16. Abstract <p>An oil spill behavior model has been developed which describes the changing area, thickness and physical properties of spills of Prudhoe Bay Crude Oil, No. 2 fuel (home heating) oil and No. 4 (heavy) fuel oil under Arctic marine conditions. The oil properties calculated are density, viscosity, pour point, aqueous solubility, flash point, fire point and interfacial tension. The model calculations include spreading into thin (sheen) and thick slicks, drift, evaporation, dispersion, and formation of water-in-oil emulsions (mousse formation). The model was calibrated by fitting the model equations to data obtained from outdoor weathering experiments conducted at the Coast Guard R&D Center, Groton, Connecticut, during the Winters of 1979/80 and 1980/81 in which arctic spring conditions were simulated. A comprehensive sampling program yielded data on the changing oil properties. The model successfully described the rate of evaporation and the physical properties under these test conditions, with the exception that interfacial tensions were not well predicted. This exception is probably due to the formation of surface active compounds by oil oxidation, and water-in-oil emulsion formation induced by rainfall. It is believed that the model provides the capability of predicting, with acceptable accuracy, the behavior and properties of the three oils when spilled under arctic marine conditions.</p>

SUMMARY

An oil spill behavior model has been developed which describes the changing area, thickness and physical properties of spills of Prudhoe Bay Crude Oil, No. 2 fuel (home heating) oil and No. 4 (heavy) fuel oil under Arctic marine conditions. The oil properties calculated are density, viscosity, pour point, aqueous solubility, flash point, fire point and interfacial tension. The model calculations include spreading into thin (sheen) and thick slicks, drift, evaporation, dispersion, and formation of water-in-oil emulsions (mousse formation). The model was calibrated by fitting the model equations to data obtained from outdoor weathering experiments conducted at the Coast Guard R&D Center, Groton, Connecticut, during the Winters of 1979/80 and 1980/81 in which arctic spring conditions were simulated. A comprehensive sampling program yielded data on the changing oil properties. The model successfully described the rate of evaporation and the physical properties under these test conditions, with the exception that interfacial tensions were not well predicted. This exception is probably due to the formation of surface active compounds by oil oxidation, and water-in-oil emulsion formation induced by rainfall. It is believed that the model provides the capability of predicting, with acceptable accuracy, the behavior and properties of the three oils when spilled under arctic marine conditions.

1.0 INTRODUCTION

There is an obvious incentive to develop a capability to predict the extent of weathering of an oil spill under Arctic conditions, and the resulting changes in the oil's physical and chemical properties. These properties influence both oil behavior, such as spreading, and the applicability and effectiveness of the various available countermeasures. The ultimate objective is to be able to respond rapidly in the event of an Arctic oil spill. A computer program which calculates oil property changes as a result of receiving input data on the oil's properties and amount, and the environmental conditions, would assist this objective.

Many oil spill models have been developed to assist with countermeasures, most being of the trajectory type in which the aim is to calculate where the oil may be at any time. Such models essentially add wind and current vectors for selected time steps. In the model described here, the aim is to predict property changes rather than location, thus the model is complementary to a trajectory model. It may be wholly or partly incorporated into a trajectory model if desired.

It is also obvious that some set of oil property measurements should be made to permit rates of processes such as evaporation to be calculated. The algorithms or equations for such calculations are not always available and of a form compatible with the data acquired or with the oil spill model. These algorithms usually arise from controlled laboratory or outdoor experiments in which the rate of a process is studied in isolation.

In this work, we have addressed the problem of integrating information from (i) physical and chemical property measurements
(ii) outdoor evaporation experiments
(iii) recently developed algorithms describing oil spill processes

into a comprehensive oil spill behavior model.

Components (i) and (iii) relied heavily on previous work undertaken at the University of Toronto with Environment Canada (Arctic Marine Oilspill Program) support as described in several contract reports, notably Mackay and Paterson (1980), Mackay (1978) and Mackay, Buist, Mascarenhas, and Paterson (1979). Measurement and correlation of physical properties were made at the University of Toronto. Component (ii) was undertaken at the U.S. Coast Guard R&D Center, Groton, CT. A final integrating effort involved joint analysis of the results and formulation of the oil spill behavior model.

Three oils were tested both in the laboratory and at Groton; home heating or No. 2 fuel oil, heavy or No. 4 fuel oil, and Prudhoe Bay crude oil. These oils were selected by the U.S. Coast Guard as being representative of oil types most likely to be encountered in spill situations in offshore Alaska.

