertec's investigations of the water resources at the Coyote Spring OB site study area as of March 1981, the text providing evaluation of the water resources of the study area, and supporting data. Currently, additional studies are being conducted in the area of the Coyote Spring OB site and will be presented in FY 82.

- Volume II - Includes the results of Ertec's investigations of the water resources in the Escalante Valley where both the Beryl and Milford candidate OB sites are located, the text providing evaluation of the water resources of the valley, and supporting data. No further investigations of the water resources in the valley are presently planned.

1.0 INTRODUCTION

1.1 PURPOSE AND SCOPE OF INVESTIGATION

The purpose of this investigation is to evaluate the water resources in the Milford and Beryl candidate OB areas in Escalante Valley with respect to quantity and quality, to assess water availability, and to assess possible impacts from withdrawals or from changes in the points of withdrawal (Figure 1).

The general approach of this investigation was to update and expand the existing data base in the siting area through literature review, field reconnaissance, drilling and testing, and water-quality analysis and to analyze and evaluate that information. Those activities are summarized as follows:

Existing Data Collection and Review

- Existing publications and data contained in agency files relating to water availability, local water use, ground-water flow systems, and aquifer characteristics were collected and reviewed.
- State and federal officials and individuals knowledgeable about ground-water conditions in Utah were contacted.

Shallow Aquifer Reconnaissance

- Field studies were performed to identify water users, measure ground-water levels, collect ground-water samples for chemical analysis, measure spring and stream discharges, conduct aquifer tests of exisiting wells, and examine general hydrogeologic conditions. Specifically,
  - Ground-water levels were measured in 86 wells in order to construct potentiometric maps for identifying ground-water migration patterns and areas of recharge or discharge;
  - Ground-water samples were collected from 28 wells and springs for field and laboratory analyses to characterize the water quality and to assess its suitability for use in

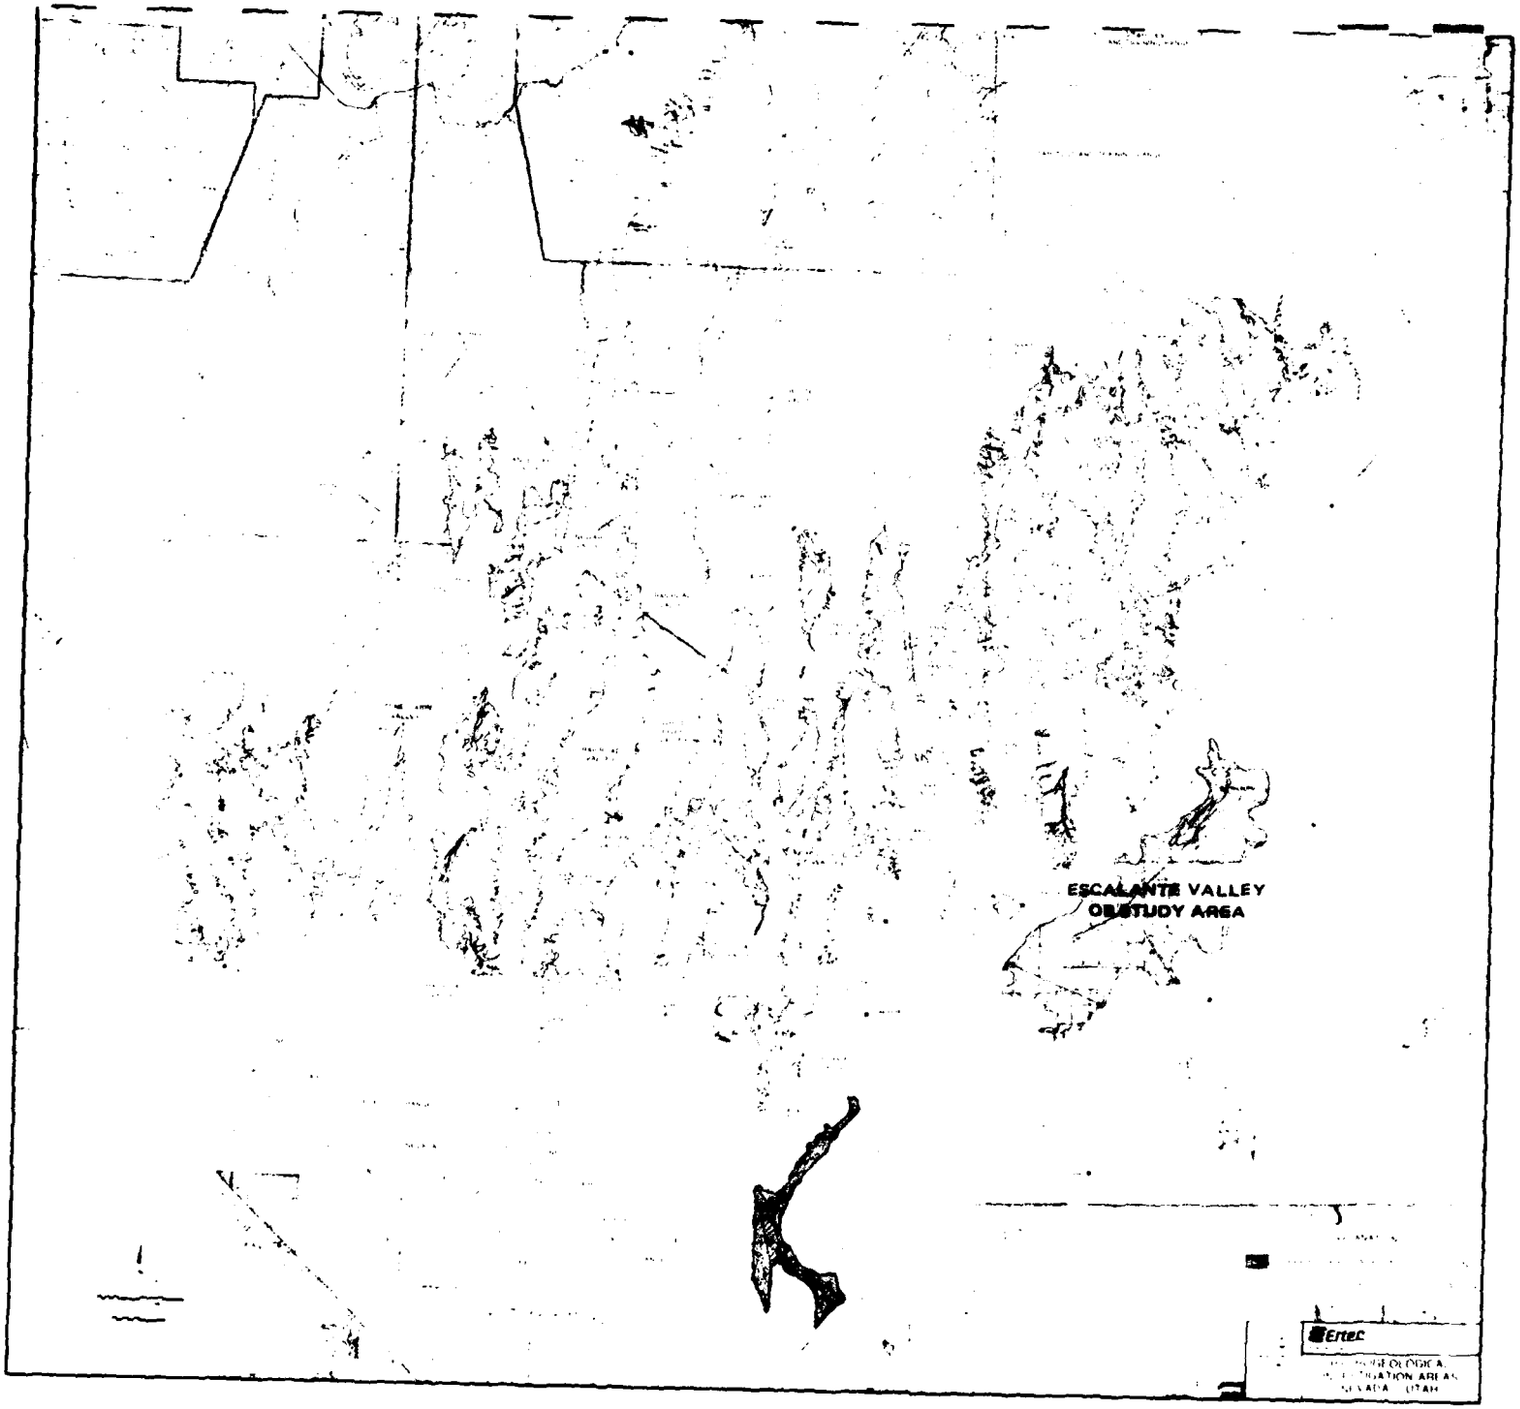

FIGURE 1

construction and for drinking purposes and to aid in identifying ground-water migration patterns and recharge areas; and

- Spring and stream discharge measurements were made at nine locations to aid in surface-water studies and to provide input to computer model simulations of the ground-water systems in the area.

Valley-Fill Aquifer Studies

o An observation and test well were drilled at each candidate site into valley-fill deposits. The drilling and testing programs are designed to gather information about aquifer characteristics, the ability of the aquifer to store and transmit water, and about ground-water flow systems where little data exist. The aquifer test data were needed to determine the effects of pumping on nearby wells and springs in support of applications for changes in points of diversion and to determine if ground water could be physically obtained locally.

Surface-Water Overview

o The surface-water regime was investigated to provide data on the availability of surface water and estimate the rates and amounts of potential recharge to the ground-water systems.

1.2 LOCATION

The study area is located in southwestern Utah and encompasses the entire Escalante Valley and surrounding drainage area (Figure 2). Escalante Valley is located in parts of Beaver, Iron, Millard, and Washington counties. The study area is approximately 100 miles (161 km) long and varies in width from approximately 50 miles (80 km) in the southern portion to 30 miles (48 km) in the northern portion. For this report, the technical discussion of the valley has been divided into two districts, Beryl and Milford. The division between the Milford district in the north and the Beryl district in the south has been arbitrarily defined as an imaginary line 3 miles (5 km) south of and parallel to the Beaver-Iron county line.

LOCATION MAP – ESCALANTE VALLEY, UTAH

28 MAY 81

FIGURE 2

The Beryl district includes that portion of Escalante Valley that lies south and west of the Blue Knoll area (Figure 2). Communities within this district include Enterprise, Newcastle, Beryl, and Modena. The Union Pacific Railroad line traverses the entire valley from Modena northeast through Beryl, Lund, the Milford district and north through the town of Black Rock, a total distance of approximately 100 miles (161 km). Utah State Highway 56 extends from Cedar City, east of the district, to the Nevada State Line, west of the district. Most agricultural development in the district occurs in the vicinity of this state highway.