The approach taken in this report is to first describe in Section 2.0 the oil spill model (a complete listing being given in Appendix A). The experimental weathering work and the physical/chemical determinations are described in Section 3.0 and the results in Section 4.0. The calibration and a discussion of the results are given in Section 5.0.

2.0 OIL SPILL MODEL

Oil spill models are of two general types; trajectory models in which the aim is to predict the location and size of a slick in a given geographical setting under the influence of prevailing wind and current vectors, and behavior models in which the properties of the oil are predicted in some detail from a knowledge of the oil composition and environmental conditions, especially temperature and wind speed. These models may become computationally complex and rarely are they combined. A recent comprehensive review of the status of models has been prepared by Huang and Monastero (1980). Several models are described in the proceedings edited by Mackay and Paterson (1980). Valuable reviews of models and their component processes have been provided by Jordan and Payne (1980).

Possibly the most advanced models currently available or under development are those developed for the U.S. National Oceanic and Atmospheric Administration including recent work on their behalf by Science Applications, Inc., Kirstein and Payne (1982).

To be useful, a model must be applicable to different oils, preferably by inserting a number of parameters into the program which characterize such things as evaporation and changes in properties such as density as a function of extent of weathering and temperature. The model equations should minimize risk of computational failure. The number of parameters should be minimized and the inherent assumptions should be apparent to the user. These requirements favor simplicity but not at the cost of loss of realism. The model described here represents an attempt to achieve this goal by modifying and updating a model developed for the Environment Canada Arctic Marine Oilspill Program (AMOP) in 1975-1980 and most recently described by Mackay and Paterson (1980).

A complete printout of the model is given in Appendix A with behavior and property parameters defined individually for Prudhoe Bay crude oil, home heating oil and heavy fuel oil. The principal features of the model are described below.

The program is written in FORTRAN. It commences by setting spill conditions of oil volume and the duration of the release. Provision for instantaneous or continuous releases is available. Environmental conditions of temperature, wind speed and sea state are defined. The oil properties are entered in the form of appropriate constants for the equations tabulated later.

Rate constants for dispersion, emulsification, spreading, drift and evaporation are calculated or entered. Provision is made to allow any process to be stopped in order to explore its effect by comparing "with" and "without" outputs.

The initial oil properties and spill thickness are set and the calculation proceeds in time increments by computing the amount of oil evaporated and dispersed, water uptake which forms water-in-oil emulsions, spreading and drift. A complete printout then follows giving the mass balance, the rates of the processes and the newly computed oil properties which have changed as a result of evaporation. Any new oil is then added (if the spill is continuous) and the calculation repeated.

The oil is assumed to spread into a thin sheen surrounding thicker patches. Most of the spill area (e.g., 70 to 90%) is sheen, but most of the oil volume is contained in the thick patches. Equations are given to calculate the increase of the thick and sheen areas during a time increment. Provision is made for the thick slick to "feed" the thin slick, a process which is observed on the ocean surface. The spreading equations have been described by Mackay, Buist, Mascarenhas and Paterson (1979).

The evaporation calculation uses the "evaporative exposure" concept in which the oil's vapor pressure is first calculated as a function of temperature and fraction evaporated, then the amount evaporated calculated from a conventional mass transfer flux equation. Separate calculations are included for sheen and thick slicks. The physical basis for these equations has been described by Mackay, Paterson and Nadeau (1980) and by Mackay and Stiver (in preparation).

Dispersion rates for thick and sheen slicks are calculated as a function of windspeed and oil-water interfacial tension and are a simplification of equations described earlier by Mackay and Paterson (1980).

Emulsion (mousse) formation is included using the equations outlined by Mackay and Zagorski (1982). The water content and viscosity of the oil are calculated.

Finally, the location and shape of the slick are calculated using a drift factor of 3.5% of the wind speed. It is possible to overlay the slick location and size in a hydrographic chart.

The variables used in the program are defined and units given in most cases by comment cards in the program but additional information is provided in Appendix A.

A specimen output of the state of spill of Prudhoe Bay crude oil is given in Table 2.1.

3.0 EXPERIMENTAL PROCEDURES

3.1 Weathering Experiment

A laboratory-scale outdoor experiment was conducted at the Coast Guard R&D Center during the Winters of 1979/80 and 1980/81 to simulate the weathering of oil under arctic conditions. Four oils were weathered outdoors on water in open boxes under natural environmental conditions for periods of up to a month with periodic sampling. Temperature and wind speed were monitored continuously to allow calculation of hourly "evaporative exposure" values. Solar radiation was also monitored to elucidate its effect on increasing the oil temperature.

The primary objective of the experiment was to document the effect of evaporation on oil weathering under cold conditions, and its role in determining the oil fraction remaining, and the physical and chemical properties of the oil. Of particular interest to the Coast Guard with regard to the physical properties were the density, viscosity, and combustibility of the oil, as these properties are likely to dictate the effectiveness of various cleanup measures such as skimming, use of suction hoses and burning.

A second objective was to determine the dependence of the rate of evaporation on the "evaporative exposure" and to verify the accuracy of the empirical formulations for modelling this dependence.

A third objective of the experiment was to investigate the dependence of the oil/air interface temperature on the air temperature, underlying surface temperature, and solar radiation. Of particular interest was the role of the solar radiation in raising the temperature of darker oils above ambient environmental levels.

This report deals with the first and second objectives as described above. The results stemming from the third objective are discussed in a separate Coast Guard R&D Center Report (Tebeau, Meehan, and Myers, 1982).

The oil weathering experiments were carried out on the roof of the main R&D Center building at Avery Point, Groton, CT. This location offered a marine environment with ample exposure to the elements. It was hoped that during the winter months, this environment would approximate conditions on the North Slope of Alaska during late spring and summer, when large quantities of oil would most likely reach the ice surface.

The experimental apparatus consisted of plywood weathering boxes (60 cm x 60 cm x 30 cm deep) lined with 5 cm of styrofoam insulation and fitted with a polyethylene liner to make the boxes reusable. Transparent covers were also fabricated and mounted 35 cm above the oil so that the weathering oil samples could be protected from rain and snow if desired as shown in Figures 3.1 and 3.2.

The experimental procedure called for freezing a block of fresh water ice in each box in the R&D Center cold room. The boxes were then transported to the roof where a 400 mL sample of the oil was deposited on the ice surface. The No. 2 and No. 4 oils were obtained from local University of

Figure 3.1 Photograph showing oil weathering experiment test site on the roof of the R&D Center.

Figure 3.2 Photograph showing the oil weathering box with oil sample and rain screen in place.

Connecticut physical plant stocks at Avery Point. The Prudhoe Bay crude oil was obtained by courtesy of the Atlantic Richfield Company. In warmer weather, the oil was initially deposited in a (30 cm x 30 cm) cavity chipped in the center of the ice block to prevent it from running down the sides of the block. Usually after a few days, enough melt water was present so that the oil covered most of the surface area inside the box. The oil samples were then allowed to weather for periods ranging from approximately 1 day to 1 month. At specified times during the period, a sample of each type of oil was removed from the weathering boxes. Descriptions of the environmental monitoring instrumentation are described by Tebeau, Meehan, and Myers (1982).

Altogether, 109 weathered oil samples (30 No. 2 oil, 31 No. 4 oil, 35 Prudhoe Bay Crude, and 13 No. 6 oil) were collected and analyzed for the Winter 1979/80 and Winter 1980/81 experiments. In addition, unweathered standard samples of each type of oil were taken at intervals throughout the experiment period. The time weathering began, time weathering ended, duration of weathering in hours, average temperature during the weathering period, average wind speed during the weathering period, and cumulative evaporative exposure for each weathered sample were calculated, the results being tabulated in Section 4.1.

A preliminary physical properties analysis was conducted at the Coast Guard R&D Center to check mass fraction remaining, specific gravity, viscosity, water content, flash point, fire point, and combustibility. Chemical analysis at the R&D Center involved running Gas Chromatograph (GC) scans on each sample to delineate its chemical composition. A complete description of this analysis and the results are given in a companion report by Tebeau, Meehan, and Myers (1982). Based on the initial results of the R&D Center analysis, various samples of the No. 2 oil, No. 4 oil, and Prudhoe Bay crude oil were selected for further analysis by the University of Toronto as described in Section 2.0. It is the result of this more detailed analysis that forms the basis of the model calibration effort described in Section 5.0.