The Milford district includes that portion of Escalante Valley that extends from the Blue Knoll area north to Black Rock. Communities in the Milford district include Minersville, Milford, and Black Rock. Besides the Union Pacific Railroad line, the area is traversed by Utah State Highways 129 and 257 to the north and State Highway 21 from southeast to northwest. Agricultural development is present near Minersville at the entrance of the Beaver River into the valley and from the vicinity of Milford south and southeast for a distance of about 10 miles (16 km) along State Highways 129 and 21.

The proposed locations of the Operational Base locations are shown on Figure 2. The Milford OB site lies approximately 17 miles (27 km) southwest of the town of Milford. The Beryl OB site is located approximately 6 miles (10 km) west of Beryl Junction.

1.3 PREVIOUS INVESTIGATIONS

The Escalante Valley has been the subject of various hydrologic studies since the 1920s due to the importance of the valley as an agricultural and mining area. A study conducted by White in 1923 focused mainly on the use of ground water by native plants in the valley (White, 1932). Hydrologic monitoring of the valley by state and federal agencies has continued since 1935. In 1950, the U. S. Geological Survey (USGS) conducted a study to assess the ground-water resources in Escalante Valley. The study was initiated in response to the rapid increase in ground-water withdrawals that occurred during the 1940s (Fix and others, 1950). Progress reports on the status and effect of irrigated agriculture in the valley were published in the 1950s by the state in cooperation with the USGS (Thomas and others 1952; and Waite and others 1954). In the early 1960s, the USGS again conducted an investigation of this basin and adjacent ground-water basins in order to correlate past studies of the developed basins in southwestern Utah and to provide a unified concept of the ground-water conditions (Sandberg, 1966).

The change of ground-water levels in the valley has been evaluated annually since 1963 by the USGS and the results published in cooperation with the State of Utah in a series of reports titled "Developing a State Water Plan." These reports are published annually each spring and describe the current ground-water conditions and related hydrologic factors that may have

had an effect on the ground-water reservoir during the preceding year.

More recent studies of the Escalante Valley have been conducted by the USGS to assess the impacts of heavy withdrawals on the ground-water basin and to project future water-level conditions in the area. The Milford district was studied in the early 1970s by Mower and Cordova (1974). Field studies of the Beryl district have been recently completed but, as of May 1981, only the basic data have been published (Mower, 1981); the interpretive report is still in preparation.

2.0 RESULTS AND CONCLUSIONS

Escalante Valley has been identified as a candidate site for either a primary or secondary Operational Base. Because existing use of water resources in the valley exceed the estimated annual rate of replenishment, the Utah State Engineer has declared this area closed to further appropriations. In order to identify a water-supply source for MX requirements an investigation was performed to evaluate the water resources of Escalante Valley. The following is a summary of the results and conclusions obtained from the investigation.

Based on field reconnaissance conducted by Ertec and a review of existing data, it is concluded that surface-water resources in Escalante Valley have a limited potential for development as an MX water supply source. The four major surface-water sources, Shoal, Meadow and Pinto creeks and the Beaver River, are fully appropriated for beneficial use within the valley. All other springs or streams are also fully appropriated and do not flow in sufficient quantities to be considered a dependable water supply for MX.

In order to obtain a water supply for MX requirements from surface-water sources, it would be necessary to lease or purchase existing water rights from present users. Because the major surface-water supplies occur on the east side of the valley, it would also be necessary to construct extensive pipelines to transport water to the west side of the valley where the candidate OB sites are located.

In order to identify the potential for development of the valley-fill aquifer in Escalante Valley, field activities as well as a review of existing data have been conducted. The field activities included the drilling of two test and two observation wells, aquifer testing, ground-water level measurements, spring- and stream-discharge measurements and water-quality sampling and analyses. A preliminary numerical analysis of the ground-water reservoir was also performed as part of the investigation.

The valley-fill aquifer at both of the proposed locations in the Milford and Beryl districts is capable of delivering water in sufficient quantities and of acceptable quality to meet MX operational base requirements. Because the state engineer will not allow new appropriations in the valley, it will be necessary to lease or purchase existing water rights from present users. To meet peak construction water requirements for a secondary OB base of 4198 acre-ft/yr (5.2 hm^3/yr), it will be necessary to temporarily retire approximately 1680 acres (680 ha) of irrigated land from present use. To meet peak construction water demands for a primary OB base of 9685 acre-ft/yr (11.9 hm^3/yr), approximately 3874 acres (1568 ha) of irrigated land would be temporarily retired from present use. These acreage retirement amounts would decrease to 1160 acres (470 ha) and 1680 acres (680 ha) for secondary and primary site long-term operational use, respectively.

Numerical analysis of a well field at each candidate OB site in the valley was performed using a computer simulation of six wells withdrawing ground-water at a total rate of 2900 acre-ft/yr (3.6 hm^3/yr) and 4200 acre-ft/yr (5.2 hm^3/yr) for 30 years. These withdrawal amounts are the latest estimates provided by the U.S. Army Corps of Engineers for secondary and primary operational base water-use. For a secondary OB site in Beryl, a water-level drawdown of less than 1 foot (0.3 m) was obtained at a 6-mile (10-km) radius of the well field after 30 years. In Milford, a drawdown of less than 1 foot (0.3 m) occurred at an 8-mile (13-km) and radius from the simulated well fields. For a primary OB site, 1 foot (0.3 m) of drawdown occurred at an 8- and 10-mile (13- and 16-km) radius from the Beryl and Milford simulated well fields, respectively.

There is no evidence of a productive carbonate aquifer system in Escalante Valley. Development of such a system to provide a water supply for MX requirements is not considered a viable alternative.

Chemical-quality analyses of water samples collected throughout the valley indicate the water is acceptable for domestic consumption and meets recommended water-quality criteria for construction water use at the candidate OB sites. With the exception of ground-water samples from an area near the town of Milford and a few isolated samples scattered throughout the valley, the water quality is within state and federal primary and secondary drinking water standards. Most samples collected

met the criteria for mixing cement recommended by the Portland Cement Association (1966). Those samples that did not meet the criteria are from wells in areas of high agricultural activity several miles from the candidate OB sites. Water from one well sampled near the Beryl OB site had a TDS concentration that was 2000 mg/l, which is the recommended limit for mixing concrete. This well is located in an area of perched shallow ground water and may be affected by surface activity in the area.

Based on the results of these analyses, it is concluded that future development of water resources for public supply in the Milford district is feasible from a water-quality standpoint in areas south of Township 29 South and west of Range 11 West. In the Beryl district, future development is feasible throughout the area.

3.0 GEOGRAPHY

3.1 PHYSIOGRAPHY

The Escalante Valley, located in the Basin and Range Physiographic Province, is an irregularly shaped, southwest-northeast trending valley (Fenneman, 1931). The study area consists of a valley bounded almost completely by two series of roughly parallel mountain ranges and hills.

The valley floor is approximately 88 miles (142 km) long with a maximum width of 32 miles (51 km) and encompasses an area of approximately 1300 square miles (mi^2) (3366 km^2). The drainage basin tributary to the Escalante Valley is over 1500 mi^2 (3884 km^2). The valley floor has an elevation ranging from 4840 feet (1475 m) in the north near Black Rock to about 5500 feet (1676 m) in the south near Modena. The highest peak in the drainage area is Frisco Peak in the San Francisco Mountains which reaches an elevation of 9660 feet (2944 m).

In the Beryl district, the valley floor slopes northeastward with a gradient of less than 5 feet per mile (0.9 m/km) near Lund, 10 feet per mile (1.9 m/km) near Enterprise, and 25 feet per mile (4.7 m/km) near Modena. Shallow drainages and sand dunes interrupt the generally smooth valley floor. Broad coalescing alluvial fans and piedmont slopes, characteristic of the intermontane desert basins of western Utah and the Great Basin (a section of the Basin and Range Physiographic Province), merge into the valley floor. Surficial materials consist of unconsolidated alluvial and eolean sediments. Next to the

mountain fronts, these deposits consist of poorly sorted sand, gravel, and boulders. The sediments generally grade to fine sands and clays toward the valley axis. There are areas along the valley axis where thick beds of coarse gravel occur. One area of this occurence is just south of Milford. Runoff from the adjacent mountains rapidly infiltrates into these fan deposits where it serves to recharge the ground-water reservoir.

In the Milford district, a broad alluvial fan associated with the Beaver River extends from the south flank of the Mineral Mountain Range northwestward approximately 12 miles (19 km). Between Minersville and Milford, the alluvial fan slopes northwest at a gradient of about 13 feet per mile (2.5 m/km). At the apex of the fan, near Minersville, the gradient is 30 feet per mile (5.7 m/km), while at Milford, the slope decreases to about 10 feet per mile (1.9 m/km). The Beaver River enters the valley at an elevation of 5250 feet (1600 m) at the apex of the fan near Minersville and flows across the fan toward Milford where the elevation is 4950 feet (1509 m).

Broad coalescing alluvial fans also extend from the mountain ranges along the western border of the district. Surficial materials in the fans are similar to those that occur in the Beryl district. Poorly sorted unconsolidated sands, gravel, and boulders occur nearest the mountain fronts and generally grade into fine sands and clay toward the center of the valley.

3.2 CLIMATE

The climate of Escalante Valley is semiarid and is characterized by mild summers and cool winters. Daytime temperatures seldom exceed 100°F (38°C) in the summer. Winter temperatures are usually below freezing at night. Mean annual temperature for the area is about 50°F (10°C) (Sandberg, 1966). The average length of the growing season during the period from mid-May to late September ranges from 105 days near Black Rock to 138 days near Modena (USGS, 1950).

Annual precipitation averages from 8 to 11 inches (20 to 28 cm) in the valley to more than 25 inches (64 cm) in the mountains. More precipitation falls near the mountain fronts along the east side of the valley than on the western side. The average May to September precipitation on the valley floor is between 3 and 4 inches (8 and 10 cm). Rainless periods of 30 days or more are common and because of this low rainfall during the growing season, irrigation of croplands is required (Sandberg, 1966).

The cumulative departure from the average annual precipitation for the period 1932 to 1979 at the Milford airport and for the period 1936 to 1979 at Modena is shown in Figure 3 (USGS, 1980). The valley is presently experiencing a period of rainfall equal to the long-term mean.

3.3 VEGETATION

In the Escalante Valley, the natural vegetative associations are characteristic of a semiarid climate and, in some cases, are indicators of the depth to ground water. Valley slopes are

CUMULATIVE DEPARTURE FROM THE ANNUAL PRECIPITATION – 1932-1979

28 MAY 81

FIGURE 3

covered largely by sagebrush, and the valley trough is covered by alkali-resistant phreatophytes. These phreatophytes, which are indicative of shallow ground water, include greasewood, shadscale, rabbitbrush, saltgrass, tussock grass, pickleweed, and seepweed.

Where the depth to water is less than 15 feet (4.6 m), saltgrass, greasewood, pickleweed, shadscale, and rabbitbrush associations are commonly found. Saltgrass is totally absent where the depth to water is greater than 15 feet (5 m). Greasewood is commonly found in areas where the depth to water is greater than 3 feet (1 m) and possibly as deep as 25 to 40 feet (8 to 12 m). Besides these shrubs and forbs, native grasses such as Indian rice, galeta, threeawn and squirreltail are also found throughout the valley (Ertec Northwest, 1980). These grasses generally obtain their water from near surface moisture that is derived from local precipitation and retained in the upper part of the soil mantel.