3.2 Physical Property Determination

Detailed analyses were conducted on 13 samples of Prudhoe Bay crude oil (designated by a prefix "PBC"), 13 samples of home heating oil (HH), and 13 samples of heavy fuel oil (FO), most obtained from the outdoor weathering experiment at Groton. The remainder were samples of the fresh oils and oils obtained by artificial weathering in the laboratory (designated AB). The artificially weathered samples were prepared by bubbling a stream of air of known flow rate through a volume of oil for specified times generally following the procedure described by Mackay and Stiver (1982). This latter group of samples gave results which were used to develop equations describing the physical properties as a function of temperature and extent of evaporation. The equations were then tested on the Groton samples.

Density

Density was measured at 0°C and 20°C using a standard pycnometer calibrated with distilled water. The results are presented in units of kg/m³. Specific gravity is thus this number divided by 1000.

Pour Point

Pour points were measured using the standard American Society for Testing Materials-Institute of Petroleum Method #D97. The general procedure was to heat the oil sample to approximately 46°C, then cool the sample steadily with cold water, then ice water, then an acetone-dry ice mixture (as necessary) until a temperature is reached at which the oil in the test vessel does not flow when tilted horizontally. The results are expressed in °C.

Viscosity

Viscosities were measured using a standard Canon Fenske viscometer at 0°C, 10°C, 20°C, the results being reported in units of centipoise (cp). The now-standard unit is Pascal-seconds (Pas), 1 Pas corresponding to 1000 cp or 1 milli-Pas (mPas) to 1 cp. In most cases, it was either not necessary or it was impossible to measure viscosities at all the above temperatures. For example, it is not feasible to measure viscosities below the pour point, thus the Prudhoe Bay samples which had pour points in the range -2 to +18°C were examined at 10 and 20°C or 20 and 30°C. Only two determinations are necessary to obtain information about the temperature dependence of viscosity.

Aqueous Solubility

Approximately 5-10 mL of the oil samples were added to a separatory funnel containing 50-100 mL of double distilled water. The separatory funnels were shaken gently in a wrist action shaker for about two hours and then allowed to settle for at least 48 hours before analysis at 20°C. 2-3 mL of the saturated aqueous solution were drawn to be analyzed by "purge-and-trap" gas chromatography. The results are given in g/m³ which is numerically equal to mg/L or ppm.

The gas chromatograph was a Hewlett-Packard Model 5840 equipped with a flame ionization detector and a Model 7675A purge-and-trap sampler. The GC column was a wide bore 50 meter long glass capillary column coated with SE-30 (WCOT from Alltech Associates, Inc.).

Typical chromatograms of the fresh oils and field samples are shown in Section 4.0. It was noted that the dissolved components were mostly aromatic in nature, e.g., benzene, toluene, xylenes, substituted benzenes and naphthalenes which is expected as their solubilities in water are higher than those of alkanes. The solubilities were determined using benzene for calibration purposes. As the oil weathered, its solubility decreased leaving the higher molecular weight components such as polynuclear aromatics in the solution. Since the solution was purged at room temperature, it was impossible to strip hydrocarbons heavier than n-C₁₆ or naphthalene from the water.

This is not regarded as a serious problem because these hydrocarbons have low solubilities and they will contribute little in addition to the measured solubility.

It should be noted that these solubilities are measured in distilled water, not seawater. It is, however, relatively simple to calculate the seawater solubility from that of distilled water, the seawater value generally being 75% of the distilled water value.

Oil-Water Interfacial Tension

Oil-water interfacial tension was measured by the spinning drop technique at 20°C in which the shape of an oil drop is observed while spinning in a horizontal column of synthetic seawater (35 g/L sodium chloride), centrifugal effects causing the oil to locate along the axis. The oil drop adopts a nearly cylindrical shape with the relative length and diameter controlled by the balance between centrifugal forces (which tend to elongate the drop) and interfacial tension forces (which tend to favor area reduction and thus resist elongation). By measurement of droplet volume and length at known spinning frequency, it is possible to calculate the interfacial tension, if phase density information is known. The technique has been described by Mackay and Hossain (1982) who give the equations which are used in this work, namely,

$$(1/\gamma)^{1/3} (3X/2)(H)^{1/3} = H r^3 / \gamma + 1$$

$$\text{where } H = \frac{\Delta\rho\omega^2}{4}$$

and γ is interfacial tension (dynes/cm), X is semi-major drop axis (cm), i.e., half the length, r is the radius of the drop sphere of equivalent volume (cm), ω is angular velocity (s^{-1}), and $\Delta\rho$ is density difference between oil and water (g/cm^3). The equation is solved iteratively for γ .