On the foothills and low mountain slopes, the dominant vegetation is junipers and scattered pinon along with blacksage, rabbitbrush, and shadscale. The higher peaks and ridges support yellow pine, spruce, fir, and scrub oak.

4.0 GENERAL GEOLOGY

4.1 GEOLOGIC SETTING

Geology in the Escalante Valley and the surrounding mountains is dominated by sedimentary and igneous rocks ranging in age from Precambrian to Quaternary and by unconsolidated sediments of Quaternary age. The unconsolidated deposits form the principal ground-water reservoir in the valley.

4.1.1 Regional Geology

Escalante Valley is a typical block-faulted valley of the Basin and Range Province with down-faulted blocks forming valleys and up-faulted blocks forming the mountains. The main ground-water reservoir is the valley-fill sediments which are the result of deposition of materials derived from the up-faulted mountain blocks. To the east of the valley, the Basin and Range structure changes abruptly to the nearly flat-lying structure of the Colorado Plateau.

4.1.2 Statigraphy

Stratigraphic sequences of rock ranging from Precambrian to Quaternary in age are found throughout the area. Rocks of upper Precambrian and lower Cambrian age are exposed in the Beaver Lake and San Francisco mountains and in a few outcrops in the Mineral Mountains. They are composed principally of quartzite with a few carbonate beds in the lower members. In the San Francisco Mountains, the strata of Precambrian age overlie rocks of Cambrian and Ordovician age as the result of major thrust

faulting. Limestones, dolomites, and clastic rocks of Cambrian age are found in these mountains.

Valley-fill deposits include sediments of Pleistocene (Bonneville and pre-Bonneville) and Holocene ages. Pleistocene deposits include alluvial fan and lake sediments. Holocene units include unconsolidated alluvial fan, stream-channel, and eolian deposits. Well logs in the valley indicate numerous sequences of sand, gravel, and boulders interfingered with clay and silt layers. It is in this valley-fill material that the main aquifer system occurs. The total thickness of the valley-fill in Escalante Valley is not known. However, available data show more than 3000 feet (914 m) of sediment in places, and in some areas, accumulations reach depths as great as 5000 feet (1524 m) (Sandberg, 1966).

4.2 STRUCTURAL GEOLOGY

Several faults, generally striking northeasterly, have been mapped in the region around Beryl and Milford. Several of these faults offset basin-fill deposits of late Quaternary age (less than 700,000 years old); in some cases, the faults also offset deposits of Lake Bonneville age (12,000 years old) or younger.

One of the more prominent northeasterly striking faults in the region is located west of Lund. The surface expression of this fault consists of a pronounced southeasterly facing scarp that averages approximately 27 feet (9 m) in height; in young alluvial deposits, the scarp is only about 1 foot (0.3 m) high.

This fault is fairly continuous from southeast of Zane to northwest of Lund, a distance of about 12 miles (19 km). This fault may continue to the northeast to join a similar fault near Section 33 of Township 31S, Range 14W. Approximately 3 miles (5 km) southeast of Zane, a smaller fault, with a northwest facing scarp, parallels the main fault at Lund.

In addition to the above, several northeasterly and east-west trending faults occur in the vicinity of Thermo and Hot Springs. In this area, aerial photographs show several scarps; hot springs emanate from two northerly striking faults within this system.

4.2.1 Landforms

The dominant landform of Escalante Valley is the lake bed of Lake Bonneville. This large Pleistocene lake extended into many of the Great Basin Valleys where it resulted in a generally smooth valley floor rimmed by scattered evidences of elevated shorelines. Merging into this valley floor and somewhat overlapping it are broad coalescing alluvial fans and piedmont slopes.

In the Escalante Valley, the generally smooth valley floor is interrupted in places by shallow channels cut by floods of short duration and by sand dunes that may be as much as 25 feet (8 m) high.

Sand dunes have developed at several locations in the valley. The largest area of dune development is at the north end of the

valley in Beaver Bottoms. These dunes have formed largely as the result of wind erosion of abandoned farm lands along the Beaver River. Interrupting the alluvial surface are occasional volcanic flows and knolls. These can be found in the area of Black Rock. Volcanic cones also form several knolls near the Black Mountains.

For the most part, the landforms only indirectly affect the surface waters of the area. The smooth ascending fans that originate from the mountains allow for the runoff of precipitation and do little to affect the ground water in the area. However, the presence of such features as volcanic flows and knolls may impede the flow of ground water and possibly act as damming features in some areas. The presence of dunes, on the other hand, may allow rapid recharge locally.

The old lake bed in the valley bottom consists of the finer sediments. Because of this, the deposits in the valley bottom tend to have a low hydraulic conductivity reflecting not only the fine-grained material present but also compaction of the material from previous episodes of ponding or flooding.

4.2.2 Drainage Basin Characteristics

The drainage area that contributes runoff and subsurface inflow to the Escalante Valley encompasses over 1500 mi^2 (3884 km^2) of mountainous terrain. Drawing 1 shows most of the limits of this drainage area.

Elevations in the surrounding drainage areas are usually less than 9000 feet (2743 m). The average elevation of the drainage

area is between 7500 to 8000 feet (2286 to 2438 m). In general, the drainage area to the east of Escalante Valley is higher and precipitation is greater. Mountainous areas to the south and west are generally lower and receive less precipitation.

Surface flows in the Beaver River originate in the Tushar Range to the east of Escalante Valley. This drainage area encompasses 535 mi^2 (1385 km^2). Elevations in this range reach 12,000 feet (3658 m).

DRAWING 1

5.0 SURFACE-WATER HYDROLOGY

5.1 SURFACE-WATER REGIME

A close relationship exists between surface water and ground water in the Escalante Valley. In the Milford district, the ground-water reservoir is replenished to a large extent by water lost from unlined canals and ditches where they traverse valley-fill deposits and from ephemeral streams originating in the surrounding mountains (Mower & Cordova, 1974). In the Beryl district, the ground-water reservoir is replenished largely by subsurface flow from bed rock in the mountains and from losses of surface flow from stream channels during spring snowmelt and during intense thunderstorms.

There are four perennial streams in the basin that provide surface water supplies to the Escalante Valley (Figure 2). These are Shoal Creek, Pinto Creek, and Meadow Creek in the Beryl district and Beaver River in the Milford district.

The Beaver River is the largest stream in the area. Prior to construction of Rocky Ford Dam in 1914, the river was perennial through the Milford district. The USGS maintains a gauging station at a point 0.5 mile (0.8 km) downstream from Rocky Ford Dam. The average annual flow for the period 1932 to 1979 was 25,390 acre-ft/yr (31.3 hm^3/yr) (USGS 1980). A maximum recorded annual flow of 55,600 acre-feet (68.6 hm^3) occurred in 1921. The minimum recorded annual flow was 9150 acre-feet (11.3 hm^3) in 1960 (Mower and Cordova, 1974). Figure 4 shows the annual flow in the Beaver River at Rocky Ford Dam for the period 1932 to 1979 (USGS, 1980).

FLOW OF BEAVER RIVER AT ROCKY FORD DAM - 1932 TO 1979

28 MAY 81

FIGURE 4

Shoal, Meadow, and Pinto creeks drain the Harmony and Bull Valley mountains and associated ranges. These streams supply water to three small areas near the mouth of each creek in the vicinity of Enterprise and Newcastle. No gauging stations have been constructed on these creeks; however, it is estimated that the combined normal base or low flows of Shoal, Pinto, and Meadow creeks range from 5 to 10 cubic feet per second (cfs) (0.1 to 0.3 m^3/s) annually (White, 1932). In addition to this amount, there are flood discharges following heavy rains and periods of rapid snowmelt.

All other streams entering Escalante Valley are ephemeral and flow only in response to heavy precipitation or during periods of active snowmelt. This water collects in ponds on the valley floor and a portion recharges the ground-water reservoir. The majority of this ponded water, however, is lost to evaporation.

5.2 SURFACE-WATER DEVELOPMENT

5.2.1 Present Development

Surface water in Shoal Creek, the largest stream entering the Beryl district, is used to irrigate land near Enterprise. Two reservoirs on Shoal Creek, constructed during the 1890s and early 1900s, provide seasonal storage of melt water from winter snow and occassional hold-over storage in years of high runoff. These reservoirs have a combined capacity of about 10,200 acre-feet (12.6 hm^3).

Flow in Pinto Creek is used to irrigate acreage in the Newcastle area. Winter flows and much of the flood water in Pinto Creek is stored in Newcastle Reservoir about 2 miles (3 km) southeast of Newcastle. Flood water in excess of the capacity of Newcastle Reservoir is a source of recharge to the ground-water reservoir in the area north of Newcastle. Meadow Creek flows are uncontrolled and are used for irrigation in the area between Newcastle and Enterprise.

The Beaver River is the only dependable source of surface water for irrigation in the Milford district and is an important source of ground-water recharge in the area. The normal flow of the river is diverted and used for irrigation in the upper part of Beaver Valley east of Escalante Valley. The winter stream flow, flood discharge, and return water from irrigation in Beaver Valley is stored in Minersville Reservoir which has a storage capacity of 23,260 acre-feet (28.7 hm^3). This water is released to fields in the Milford district during the irrigation season.

All of the flow of the Beaver River into the Escalante Valley is diverted westward into Minersville Canal and Utopia Ditch for irrigation in the vicinity of Minersville and northward into the Low Line Canal for use on land southeast of Milford. Rights to the first 10,000 acre-feet (12.3 hm^3) of Beaver River water are held by landowners of the fields southwest of Minersville. In years of low runoff, practically all the surface flow is diverted to that area. When Beaver River flow is more than 10,000

acre-feet (12.3 hm^3), water is diverted into the Low Line Canal which has a capacity to carry 16,000 acre-feet (19.7 hm^3) in an irrigation season (Thomas and others, 1952). In years when the maximum flow exceeds the diversions, the surplus flows down the natural channel of the Beaver River most of which recharges the aquifer in the Milford district. There have been occasional small flows in the Beaver River beyond the Milford area.

Prior to 1916, the Beaver River was the main source of water in the Milford district. Since then, irrigation wells began to provide a portion of the irrigation water. Since the early 1950s, ground-water pumping from large irrigation wells has supplemented surface-water supplies and presently (in 1981) serves as the principal water supply.

5.2.2 Appropriations

Although a complete listing of the certificates, proofs, permits, and applications filed in the Milford and Beryl districts is not available at this time, it is known that current water rights exceed the available surface-water supply for the area. There are 25 certificates and proofs in the Milford district for the appropriation of 30,720 acre-feet (37.9 hm^3) annually (DRI, 1980). In the Beryl district, the number or quantity of surface-water rights is not available; however, local water commissioners indicate that approximately 8000 acre-feet (10 hm^3) of surface water has been delivered annually to existing water-right owners in recent years.

6.0 GROUND-WATER HYDROLOGY

6.1 GROUND-WATER REGIME

The Escalante Valley has developed into one of the largest agricultural areas in the state of Utah because of its large ground-water reservoir. It is because of the development of ground-water resources over the last 40 years that the productivity, wealth, and population of Escalante Valley have increased so rapidly.

Ground water stored in the valley-fill totals several million acre-feet. This is many times the quantity pumped from wells annually. The extent to which the ground-water reservoir is replenished depends upon the precipitation in the drainage basin and the amount of precipitation that percolates downward through the soil zone. Current pumpage is in excess of the rate of annual replenishment and is slowly depleting the storage of the ground-water reservoir. Drawing 1 indicates the potentiometric water surface and depth to water of the valley-fill aquifer based on measurements obtained by Ertec in November and December 1980 and February 1981.

6.1.1 Occurrence and Movement

A large part of the valley-fill material which constitutes the ground-water reservoir is coarse-grained and easily transmits water. These permeable beds of uncemented gravel and coarse sand yield sufficient quantities of water to irrigation and other large-yielding wells. The cemented gravels and

sands and fine-grained sediments also found in the valley do yield a smaller quantity of water to wells to meet stock and domestic needs. The annual average withdrawals of water from the ground-water reservoir for the 10-year period, 1969 to 1978, is 60,000 acre-feet (74.0 hm^3) in the Milford district and 79,000 acre-feet (97 hm^3) in the Beryl district for a total of 139,000 acre-feet (171 .4 hm^3) (USGS 1980).

The natural surface outlet of the valley is at the north end near Black Rock. This was once the location of a strait connecting the Escalante Valley area with the main body of ancient Lake Bonneville. There has been no significant surface outflow from the valley since surface diversions for irrigation have diminished the flow in the Beaver River to such small amounts that the remainder evaporates or infiltrates before it reaches the northern boundary. Subsurface outflow through the area is negligible as most of the ground water is discharged by pumping or evapotranspiration before it reaches the northern boundary. Because of this lack of significant outflow, the Escalante Valley is considered a hydrologically closed basin.

The natural ground-water system in the Escalante Valley has been altered by heavy irrigation withdrawals. Potentiometric contours representing the ground-water surface prior to about 1960 indicate the general ground-water movement was inward toward the axis of the valley and northeastward toward the north end of the valley. With present irrigation demands on the ground-water reservoir, most of the water in the upper zones of

saturation is been intercepted and withdrawn. Ground-water movement is still toward the axis of the valley and northeastward, but the slope of the hydraulic gradient has decreased in the Milford district. In the Beryl district, the northward gradient was reversed beginning in about 1964. Movement of ground water in the southern half of the Beryl district is inward toward the heavy pumping area near Beryl Junction.

Recharge to the ground-water reservoir is approximately 99,400 acre-ft/yr (122.6 hm^3/yr) and is from several sources as shown in Table 1 (see page 41). In the Beryl district, nearly all recharge originates from precipitation occurring in the district or on the surrounding drainage area. However, in the Milford district, some recharge is from water originating outside the area to the east in the Tushar Mountains. This drainage area is tributary to the Beaver River and water from the Beaver River is used in Beaver Valley prior to entering the Milford district.

Infiltration of waters that are lost from flow in canals in the valley is variable. In the Minersville area, losses from canals have been dramatically reduced with the construction of a pipeline in 1978 to transport the water. The canals in the Milford district area are still largely unlined, and loss of water from these canals is estimated to be 30 percent of their total flow (Mower and Cordova, 1974). This amount, estimated to be approximately 4600 acre-ft/yr (5.7 hm^3/yr), recharges the ground-water reservoir. Infiltration of water from ephemeral streams is also considered to be a source of recharge to the ground-water reservoir. Estimated recharge to the Milford

district from this source is 7200 acre-ft/yr (8.9 hm^3/yr) (Mower and Cordova, 1974). In the Beryl district, approximately 3000 acre-ft/yr (3.7 hm^3/yr) of recharge to the ground-water reservoir is from infiltration of ephemeral streams.

Water delivered to farms is either consumed by evapotranspiration or infiltrates to the ground-water reservoir. Mower and Cordova (1974) estimate that approximately 30 percent of the applied water infiltrates based on an analysis of existing methods of irrigation used in the valley. In the Milford district, recharge from this source is approximately 20,000 acre-ft/yr (24.7 hm^3/yr) and 17,5000 acre-ft/yr (21.6 hm^3/yr) in the Beryl district.

Precipitatin falling on acreage during the irrigation season also contributes to recharge of the ground-water reservoir. During the irrigation season, the soil would be saturated, therefore any additional moisture would infiltrate to the ground-water reservoir. In the Milford district, the amount of recharge from this source is estimated to be 1300 acre-ft/yr (1.6 hm^3/yr) and 2000 acre-ft/yr (2.5 hm^3/yr) in the Beryl district.

The movement of ground water into Escalante Valley from surrounding valleys is generally restricted by impermeable bed-rock divides. Although nearly all recharge originates as percipitation in the Beryl District, some water does move through the thin alluvial deposits which provide limited connection with valleys to the east of the Escalante Valley basin. The amount

of underflow through these thin alluvial deposits is estimated to be 600 acre-ft/yr (0.7 hm^3/yr) (Thomas and Taylor, 1946). The amount of underflow from Beaver Valley to the east of the study area into the Milford district is estimated to be 700 acre-ft/yr (0.9 hm^3/yr) (Mower and Cordova, 1974).

Subsurface inflow to the ground-water reservoir also occurs from the precipitation falling on the mountainous areas. Estimates of subsurface inflow from bedrock in the mountains for the Milford district are based on water budget imbalances for the period before the natural hydrological regime was disrupted. Mower and Cordova (1974) estimated this to be 16,000 acre-feet (19.7 hm^3) annually. For the Beryl district, this annual recharge is estimated by Ertec to be approximately 27,000 acre-feet (33.3 hm^3). This value was computed by the method of recharge estimation developed by Maxey and Eakin (1949).

Discharge from the ground-water system, as shown in Table 2 (see page 42), occurs as pumpage from wells and from evapotranspiration that occurs in the low-lying areas of the valley that support various species of phreatophytes. The losses due to evapotranspiration in the Milford district in 1971 were estimated by Mower and Cordova (1974) to be approximately 24,000 acre-feet (29.6 hm^3) based on a modification of estimates made by White in 1932. This estimate was modified to 22,700 acre-ft/yr (28.0 hm^3/yr) based on the present areal extent of phreatophytes in the valley. In the Beryl district, the areas mapped by White were reanalyzed by Ertec, and the original estimate of 5000

acre-feet (6.2 hm^3) annual loss due to evapotranspiration was increased to approximately 30,300 acre-feet (37.4 hm^3). This was due to the inclusion of a larger area than that previously used by White. This larger area is contained within the 30-foot (9-m) to-water line shown on maps used by White in 1932 and is supported through numerical model efforts conducted by Ertec. Average annual pumpage for the period 1969 to 1978 are 60,000 acre-feet (74.0 hm^3) in the Milford district and 79,000 acre-feet (97.4 hm^3) for the Beryl district (USGS, 1978).

6.1.2 Springs

There are a number of small springs around the margins of the valley which are meteoric in nature. These springs discharge only a few gallons per minute and are used primarily for stock watering. Some of this water may seep into the valley-fill ground-water reservoir, but its contribution is negligible.

The largest spring in the Milford district is Hay Springs which formerly discharged from the valley-fill materials south of Milford. This spring, however, ceased flowing by 1972 (Mower and Cordova, 1974). Before large withdrawals from irrigation began, discharge from this spring varied as the water table fluctuated; maximum flows were 2 to 3 cfs (0.06 to 0.08 m^3/s).

There are two hot spring systems in the Milford district. Roosevelt Hot Springs, which ceased flowing in May 1966, is located 12 miles (19 km) northeast of Milford. Peterson (1975) proposes two explanations for the cessation of flow: 1) the channel ways through which the water reached the surface were

gradually scaled by deposition of dissolved solids, especially silica, or 2) a general lowering of the water table in the valley caused a change in ground-water flow patterns, resulting in the flow ceasing at Roosevelt Hot Springs. The second explanation assumes that the springs are connected hydraulically with the shallow ground-water system. This connection has not been established.

Thermo Hot Springs is a collective name for numerous springs that are located about 20 miles (32 km) southwest of Milford. These springs issue from mounds on the valley floor. Mower and Cordova (1974) estimated Thermo Hot Springs to discharge about 100 acre-ft/yr (0.1 hm^3/yr).

6.2 EXPLORATORY DRILLING AND TESTING

6.2.1 Drilling Program

To determine subsurface geology, aquifer characteristics, and the chemical quality of the water at and near the proposed OB sites in Escalante Valley, a drilling and testing program was conducted by Ertec commencing in November 1980. Drilling sites were selected based on several criteria. These criteria are as follows:

- Proximity to the proposed Operational Base location;
- Proximity to other wells - test wells should be located between 1 to 3 miles (2 to 5 km) from any existing wells or springs so that the existing wells can be monitored and to allow for assessing the proper set-back distances for future withdrawals;
- Land status - lands must be public domain lands not being considered for future wilderness area, not presently under wilderness control, or not part of a national park or forest;

- Accessibility - well site should be easily accessed from existing roads; and
- Hydrogeologic considerations - depth to water, depth to bedrock, and proximity to any recharge-discharge areas.

The Milford OB drill site is located at T31S, R13W, Section 5bb in Iron County, Utah. Situated on a relatively flat surface at about 5060 feet (1542 m) elevation, the site is approximately 1 mile (2 km) west of an eastward sloping alluvial fan. Access to the site is by a BLM maintained road. Hydrologic reconnaissance of the Milford area indicated that the anticipated water level at the drilling site would be between 65 feet (20 m) and 80 feet (24 m).

In November 1980, a test hole was drilled to a total depth of 600 feet (183 m) and an observation well located 500 feet (152 m) from the test well was drilled to 340 feet (104 m). Geophysical logs indicated possible water-bearing zones between 100 to 320 feet (30 to 98 m). Static water levels were measured at about 30 feet (9 m) below ground surface. Well designs were developed based on an interpretation of potential water-bearing zones from the lithologic samples and geophysical logs. A complete description of the drilling and testing activities, well designs, and other data are included in Appendix E.

The Beryl OB drill site is located at T33S, R17W, Section 21dd. The site is located on a relatively flat surface at an elevation of 5300 feet (1615 m). The site is approximately 5 miles (8 km) northwest of Beryl and is accessed by a BLM maintained road.