The calculation if done in SI units gives interfacial tension in Newtons/meter (N/m). The commonly used CGS unit of 1 dyne/cm is 10^{-3} N/m or 1 milli-Newton/meter (mN/m). An advantage of the technique is that there is no solid surface in contact with the oil as occurs in the pendant, sessile drop, or de Nouy ring tests.

For selected samples of low viscosity, oil-air interfacial tensions were also measured at 20°C (using the de Nouy ring method).

Oil sheen spreading properties are influenced by these interfacial tensions, the net spreading tendency (ST) being given by

$$ST = \gamma_{AW} - \gamma_{OW} - \gamma_{OA}$$

where the interfacial tensions (γ) are subscripted AW (air/water interface), OW (oil/water interface) and OA (oil/air interface). A positive value of ST results in spreading.

Gas Chromatographic Analysis

To estimate the fraction of the oil which had evaporated, GC analyses were done and the traces compared with samples which had been evaporated to known extents.

A 0.5 μ L sample was injected into a Hewlett-Packard Model-5750 gas chromatograph. The column was temperature programmed from 50°C to 280°C at 15 degrees/min with a one-minute post injection interval. The column used was a 10 foot long, 1/8 inch O.D. stainless steel column, coated with 10% SE30 ultraphase on chromosorb P, A/W, DMCS, mesh 60/80. A flame ionization detector was maintained at 320°C and the injection port was held at 300°C. The carrier gas and the hydrogen flow rate were at about 30 mL/min. The air flow rate was 500 mL/min. A Shimadzu C-RIA Chromatopac integrator recorder was used.

The fuel oil samples which were much less volatile were analyzed in the same manner using a HP 700 Laboratory Chromatograph.

Laboratory Evaporation (Air Bubbling)

To prepare oil samples of known extents of evaporation, oils were subjected to air bubbling under controlled flow and temperature conditions. This gives data which can be used to estimate environmental weathering.

In addition, samples of this "artificially weathered" oil were taken and selected properties determined; namely, the distillation curves and other property curves discussed earlier.

The oils were air bubbled in a 250 mL graduated cylinder. The small cylinder size forced the use of low air flowrates, generally in the range of 1 L/min. The oil was evaporated for selected "exposures" to obtain evenly spaced samples.

To take each sample, the cylinder mass and the volume of oil at both 0°C and 20°C were measured and approximately 40 mL was poured into the pour point apparatus. This 40 mL was used for all the remaining tests. The cylinder was then reweighed and the volume of oil was measured at 20°C only. At this point the amount of air which passed through the oil was recorded.

In the case of the home heating oil there was an accidental loss of approximately 60 mL during the experiment. Fortunately, there was still sufficient oil remaining to complete the experiment.

Distillation

The distillation method used (which gives oil volatility data) is not the ASTM method. The process used was altered in order to predict the evaporation rate more accurately. This is done by measuring the liquid's boiling temperature not the lower condensing vapor temperature. The flask from which the oil was boiled was insulated to reduce superheating, and the liquid contained glass beads (or boiling chips) and a magnetic stirrer to maintain uniformity. A thermocouple was used to measure the liquid temperature.

The amount of condensing liquid was measured against boiling temperature. Precautions were taken to prevent the evaporation of the liquid once it reached the end of the distillation column.

Flash and Fire Points

Flash and fire points were measured for selected oil samples to provide an indication of the ease of ignition. The standard ASTM Cleveland Open Cup method was used and the results reported in °C.

Emulsion Stability

The wax and asphaltene contents of the fresh oils were also measured as mass fractions by standard methods. Assuming that these components do not evaporate, the values for evaporated oils could be calculated readily. These quantities are used later in estimating stability of water-in-oil emulsions as described by Mackay and Zagorski (1982).

In addition, the fresh oils were subjected to a recently developed emulsion formation and stability test described by Mackay and Zagorski (1982).

In total, this work gave a comprehensive set of data which could be used to develop expressions relating the properties as discussed in Section 5.0.