Drilling activities commenced in December 1980 with the drilling of an observation well to a total depth of 504 feet (154 m) below ground surface. Geophysical logs and lithologic samples indicated that the potential water-bearing zone occurs from a depth of 189 to 235 (58 to 72 m) and from 255 to 332 feet (78 to 101 m) below ground surface. Static water levels were measured between 185 to 193 feet (56 to 59 m) below ground surface. An interpretation of the resistivity logs indicated a confining layer occurred from 235 to 255 feet (72 to 78 m). A test well located 500 feet (152 m) south of the observation well and was drilled to a total depth of 350 feet (107 m) and an aquifer test was performed. A complete description of the drilling and testing activities, well designs, and other data are included in Appendix E.

6.2.2 Aquifer Testing

Aquifer tests were performed at each of the Milford and Beryl test well sites to determine the hydraulic characteristics of the aquifer, chemical characteristics of the ground water, and the potential impact on nearby wells. In December 1980, step-drawdown and constant discharge aquifer tests were made at the Milford OB site. Ground-water level measurements were made using a Sinco Electro-Piezo recorder with periodic checks made with an electric sounder. The step-drawdown test was made at five different discharge rates which varied between 205 and 550 gallons per minute (gpm) (13 and 35 l/s) with drawdowns varying between 29 and 180 feet (9 and 55 m).

Drilling activities commenced in December 1980 with the drilling of an observation well to a total depth of 504 feet (154 m) below ground surface. Geophysical logs and lithologic samples indicated that the potential water-bearing zone occurs from a depth of 189 to 235 (58 to 72 m) and from 255 to 332 feet (78 to 101 m) below ground surface. Static water levels were measured between 185 to 193 feet (56 to 59 m) below ground surface. An interpretation of the resistivity logs indicated a confining layer occurred from 235 to 255 feet (72 to 78 m). A test well located 500 feet (152 m) south of the observation well and was drilled to a total depth of 350 feet (107 m) and an aquifer test was performed. A complete description of the drilling and testing activities, well designs, and other data are included in Appendix E.

6.2.2 Aquifer Testing

Aquifer tests were performed at each of the Milford and Beryl test well sites to determine the hydraulic characteristics of the aquifer, chemical characteristics of the ground water, and the potential impact on nearby wells. In December 1980, step-drawdown and constant discharge aquifer tests were made at the Milford OB site. Ground-water level measurements were made using a Sinco Electro-Piezo recorder with periodic checks made with an electric sounder. The step-drawdown test was made at five different discharge rates which varied between 205 and 550 gallons per minute (gpm) (13 and 35 l/s) with drawdowns varying between 29 and 180 feet (9 and 55 m).

Drilling activities commenced in December 1980 with the drilling of an observation well to a total depth of 504 feet (154 m) below ground surface. Geophysical logs and lithologic samples indicated that the potential water-bearing zone occurs from a depth of 189 to 235 (58 to 72 m) and from 255 to 332 feet (78 to 101 m) below ground surface. Static water levels were measured between 185 to 193 feet (56 to 59 m) below ground surface. An interpretation of the resistivity logs indicated a confining layer occurred from 235 to 255 feet (72 to 78 m). A test well located 500 feet (152 m) south of the observation well and was drilled to a total depth of 350 feet (107 m) and an aquifer test was performed. A complete description of the drilling and testing activities, well designs, and other data are included in Appendix E.

6.2.2 Aquifer Testing

Aquifer tests were performed at each of the Milford and Beryl test well sites to determine the hydraulic characteristics of the aquifer, chemical characteristics of the ground water, and the potential impact on nearby wells. In December 1980, step-drawdown and constant discharge aquifer tests were made at the Milford OB site. Ground-water level measurements were made using a Sinco Electro-Piezo recorder with periodic checks made with an electric sounder. The step-drawdown test was made at five different discharge rates which varied between 205 and 550 gallons per minute (gpm) (13 and 35 l/s) with drawdowns varying between 29 and 180 feet (9 and 55 m).

Ground-water level measurements were made using a Sinco Electro-Piezo recorder with periodic checks made with an electric sounder. The step-drawdown test was made at five different discharge rates which varied between 205 and 550 gallons per minute (gpm) (13 and 35 l/s) with drawdowns varying between 29 and 180 feet (9 and 55 m).

Drilling activities commenced in December 1980 with the drilling of an observation well to a total depth of 504 feet (154 m) below ground surface. Geophysical logs and lithologic samples indicated that the potential water-bearing zone occurs from a depth of 189 to 235 (58 to 72 m) and from 255 to 332 feet (78 to 101 m) below ground surface. Static water levels were measured between 185 to 193 feet (56 to 59 m) below ground surface. An interpretation of the resistivity logs indicated a confining layer occurred from 235 to 255 feet (72 to 78 m). A test well located 500 feet (152 m) south of the observation well and was drilled to a total depth of 350 feet (107 m) and an aquifer test was performed. A complete description of the drilling and testing activities, well designs, and other data are included in Appendix E.

6.2.2 Aquifer Testing

Aquifer tests were performed at each of the Milford and Beryl test well sites to determine the hydraulic characteristics of the aquifer, chemical characteristics of the ground water, and the potential impact on nearby wells. In December 1980, step-drawdown and constant discharge aquifer tests were made at the Milford OB site. Ground-water level measurements were made using a Sinco Electro-Piezo recorder with periodic checks made with an electric sounder. The step-drawdown test was made at five different discharge rates which varied between 205 and 550 gallons per minute (gpm) (13 and 35 l/s) with drawdowns varying between 29 and 180 feet (9 and 55 m).

Drilling activities commenced in December 1980 with the drilling of an observation well to a total depth of 504 feet (154 m) below ground surface. Geophysical logs and lithologic samples indicated that the potential water-bearing zone occurs from a depth of 189 to 235 (58 to 72 m) and from 255 to 332 feet (78 to 101 m) below ground surface. Static water levels were measured between 185 to 193 feet (56 to 59 m) below ground surface. An interpretation of the resistivity logs indicated a confining layer occurred from 235 to 255 feet (72 to 78 m). 6.2.2 Aquifer Testing

Aquifer tests were performed at each of the Milford and Beryl test well sites to determine the hydraulic characteristics of the aquifer, chemical characteristics of the ground water, and the potential impact on nearby wells. In December 1980, step-drawdown and constant discharge aquifer tests were made at the Milford OB site. Ground-water level measurements were made using a Sinco Electro-Piezo recorder with periodic checks made with an electric sounder. The step-drawdown test was made at five different discharge rates which varied between 205 and 550 gallons per minute (gpm) (13 and 35 1/s) with drawdowns varying between 29 and 180 feet (9 and 55 m).

Drilling activities commenced in December 1980 with the drilling of an observation well to a total depth of 504 feet (154 m) below ground surface. Geophysical logs and lithologic samples indicated that the potential water-bearing zone occurs from a depth of 189 to 235 (58 to 72 m) and from 255 to 332 feet (78 to 101 m) below ground surface. Static water levels were measured between 185 to 193 feet (56 to 59 m) below ground surface. An interpretation of the resistivity logs indicated a confining layer occurred from 235 to 255 feet (72 to 78 m). A test well located 500 feet (152 m) south of the observation well and was drilled to a total depth of 350 feet (107 m) and an aquifer test was performed. A complete description of the drilling and testing activities, well designs, and other data are included in Appendix E.

6.2.2 Aquifer Testing

Aquifer tests were performed at each of the Milford and Beryl test well sites to determine the hydraulic characteristics of the aquifer, chemical characteristics of the ground water, and the potential impact on nearby wells. In December 1980, step-drawdown and constant discharge aquifer tests were made at the Milford OB site. Ground-water level measurements were made using a Sinco Electro-Piezo recorder with periodic checks made with an electric sounder. The step-drawdown test was made at five different discharge rates which varied between 205 and 550 gallons per minute (gpm) (13 and 35 l/s) with drawdowns varying between 29 and 180 feet (9 and 55 m).

Drilling activities commenced in December 1980 with the drilling of an observation well to a total depth of 504 feet (154 m) below ground surface. Geophysical logs and lithologic samples indicated that the potential water-bearing zone occurs from a depth of 189 to 235 (58 to 72 m) and from 255 to 332 feet (78 to 101 m) below ground surface. Static water levels were measured between 185 to 193 feet (56 to 59 m) below ground surface. An interpretation of the resistivity logs indicated a confining layer occurred from 235 to 255 feet (72 to 78 m). A test well located 500 feet (152 m) south of the observation well and was drilled to a total depth of 350 feet (107 m) and an aquifer test was performed. A complete description of the drilling and testing activities, well designs, and other data are included in Appendix E.

6.2.2 Aquifer Testing

Aquifer tests were performed at each of the Milford and Beryl test well sites to determine the hydraulic characteristics of the aquifer, chemical characteristics of the ground water, and the potential impact on nearby wells. In December 1980, step-drawdown and constant discharge aquifer tests were made at the Milford OB site. Ground-water level measurements were made using a Sinco Electro-Piezo recorder with periodic checks made with an electric sounder. The step-drawdown test was made at five different discharge rates which varied between 205 and 550 gallons per minute (gpm) (13 and 35 l/s) with drawdowns varying between 29 and 180 feet (9 and 55 m).

After the water level had recovered to the approximate pretest level, a constant discharge aquifer test was initiated. The pump ran for 10 days at a rate of 350 ± 10 gpm (22 ± 0.6 l/s). Maximum drawdown in the test well was about 90.3 feet (27.5 m) and in the observation well about 4.9 feet (1.5 m). Selected wells within 3 miles (5 km) of the site were measured daily to determine if any drawdown occurred in response to the test pumping. No drawdown was noted in any of the existing wells. Water samples were also collected from the test well for both field and laboratory water-quality determinations. Complete water-level recovery occurred within two days of cessation of pumping.

In January 1981, step-drawdown and constant discharge aquifer tests were conducted at the Beryl OB test well. The step-drawdown test was made at four discharge rates which varied between 250 and 775 gpm (16 and 49 l/s) with drawdowns varying between 3 and 21 feet (1 and 6 m). Following this test, a 10-day constant discharge test was performed at 600 gpm ± 10 gpm (38 ± 0.6 l/s). Maximum drawdown in the test well was about 14.1 feet (4.3 m) and about 0.3 feet (0.1 m) in the observation well. Water samples were collected from the discharge at the test well site for both field and laboratory water-quality determinations. Complete water level recovery occurred within two days of cessation of pumping.

Water-level monitoring of one existing well within 3 miles (5 km) of the test site was conducted daily. No drawdown was

observed in this well during the test period. No other wells were monitored in the 3-mile (5-km) radius of the test well site because permission to access other wells could not be obtained.

Based on the results of the aquifer tests at the Milford and Beryl OB sites, aquifer characteristics including transmissivity, storage coefficient, and leakance (Milford OB only) were determined.

At the Milford OB test site, evaluation of the test data and the lithologic logs indicates the possibility of a semiconfined aquifer. The following coefficients were calculated:

Transmissivity	5,400 ft^2/day (500 m^2/day)
Storage Coefficient	0.0004
Leakance	1.5×10^{-3} ft^2/day ($1.4 \times 10^{-4} m^2$/day)

The value for transmissivity at the site is in line with the values that Mower and Cordova (1974) indicate for the valley. The storage coefficient, however, represents only the initial or early test results and should not be used to estimate long-term impacts. Mower and Cordova (1974) estimate the average storage coefficient for the Milford district to be 0.2 for long-term withdrawals (one to 20 years). Based on the results of preliminary numerical modeling of the valley conducted by Ertec, a figure of 0.1 was found to be reasonable for the area of the valley where the test well site is located. The fact that ground-water levels along the unlined canals respond rapidly to surface-water flow and infiltration indicate water table conditions and the absence of shallow confinement on the east side

of the valley. The presence of a possible confining unit at the Milford test site suggests that confining layers in the valley-fill material may not be continuous over a large area. Therefore, if locally confined or semiconfined, long-term pumping at moderate to high withdrawal rates will stress the aquifer to where it will respond as a water-table aquifer.

At the Beryl site, evaluation of data indicates an unconfined aquifer condition. The average calculated transmissivity is 8600 ft^2/day (800 m^2/day), and the storage coefficient is 0.05. However, the storage coefficient represents only the early stages of water coming from storage and should not be used to estimate long-term impacts. A figure of 0.2, as estimated for similar sediments in the Milford district by Mower and Cordova (1974), is considered more reasonable for long-term withdrawals (one to 20 years) at the Beryl test site. This value is supported by the results of preliminary modeling efforts conducted by Ertec. Aquifers with transmissivities and storage coefficients such as those indicated in this report are capable of producing large quantities of ground water.

6.3 GROUND-WATER DEVELOPMENT

6.3.1 Ground-Water Availability

The quantity of ground water in storage in the valley-fill aquifer is dependent upon the porosity of the valley fill as well as the volume of saturated fill. The principal ground-water reservoir generally consists of less that 50 percent sand and coarser material with some areas having less than 25 percent sand and

coarser materials. This indicates that a large part of the reservoir is made up of clay and silt, and it is estimated that this type of saturated valley-fill material contains an average of 40 percent water by volume (Mower and Cordova, 1974). This would mean that the amount of water in storage in the upper 100 feet (31 m) of saturated thickness would be approximately 14.3 million acre-feet (17,700 hm^3) in the Beryl district and 13.6 million acre-feet (16,800 hm^3) in the Milford district for a total of about 27.9 million acre feet (34,400 hm^3). The amount of ground water in storage in an aquifer is greater than the amount that can be withdrawn. Specific yield is a measure of the amount of water that can be obtained from aquifer materials due to gravity drainage (water-table conditions). Estimates by Mower and Cordova (1974) for specific yield of this saturated material range from 0.15 to 0.20. Based on these estimates, the amount of water that can be withdrawn from the upper 100 feet (30.5 m) of saturated material is 6.4 million acre-feet (7890 hm^3) for the Beryl district and 6.2 million acre-feet (7645 hm^3) for the Milford district for a combined total of 12.6 million acre-feet (15,535 hm^3).

Declines in the water table in some parts of Escalante Valley have been occurring for over 40 years due to more water being withdrawn annually from the ground-water reservoir than is being recharged. To determine the amount of this overdrafting, several factors must be considered in the hydrologic balance of recharge and discharge.

Tables 1 and 2 (Section 6.1.1) present a summary of the current recharge and discharge occurring in the Milford and Beryl districts. The amount of ground water lost due to evapotranspiration as well as the quantity of water withdrawn by pumpage must be considered as discharge from the ground-water reservoir. Comparison of current recharge with discharge indicates more than 32,900 acre-ft/yr (40.6 hm^3/yr) of water is being overdrafted from the Milford district. In the Beryl district, almost 60,000 acre-ft/yr (74 hm^3/yr) of water is being overdrafted from the ground-water basin at present rates of usage. Because of this trend, the Utah State Engineer has declared both districts closed and will allow no new appropriation of ground water.

6.3.2 Present Development

The Escalante Valley for many years supported a small population where culinary water supplies were obtained largely from perennial streams or springs. Irrigation from wells in the area began in about 1916 and increased markedly after the mid-1940s.

Most of the early wells were constructed in the Milford district with development in the Beryl district beginning in the late 1920s and increasing markedly after the late 1940s, as in the Milford district.

The area in the Beryl district irrigated by ground water during the 1940s increased from 900 acres (364 ha) to 16,000 acres (6475 ha). Annual pumping in the district rose from 2600 to 51,000 acre-feet (3.2 to 62.9 hm^3). Further development

Source	AVERAGE ANNUAL QUANTITY (ACRE-FEET) Milford District	Beryl District	Total
1. Subsurface flow-tributary valleys and from bedrock in the mountains	16,700	27,100	43,800
2. Losses from stream channels	7,200	3,000	10,200
3. Losses from major canals (a)	4,600	--	4,600
SUBTOTAL	28,500 (35 hm^3)	30,100 (37 hm^3)	58,600 (72 hm^3)
4. Infiltration from irrigated lands (b)	20,000	17,500	37,500
5. Infiltration from precipitation on valley floor (c)	1,300	2,000	3,300
TOTAL	49,800 (61 hm^3)	49,600 (61 hm^3)	99,400 (123 hm^3)

a. Average annual discharge at Rocky Ford Dam for period 1932-79 is 25,400 acre-feet (31.3 hm^3) (USGS, 1980).

b. Average annual withdrawals from ground-water reservoir for 10 years 1969-78 were 60,000 acre-feet (74 hm^3) in Milford and 79,000 acre-feet (97 hm^3) in Beryl (USGS, 1980) and irrigation percolation rate of 25 percent. Milford figure includes 5000 acre-feet (6 hm^3) from application of surface-water supplies.

c. Approximately 19,000 acres (7700 ha) in Milford district and 20,000 acres (8100 ha) in Beryl district of irrigated lands.

SUMMARY OF CURRENT DISCHARGE FROM ESCALANTE VALLEY

28 MAY 81 TABLE 2

since that period has increased this annual rate to 79,000 acre-feet (97.4 hm^3) with more than 20,000 acres (8000 ha) being irrigated in the Beryl District in 1979. In the Milford district, pumping increased from 60 acre-feet (.07 hm^3) in 1918 to 30,000 acre-feet (37.0 hm^3) in 1950. Continued development has increased the average annual withdrawals from the ground-water reservoir to approximately 60,000 acre-feet (74.0 hm^3) in the Milford district with irrigated acreage being about 19,000 acres (7700 ha) in 1979.

The increase of pumping since the 1940s has resulted in a marked decline of ground-water levels in both districts. In the Beryl district, the static water levels have declined as much as 55 feet (16.8 m) in wells near the center of the heavy pumping area. The amount of decline in the water level decreases away from the pumping center to the margins of the valley. Throughout the district, water levels have declined an average of 20 feet (6 m) since 1950.

In the Milford district, water levels have declined an overall average of 15 feet (4.6 m) since 1950 with the greatest declines occurring in the area from about 2 to 6 miles (3 to 10 km) south of Milford.

6.3.3 Allocations

A listing of the certificates, proofs, permits, and applications filed in the Milford and Beryl districts is provided in Appendix F. In the Milford district area there are 250 claims totaling 55,500 acre-ft/yr (68.4 hm^3/yr) and in the Beryl

district area there are 471 claims for 108,200 acre-ft/yr (133.4 hm^3/yr). These claims greatly exceed the estimated 88,000 acre-ft/yr (108.5 Hm^3/yr) perennial yield for the valley. This perennial yield estimate includes 58,000 acre-ft/yr (71.5 hm^3/yr) in Milford district and 30,000 acre-ft/yr (32.0 hm^3/yr) for the combined Lund/Beryl-Enterprise hydrographic area. The Lund Beryl-Enterprise figure is an average of the reported range (Ertec Western, 1980).

7.0 WATER QUALITY

7.1 CHEMICAL CONSTITUENTS

Chemical analyses of ground water from 38 wells and two springs were used to evaluate water quality of the Milford district. A complete listing of the data is presented in Appendix D, Table D-1. Six water samples (from four wells and six springs) were collected by Ertec during a field reconnaissance study in November 1980. Other water-quality data used in the analyses were obtained from the USGS records of water samples collected after 1970. Additional chemical data were available for numerous wells and five springs in the Milford district and are listed in Appendix D, Table D-2, however, these data were not used for the water-quality evaluation due to the date of sampling (pre-1970), repetition in sampling, or incomplete analyses.

Chemical data from 22 wells and six springs were used in the evaluation of the water quality of the Beryl district and the data are also presented in Appendix D, Table D-1. Water samples were collected from 12 wells and six springs by Ertec in December 1980. The remaining data are from the analyses of water samples collected by the USGS after 1970. Additional chemical data for numerous wells and springs in the Beryl district were available and are listed in Appendix D, Table D-2, but were not considered in the water-quality evaluation for the same reasons as stated above.

Trilinear diagrams (Piper, 1944) are presented to illustrate the differing water types. As the total dissolved solids (TDS)

concentration increases, the ground-water quality gradually evolves from a bicarbonate to sulfate to chloride type (anions).

Figure 5 is a trilinear diagram showing wells in the Milford district which have TDS concentrations ranging from 224 mg/l to 463 mg/l. Most of the water from these wells has a calcium bicarbonate composition; water from one well is indicated as sodium bicarbonate in type. These water samples are from wells in various locations throughout the district. Figure 6 is a trilinear diagram showing wells having TDS concentrations ranging from 476 mg/l to 584 mg/l. These water compositions vary from mixed calcium sulfate-chloride to calcium bicarbonate. Most of these wells are located in the heavily irrigated area in the immediate vicinity of Milford. Water having TDS concentrations ranging from 610 mg/l to 954 mg/l are shown in Figure 7. These water samples are classified as calcium-sodium sulfate and calcium-sodium chloride and are located throughout the entire Milford district.

Figure 8 is a trilinear diagram showing wells having TDS concentrations which exceed 1000 mg/l. These water samples are predominantly sodium chloride in composition. Water of the poorest quality is located within a 5-mile (8-km) radius of the town of Milford. The poorer water quality in the area is probably attributable to the infiltration of irrigation water. Typically, salts naturally occurring in the applied irrigation water are concentrated through evaporation and remain in the soil as concentrations of leachable minerals. Subsequent applications

of water move these minerals downward to the ground-water reservoir. Chemicals from fertilizers and pesticides, which are applied at the surface, may also be carried into the ground-water system.

Figure 9 shows the water types of two springs sampled in the Milford district. One spring has bicarbonate water and one has chloride water. Both springs are located in or near volcanic terrain.

In summary, the water chemistry in the Milford district is widely varied. Concentrations of TDS in water samples range from 224 mg/l to 4130 mg/l. Water types noted include calcium bicarbonate, sodium bicarbonate, calcium sulfate, sodium sulfate, magnesium sulfate, calcium chloride, and sodium chloride. The pH values remained relatively constant among the samples collected. The values ranged from 7.1 to 8.9 pH units and averaged 7.9 pH units.