4.0 RESULTS

4.1 Weathering Experiments

The time of year during which the samples were weathered, the condition of the underlying surface, and the prevailing weather conditions during certain weathering periods have led to specific groupings of the samples for the various types of oil as outlined below:

<u>Group</u>	<u>Weathering Period</u>	<u>Samples</u>
<u>Prudhoe Bay Crude</u>		
Winter 1980	4 Feb - 22 Feb 1980	1 - 8
Winter 1981	1 Dec - 4 Feb 1980	9 - 18
Winter 1981 (emulsified)	3 Feb - 26 Feb 1981 and 10 Mar - 13 Apr 1981	19 - 25 and 34 - 35
Spring 1981	2 Mar - 30 Apr 1981	26 - 33
<u>No. 2 Home Heating Oil</u>		
Winter 1980	11 Feb - 25 Feb 1980	1 - 7
Winter 1981	6 Jan - 25 Feb 1981	8 - 18
Spring 1981	26 Feb - 10 Mar 1981	19 - 30
<u>No. 4 Fuel Oil</u>		
Winter 1980	18 Feb - 6 Mar 1980	1 - 6
Winter 1981	6 Jan - 4 Feb 1981	7 - 14
Winter 1981 (emulsified)	3 Feb - 26 Feb 1981 and 2 Mar - 6 Apr 1981	15 - 21 and 25,27,29,30
Spring 1981	2 Mar - 13 Apr 1981	22-24,26,28,31

Tables 4.1 and 4.3 give start and end times, duration, average temperature, wind speed, and evaporative exposure (θ) for each sample. θ , the evaporation exposure, is calculated as KAt/V_o where

K is the mass transfer coefficient calculated from the wind speed (U (m/s)) by $K = 0.0025 U^{0.78}$ (Mackay and Matsugu, 1973)

A is the oil area (m^2)

t is time (s)

V_o is the initial volume of spilled oil (m^3)

The first (Winter 1980) group of samples were weathered during cold weather in February-March 1980 when the ice blocks were generally intact and air temperatures were generally below freezing. The samples were covered with the transparent covers to protect them from precipitation. These samples were initially deposited in cavities in the ice so that the spill area was generally less than the box area for the first few days. Although these samples started out on a solid ice surface, by the end of the period some melting had occurred so that a simulated melt pond situation existed.

The second (Winter 1981) group contains those samples which were weathered during very cold weather in January 1981 for the most part on a solid ice surface. They were not initially deposited in a cavity so that the oil covered the major portion of the box area. The samples were not sheltered by the plastic screens so that snow was allowed to accumulate on the samples. This led to some interesting observations of oil/snow/ice interaction for the darker oils (No. 4 and Prudhoe Bay crude) when solar radiation and warmer temperatures melted the snow. It appears that the darker oils are initially sheltered from the atmosphere by the snow. As solar radiation warms the snow and the oil underneath, the oil appears to pocket in small depressions in the snow and ice (up to a few cm in diameter) (Figures 4.1 and 4.3). It is quite possible that this initial sheltering followed by the collection of the oil into small pockets with a local increase in slick thickness may have a significant short-term effect on the weathering rate. The lighter No. 2 home heating oil did not show this pocketing tendency. It saturated the snow evenly shortly after being covered.

The third group of samples (Winter 1981 emulsified), refer primarily to those samples that were weathered during February 1981. These samples were deposited in 30 cm x 30 cm cavities in the ice to prevent runoff during a warming period in February 1981. The samples were not covered with the transparent screens. Melt pond conditions prevailed throughout the period. During the night of 7-8 February, heavy rains fell inundating the samples. Although the samples remained intact with little oil loss, some oil emulsification was immediately noticed. The emulsification significantly affected the physical properties and possibly the weathering rates of the samples. Accordingly, some of the later samples (March-April 1981) which showed indications of emulsification are also included in this group.

The fourth group (Spring 1981) consists of those samples which were weathered during March-April 1981 when warmer weather prevailed (daytime temperatures well above 0°C), and clear skies led to significant solar radiation levels at the test site. As periods of melting and rainfall were expected, the samples were deposited in the 30 cm x 30 cm cavities and covered with the transparent screens. These samples generally experienced a progression of underlying surface conditions as the ice blocks deteriorated. The samples would rest on solid ice for the first day or so, spread out as melt water created a melt pool situation after a few days, and eventually weather in open water about 20-30 cm deep as the ice block deteriorated completely. This hopefully simulated late summer conditions on the North Slope when accelerated weathering of a spill is likely to occur.

The No. 6 fuel oil samples were not separated into groups and were analyzed in only a cursory fashion, as very little weathering was observed. In fact, the No. 6 oil congealed into a semi-solid mass at the colder ambient temperatures on the roof and did not spread into a slick as did the other oils. When periods of warmer temperatures and increased solar radiation melted the ice around the oil, the semi-solid mass would become partially submerged in the melt water. If the melt water refroze, the oil mass would then be largely encapsulated in the ice, further sheltering the oil from the atmosphere. The fraction of oil remaining and density values for these samples confirmed the absence of any appreciable weathering.

4.2 Physical/Chemical Properties

The results of the physical properties analysis conducted for selected oil samples by the University of Toronto are given in Tables 4.4, 4.5, and 4.6 for the Prudhoe Bay crude oil, the home heating oil, and the heavy fuel oil. The distillation curves are presented in Figure 4.4. Gas chromatographic traces are given in Figures 4.5 to 4.10 for the fresh oil samples and for selected degrees of evaporation. Figure 4.11 illustrates the results obtained in the "purge and trap" analysis for water solubility. The emulsion stability test results are given in Table 4.7.

These results form the basis of the model calibration work described in Section 5.0. A more detailed discussion of the changes in physical and chemical properties with weathering, and the implications on oil spill countermeasures and cleanup is contained in the report by Tebeau, Meehan, and Myers (1982).

5.0 MODEL CALIBRATION AND DISCUSSION

Having obtained the analytical and property data for the oils and having developed the model for these oils, the final stage was to parameterize and run the model equations for the outdoor test conditions at Groton and predict the rates of oil evaporation and the resultant changes in oil properties. Comparison was then made against the actual properties measured experimentally. Because the outdoor conditions were not of constant windspeed and temperature, there is inevitably some loss of fidelity between model and experiment, and accommodation is possible by adjusting the rate constant for evaporation and the environmental conditions.

In practice, the full oil spill model was not used because spreading and dispersion did not occur. Some mousse formation did occur but it was believed to be due to rainfall and is not properly described by the model equations which apply to oceanic conditions. Accordingly, those sections of the model which apply to weathering and physical properties were removed and set up as a separate model.

From previous work, equations were proposed for the dependence of the properties on temperature and volume fraction evaporated (F), given in Table 5.1. These equations were then calibrated to the specific oil types by determining the equation constants, which are listed in Table 5.2. These constants were derived by fitting these equations to the experimental data on the samples obtained from the air-bubbling laboratory weathering procedures described in Section 4.1. The laboratory weathering data were used to derive the constants as this simulated weathering is caused exclusively by evaporation, which is the only process accounted for by the model equations. In the interests of simplicity, an attempt was made to fit the same constants (e.g., K_1 , K_2 , etc.) to all three oils, but this was not possible for viscosity and flash and fire points.

The first step in the calibration process is to relate the volume fraction evaporated (F) to the oil's degree of evaporation, i.e., the evaporative exposure.

The evaporation calculation is based on recent work by Stiver (1982) and Mackay and Stiver (1982) and is an extension of the evaporative exposure concept developed by Mackay and Paterson (1980).

The evaporation rate N (m^3/s) is given by

$$N = KAPv/RT$$

where K is a mass transfer coefficient (m/s), A is the oil area (m^2), P is the oil vapor pressure (atm), v is the oil liquid molar volume (m^3/mol), R is the gas constant ($82 \times 10^{-6} atm m^3/mol K$) and T is absolute temperature (K). The dimensionless group (Pv/RT) is the oil's Henry's law constant, i.e., the ratio of the concentration in air (P/RT) to concentration in the oil (v), both in units of mol/m^3 . This group varies both with temperature and with extent or volume fraction of evaporation, F .

Table 5.1 Properties Measured and Correlated against F (volume fraction evaporated) and T (temperature K). A subscript 0 refers to conditions at 298 K ie. 25°C and F = 0, ie. fresh oil.

ASP ₀	0.024	0.0036	0.032

If the oil's initial volume is $V_0(m^3)$ then

$$N = V_0 dF/dt$$

hence $dF/dt = KAPv/V_0RT$

or $dF/d\theta = Pv/RT$ where $\theta = KAt/V_0$

θ is a dimensionless group termed the "evaporative exposure."

The problem is now to obtain an equation relating Pv/RT to F and temperature. The simplest procedure, which is suitable for fairly volatile oils, is to obtain the atmospheric pressure distillation equation of boiling point vs. F , namely,

$$T_B = A_n + B_n F \quad (A_n \text{ and } B_n \text{ are coefficients})$$

For several oils, the following relationship applies to give (Pv/RT) at 22°C:

$$\ln(Pv/RT) = 6.3 - 0.035 T_B$$

hence $\ln(Pv/RT) = 6.3 - 0.035A_n - 0.035 B_n F$

and substituting from above

$$\ln(dF/d\theta) = 6.3 - 0.035 A_n - 0.035 B_n F$$

Integrating this, and applying the initial condition that $\theta = 0$ at $F = 0$, gives

$$\theta = (\exp(0.035 B_n F) - 1)/(0.035 B_n \exp(6.3 - 0.035 A_n))$$

which gives an analytical relationship between θ and F , the evaporative exposure and mass fraction evaporated.