Figure 10 shows the water types from wells in the Beryl district which have TDS concentrations ranging from 230 mg/l to 490 mg/l. These water samples are calcium bicarbonate in composition except for water from one well located at (C-35-16)9add1 which has a higher concentration of chloride. Most of these wells are located in the southwestern periphery of the heavily pumped area.

Figure 11 is a trilinear diagram showing water types from wells in the Beryl district which have TDS concentrations ranging from 609 mg/l to 2000 mg/l. These wells are located throughout the

ESCALANTE VALLEY
WELLS – WATER CHEMISTRY

28 MAY 81 FIGURE 11

Beryl district. The water has compositions which are predominantly sulfate and chloride type. Figure 12 shows the water types from six springs in the Beryl district. Five of the springs have bicarbonate type compositions and have low TDS concentrations ranging from 218 mg/l to 440 mg/l. One spring located at (C-32-14)18daa has a sodium chloride composition and a TDS of 773 mg/l. All six springs are located near the rock boundary on the northwestern side of the Beryl district.

7.2 SUITABILITY OF WATER FOR PUBLIC SUPPLY

Most of the waters analyzed are suitable for use as domestic drinking water as indicated in Drawing 2. Table 3 lists primary drinking water standards of the EPA and Tables 4 and 5 list primary and secondary drinking water standards of the state of Utah. Utah standards are similar to, but more stringent than, those required by the federal government. For example, there is no federal primary standard for sulfate or TDS concentrations, but the state of Utah has set primary standards of 500 mg/l for sulfate and 2000 mg/l for TDS.

One well in the Milford district, (C-27-11)34dba, has water which exceeds federal and state standards for nitrate concentrations. This well is located near the town of Milford in an area of heavy agricultural activity. Nitrate contamination may be due to the use of fertilizers in this region.

Two wells sampled in the Milford district have water with fluoride concentrations which exceed both the federal and the

UTAH SECONDARY DRINKING WATER STANDARDS MAXIMUM CONTAMINANT LEVELS FOR INORGANIC CHEMICALS

28 MAY 81 TABLE 5

state primary drinking water standards. These wells are also located in the immediate vicinity of the town of Milford.

Utah primary standards for both sulfate and TDS are exceeded in five wells in the Milford district. Water from one additional well exceeds the sulfate standard only. The wells are all located in the immediate Milford vicinity. These high sulfate and TDS concentrations are probably the result of intensive agricultural activity.

One well in the Beryl district, located in (C-36-15)7dcc1, has water quality that exceeds Utah sulfate standards. Two wells had TDS concentrations that were close to or equal to the Utah standard of 2000 mg/l. Two of these wells are located in the northwestern portion of the Beryl district near the rock boundary and may be the result of a relatively shallow perched ground-water zone being affected by surface activity in the area.

Future development of water resources for public supply in the Milford district is feasible from a water-quality standpoint in areas south of Township 29 South and west of Range 11 West. Ground-water samples in this area meet federal and state drinking water standards for all inorganic constituents tested. Large-scale development of additional water supplies is not recommended in the immediate Milford vicinity. Development of water resources in the Beryl district for public supply is also feasible when considering the water quality.

7.3 WATER QUALITY SUITABILITY FOR CONSTRUCTION

Construction water uses are summarized in Table 6. The only construction use where water quality poses a potential problem is in the mixing of cement. Water suitable for cement mixing is unlikely to cause problems in soil compaction for road and rail construction or in dust suppression.

The recommended limits on the quality of mixing water for cement are summarized in Table 7. The Portland Cement Association (1966) suggests that water containing less than 2000 mg/l of TDS is generally satisfactory for mixing cement. All but five water samples from the Milford district meet this criterion. The five wells, which exceed TDS criteria, are all located in the immediate vicinity of Milford. All but one of water samples from the Beryl district fall within all construction criteria limits.

WATER QUALITY MAP
ESCALANTE VALLEY – UTAH

28 MAY 81

DRAWING 2

8.0 IMPACTS OF WATER DEVELOPMENT

Ground-water use in Escalante Valley presently exceeds estimates of the annual ground-water recharge. As a result, the Utah State Engineer's Office has declared the valley to be closed and will not allow new ground-water appropriations.

The peak year MX water demands for construction of a secondary OB site, as estimated by the U.S. Army Corp of Engineers, is 4198 acre-feet (5.2 hm^3). This is equal to 5.3 percent of the present ground-water use in the Beryl district and seven percent in the Milford district. Maximum anticipated water use for operations (2900 acre-ft/yr [3.6 hm^3/yr]) represents 3.7 percent of the present annual use in the Beryl district and 4.8 percent of the annual use in the Milford district. If Escalante Valley is selected as a primary OB site, the peak year water demands for construction, as estimated by the U.S. Army Corps of Engineers, is 9685 acre-feet (11.9 hm^3/yr). This is equal to 12.3 percent of the present ground-water use in the Beryl district and 16.1 percent in the Milford district. Maximum anticipated water demand for primary base site operational use (4200 acre-ft/yr [5.2 hm^3/yr]) represents 5.3 percent of present annual use in the Beryl district and seve -ent of the present use in the Milford district.

Construction is expected to begin in 1983 and be completed in 1990. The operation phase will begin after most of the construction has been completed, therefore, peak withdrawals will

occur only during the construction phase. Because no new appropriations of water will be allowed in Escalante Valley, this water will have to be purchased or leased from existing water-right owners. This will result in no new increase in ground-water withdrawals in the valley.

To provide the anticipated peak water demand for MX construction of a secondary OB site, approximately 1680 acres (680 ha) of irrigated land will have to be temporarily retired from present use. Approximately 3874 acres (1568 ha) of irrigated land would have to be temporarily retired from present use to provide water for construction of a primary OB site. These acreage retirement amounts would decrease to 1160 acres (470 ha) and 1680 acres (680 ha) for secondary and primary site long-term water use, respectively. These estimates are based on the State Engineer's guideline (2.5 acre-feet/acre) for retiring agricultural land and converting water rights to other uses.

The location of the points of withdrawal will have to be shifted to areas near the candidate OB sites. By shifting the demand for ground water from the heavily pumped areas of the valley to lightly pumped areas, a positive impact could result. A change in points of withdrawal would slow the decline of water levels in the heavily pumped parts of the Escalante Valley by spreading the effects of pumping over a larger area. This could also slow possible deterioration of the water quality in those areas where return flow to the aquifer leaches fertilizers and pesticides from the soil layers into the ground-water reservior.

Maintaining the existing rate and location of ground-water withdrawals for irrigation in Escalante Valley will continue to impact the ground-water system. Water quality will continue to change due principally to recirculation of ground water used for irrigation and the reversal of the potentiometric gradient in some places. Natural areas of ground-water discharge may be impacted and some phreatophyte vegetation may be eliminated which in turn could affect wildlife habitat and livestock grazing areas. Land subsidence due to withdrawal of ground water is already occurring in portions of the Escalante Valley and may become a problem in those areas where irrigation well fields are in close proximity to populated areas, highways, and railroads. Conversely, withdrawing ground water in those areas near the proposed OB sites would shift pumpage away from areas of heavy withdrawals. This would reduce the impacts on existing pumping centers.

The impact of development of ground-water supplies in the proposed OB areas in Escalante Valley depends both on the hydrologic conditions at the well sites and the method of development. Declines of the ground-water levels in neighboring wells may occur, however, the interference between wells is expected to be minimal. Computer simulations using a Trescott, Pinder, Larson two-dimensional finite difference model for aquifer simulation (1976) were performed to predict the long-term effects of MX withdrawls on the ground-water levels in the valley. The first simulation was run at a withdrawal rate of 2900 acre-ft/yr

(3.6 hm^3/yr) which is the anticipated operational water requirement for a secondary OB site in the valley. The second simulation maintained a withdrawal rate of approximately 4200 acre-ft/yr (5.2 hm^3/yr) as would be expected during operation of a primary OB site. Peak construction water demand, which is higher was not used in the early part of the simulation.

In the first simulation for a secondary OB withdrawal rate for each candidate OB area, six wells, spaced at distances ranging from 1 to 3 miles (2 to 5 km), were pumped at a rate of 300 gpm (19 l/s) for the anticipated 30 year life of the system. Transmissivities used in the simulation ranged from 6000 to 21,000 ft^2/day (556 to 1945 m^2/day) at the Beryl well field site and 4500 to 10,500 ft^2/day (417 to 973 m^2/day) in the vicinity of the Milford site. A storage coefficient of 0.2 and 0.1 was assumed for the Beryl and Milford sites respectively.

At the end of the 30 year pumping period, a drawdown of 5 feet (2 m) occurred one-half mile (1 km) from the Beryl well field site and at a distance of 6 miles (10 km), the simulated drawdown was less than 1 foot (0.3 m). At the Milford site a drawdown of 5 feet (2 m) occurred 2 miles (3 km) from the well field and at 8 miles (13 km) the drawdown was less than 1 foot (0.3 m).

A second simulation maintained a withdrawal rate of 4200 acre-ft/yr (5.2 hm^3/yr) with six wells at each location pumping at 440 gpm (28 l/s) for the 30-year period. At the Beryl site,

5 feet (2 m) of drawdown occurred 3 miles (5 km) from the well field and at 8 miles (13 km) the drawdown was less than 1 foot (0.3 m). At the Milford site a drawdown of 5 feet (2 m) occurred 5 miles (8 km) from the well field and at 10 miles (16 km) the drawdown was less than 1 foot (0.3 m).

These simulated drawdowns can be considered a worse case situation but are useful in assessing the approximate impacts which would likely occur from the proposed withdrawals. A more selective and exacting well field would reduce expected drawdowns.

The transmissivity ranges used in the above simulations are based on the results of aquifer tests conducted by Ertec in December 1980 and January 1981 and specific capacity data found in the literature. The values in the Milford area are within the range reported by Mower and Cordova (1974) from their study of that area. The storage coefficients are also within the range estimated by Mower and Cordova (1974) based on a neutron radiation method of analysis of borehole samples. These storage coefficients are indicative of an unconfined aquifer and support other geologic evidence which suggests that along the margins of the valley where proposed OB wells would be located there is a lack of fine-grained lacustrine and fine-grained alluvial fan materials. Fine-grained sediments occur commonly near the axis of the valley with coarser sediments predominately at the margins. Indications are that the aquifer is confined along the axis and is probably unconfined or locally semi-confined near the margins of the valley.

There would be no impact due to pumping of proposed MX wells on springs because most of the existing springs in the Escalante Valley drainage basin are in the mountains and hills and meteoric in origin. Based on available information, there is no proven hydraulic connection between the valley-fill aquifer and the source-waters for the limited hot spring activity in the valley.

9.0 FUTURE DEVELOPMENT

9.1 POTENTIAL FOR SURFACE-WATER DEVELOPMENT

There are four important surface-water sources in Escalante Valley. Of these, only Meadow Creek is unregulated and has an undependable supply. The other three streams are fully controlled with reserviors retaining surface flows for distribution to present water-right holders. The total certificates and proofs for the Beaver River water that enters the Milford district through Rocky Ford Dam currently exceed the average annual discharge through the dam. The water in the other three streams is also fully appropriated, therefore, no further appropriations or no new developments of surface water can be made from them. Because all regulated surface flows are located a considerable distance from the proposed OB sites, the purchase or lease of surface-water rights is not considered a practical alternative for obtaining a water supply for MX needs.

There are no springs in the Escalante Valley drainage basin that are available for appropriation. None of the springs in the basin flow in sufficient quantities for them to be considered a viable source for the MX Operational Base.

9.2 POTENTIAL FOR GROUND-WATER DEVELOPMENT

Any ground-water development in Escalante Valley for MX purposes will have to be accomplished through the purchase or lease of existing ground-water rights. To provide a secondary MX Operational Base water supply, it will be necessary to retire approximately 1680 acres (680 ha) of irrigated land and shift pumping

well(s) to those areas found to be favorable for MX needs. For a primary site, approximately 3874 acres (1568 ha) of irrigated land would have to be retired during the construction phase only. Aquifer tests performed at the probable OB siting areas indicate the valley-fill aquifer is capable of yielding water in sufficient quantities, of acceptable quality, and at rates needed to meet estimated MX requirements.

Another potential source of water supply in the Beryl district is water being discharged during the dewatering of a mine at the Escalante Silver Mine property. The water is being pumped from fractured volcanic rock which is assumed but not proven to be hydraulically connected to the valley-fill aquifer. If the systems are hydraulically linked the discharge, water does not constitute an independent source of supply.

Discharge from dewatering is piped to North Canal and Shoal Creek and is available for agricultural and other uses. Mining, including dewatering at rates between 31,800 to 61,200 acre-ft/yr (39.2 to 75.5 hm^3/yr), is projected to continue until about 1992-95 (Dames and Moore, 1979). Approximately 4300 acre-ft/yr (5.3 hm^3/yr) is diverted into North Canal with the remainder released into Shoal Creek. It is expected that all of the flow in Shoal Creek will infiltrate into the valley fill within 5 miles (8 km) of its release point. Approximately 52 percent of the annual flow in North Canal is expected to infiltrate along its 12 mile (19 km) length with the remainder ponding at the end point approximately 6 miles (10 km) southeast of the town of Beryl (Dames and Moore, 1979).

APPENDIX A

WELL AND SPRING NUMBERING SYSTEM

WELL AND SPRING NUMBERING SYSTEM

The system of numbering wells and springs in Utah is based on the cadastral land-survey system of the U. S. Government. The number, in addition to designating the well or spring, describes its position on the land net. By the land-survey system, the state is divided into four quadrants by the Salt Lake baseline and meridian, and these quadrants are designated by the upper-case letters A, B, C, and D indicating the northeast, northwest, southwest, and southeast quadrants, respectively. Numbers designating the township and range (in that order) follow the quadrant letter, and all three are enclosed in parentheses. The number after the parentheses indicates the section and is followed by three letters indicating the quarter section, the quarter-quarter section, and the quarter-quarter-quarter section. Figure A-1 is a graphical illustration of this system. Although the basic land unit, the section, is theoretically a 1 mile (2 km) square, many sections are irregular. Such sections are subdivided into 10-acre (4-ha) tracts, generally beginning at the southeast corner, and the surplus or shortage is taken up in the tracts along the north and west sides of the section. The letters a, b, c, and d indicate, respectively, the northeast, northwest, southwest, and southeast quarters of each subdivision. The number after the letters is the serial number of the well or spring within the 10-acre (4-ha) tract.

DRILLING AND TESTING ACTIVITIES

SUMMARY OF DRILLING AND TESTING ACTIVITIES

To ascertain the aquifer characteristics at both of the proposed Operational Base locations in the Escalante Valley, exploratory drilling and testing was conducted by Ertec in November and December of 1980 and January 1981. Field activities were conducted at valley-fill test sites in the Milford district (C-31-13)5bb and the Beryl district (C-33-17)21dd.

Milford OB Exploratory Drilling

Exploratory drilling began at the Milford OB site (C-31-13) 5bb1 in mid-November 1980. Prior to drilling, field reconnaissance of the area indicated that the minimum depth to water at this location would be between 65 to 80 feet (20 to 24 m). A pilot bore hole for the test/production well was drilled to a depth of 600 feet (182 m). The well was geophysically logged and the logs were correlated with the well cuttings. Due to an increasing amount of fines (clays and silts) with depth, the well was completed to a depth of only 340 feet (104 m). Figure E-1 shows a summary of lithologic units penetrated and construction details of the completed test well.

The observation well at the Milford OB site (C-31-13)5bb2 was installed to 342 feet (104 m). This well is approximately 500 feet (152 m) northeast of the test well and constructed as a multi-piezometer so that two aquifer intervals could be monitored (Figure E-2).

LITHOLOGIC LOG AND WELL COMPLETION SUMMARY–MILFORD OBSERVATION WELL

28 MAY 81

FIGURE E-2

Milford OB Aquifer Testing

An aquifer test was conducted in December 1980 at the Milford site to determine the hydraulic characteristics of the valley-fill material at this location. The test consisted of two pumping stages, 1) a step-drawdown test to determine the optimum pumping rate of the aquifer, and 2) a constant discharge test over a period of 10 days to provide data for analysis of the aquifer characteristics and to monitor the effects of the test on water levels in nearby wells (within a 3-mile [4.8-km] radius).

The step-drawdown test consisted of five discharge rates measured by an in-line water meter with a totalizer. The following data were obtained:

Discharge (gpm)	Maximum Drawdown (ft)	Specific Capacity (gpm/ft dd)
205	29.5	7.0
300	62.8	4.8
400	94.0	4.3
500	160.0	3.1
550	180.0	3.1

A plot of discharge versus drawdown and specific capacity versus drawdown is presented in Figure E-3.

The constant discharge aquifer test began after complete recovery of the aquifer from the step drawdown test and continued 240 hours at a rate of 350 $\pm$ 10 gpm (22 $\pm$ 1 l/s). Static water level in the test well was 29.36 feet (8.95 m) and in the observation well 28.80 feet (8.78 m) below ground surface. Maximum drawdown in the test well was 90.30 feet (27.52 m) and

FIGURE E-3

in the observation well 4.93 feet (1.50 m). Recovery began and the original static water levels were reached within two days. Monitoring was continued for an additional 60 hours.

Water levels were monitored in five nearby wells during the test. No significant drawdown resulting from pumping the test well was observed in any of the wells as shown in Table E-1.

Aquifer hydraulic coefficients were calculated through an analysis of drawdown and recovery data in both test and observation wells. The transmissivity was calculated to be approximately 5400 ft^2/d (502 m^2/d). The storage coefficient was found to be 0.0004. The small storage coefficient does not necessarily indicate a confined aquifer. This analysis and the well log indicate the likelihood of a local semiconfined aquifer, and the small storage coefficient represents only the initial or early stage test results.

The location of the well near the base of an alluvial fan and near lake sediments of Tertiary age may provide some indication of whether or not the well is situated in a semiconfined or water table condition. The semiconfined data represent areas near the center of the valley where the concentrations of clays are greater and at relatively shallow depths. The water table conditions are more representative of the alluvial fan deposits along the valley margins where grain size increases. Mower and Cordova (1974) estimate the values for the storage coefficient throughout the valley to be approximately 0.2 representing water table conditions. The figures obtained by Ertec from aquifer

testing are less than this because they represent only the very early results of removing ground water from storage in the area. Mower and Cordova (1974) also indicate that the figure for storage is representative of a one- to 20-year period of pumping.

Transmissivity	5400 ft^2/day
Storativity	0.0004
Leakance	0.0015 ft^2/day

Water Quality

Water samples were collected three times daily from the discharge of the test well for field analyses of temperature, pH, Eh, specific conductivity, and alkalinity. All parameters remained relatively constant throughout the pumping period. Samples were also collected on the first, fifth, and tenth days of the constant discharge test from the test well for laboratory analyses. The following is a summary of the field water-quality samples:

EC	865 - 920 µmhos/cm
pH	6.7 - 6.9
Eh	116 -120 mv
Temperature	13- 14°C
Alkalinity	154 - 160 mg/l

The results of laboratory testing for water quality of the samples obtained through testing are listed in Appendix D, Table D-1.

Beryl OB Exploratory Drilling

Exploratory drilling began at the Beryl OB site (C-33-17)21dd1 in early December 1980. A pilot bore hole was drilled to a depth of 504 feet (154 m). Due to an increasing amount of fines

deeper than 330 feet (101 m) (clays and silts) the well was completed as a multi-piezometer to a depth of 330 feet (101 m). Figure E-4 shows a summary of lithologic units penetrated and construction details of the completed observation well.

The test well (C-33-17)21dd2 was installed to 350 feet (107 m) and is approximately 500 feet (152 m) south of the observation well. The lithology, geophysical logs, construction details, and other information for the test well are shown in Figure E-5.

Beryl OB Aquifer Testing

An aquifer test was conducted in January 1981 at the Beryl OB site. The test consisted of two pumping stages; 1) a step-drawdown test to determine the optimum withdrawal rate of the aquifer; and 2) a constant discharge test over a period of 10 days to provide data for analysis of the aquifer hydraulic characteristics and for the monitoring of the effects of the test on water levels in nearby wells.

The step-drawdown test consisted of four discharge rates measured by an in-line water meter with a totalizer. The following results were obtained:

Discharge (GPM)	Maximum Drawdown (ft)	Specific Capacity (GPM/ft)
250	3.34	74.8
450	6.64	67.7
675	13.77	49.0
775	20.72	37.4

Plots of discharge versus drawdown and specific capacity versus drawdown are presented in Figure E-6.

A constant discharge test began after complete recovery of the aquifer from the step-drawdown test and continued for 240 hours at a rate of 600 ± 10 gpm (38 ± 1 l/s). Static water level in the test well was 185.45 feet (56.53 m) and in the observation well 193.2 feet (58.90 m) below ground surface. Maximum drawdown in the test well was 14.07 feet (4.29 m) and in the observation well 0.25 feet (0.08 m). Recovery began and the original static water levels were reached within two days. Monitoring was continued for an additional 48 hours.

One well located approximately 2 miles (3 km) from the site was measured daily to determine if any drawdown was occurring because of the test. No effect was observed as shown in Table E-2.

Aquifer coefficients were calculated through an analysis of drawdown and recovery data in both the test and observation wells. Transmissivity was calculated to be approximately 8600 ft^2/d (799 m^2/d) and the storage coefficient was 0.05. As indicated in the Milford test, the calculated storage coefficient represents only the initial or early stage test results.

Water Quality

Water samples were collected from the test well three times daily for field analysis of temperature, pH, specific conductivity, and alkalinity. All parameters measured remained relatively constant throughout the test. Samples were also collected from the test well on the first, fifth, and tenth days of