This approach was satisfactory for the Prudhoe Bay crude oil, but it failed for the distillates because of their high boiling points. Accordingly, separate constants were fitted for these oils, the 0.035 and 6.3 being changed. The final constants are given below.

Prudhoe Bay crude oil

$$\ln(Pv/RT) = 6.3 - 0.035T_B$$

$$T_B = A_1 + B_1 F \quad A_1 = 439 \quad B_1 = 804$$

Home Heating Oil

$$\ln(Pv/RT) = 50.1 - 0.12T_B$$

$$T_B = A_2 + B_2 F \quad A_2 = 521 \quad B_2 = 126$$

No. 4 Fuel Oil

$$\ln(Pv/RT) = 50.1 - 0.12T_B$$

$$T_B = A_3 + B_3 F \quad A_3 = 518 \quad B_3 = 239$$

It is hoped in future work to fit a single equation to cover the entire range of oils likely to be encountered environmentally.

For temperatures $T_E(K)$ other than $22^\circ C$ ($295^\circ K$), a correction is applied, namely

$$\ln(P_E/P_{22}) = 10.6 T_B(1/295 - 1/T_E)$$

Here T_E is the actual environmental temperature.

Now v also changes with temperature (as density ρ changes) as follows:

$$\rho_E = \rho_{22} (1 - K_1(T_E - 295))$$

therefore $v_E = v_{22}/(1 - K_1(T_E - 295))$

Combining these two corrections, and assuming that $\ln(RT)_E \approx \ln(RT)_{22}$ yields

$$\ln(Pv/RT)_E = \ln(Pv/RT)_{22} - \ln(1 - K_1(T_E - 295)) - 10.6T_B(1/295 - 1/T_E)$$

The constant K_1 is given in Table 5.2.

In this manner, a set of calibrated equations was obtained for each oil type, which calculates the volume fraction evaporated (F) from the "evaporative exposure," and then calculates the oil physical properties as a function of F . The next step in the modelling effort was to compare the predicted values of F and the oil physical properties to the experimental data, to judge the accuracy of the model equations. A complete tabulation was prepared (which is not presented here, but is available at the R&D Center) of the individual experimental and calculated values for each oil sample. The summary results are presented in Figures 5.1 and 5.19 in the form of graphs of predicted versus experimental property values for volume fraction remaining, density, viscosity, solubility, pour point, flash point, fire point, and interfacial tensions. The data for each oil type are plotted separately.

The plots for volume fraction evaporated are given in Figures 5.1 to 5.3. The predicted values were obtained by first computing the evaporative exposure (θ), from the time duration, average wind speed, and average temperature values in Tables 4.1 to 4.3, and then using evaporative exposure to compute F according to the formulation outlined above. Experimental data, for the air-bubbled samples, were measured directly in the laboratory. However, such data were unavailable for the samples weathered under environmental conditions at the R&D Center due to inaccuracies in the measurement procedures. For these samples, volume fraction evaporated could only be estimated by inspecting the GC traces and matching with samples of known F . The estimated F values are given in Tables 4.4 to 4.6.

The comparisons between predicted and calculated oil physical properties are given in Figures 5.4 to 5.19. Predicted values were calculated according to the formulations set forth in Tables 5.1 and 5.2. Experimental values were obtained from the University of Toronto analysis, the results being summarized in Tables 4.4 to 4.6. For the density and viscosity plots, values for samples which were subject to emulsification have been identified, as these experimental values are not expected to agree with the values predicted by the evaporation model.

The agreement between the predicted values and those measured as indicated in these figures was judged to be satisfactory in most cases. Prediction of the extent of evaporation is reasonably accurate considering the variability in environmental conditions and the uncertainty of the measured extent of evaporation. Density predictions were satisfactory with the exception of a few samples in which the discrepancy is attributed to formation of water-in-oil-emulsions which formed because the samples were exposed to rain. This phenomena is believed to cause the only major discrepancies in the viscosity predictions as well. Aqueous solubility, pour point, and flash and fire point estimation gave good results. Interfacial tensions were unpredictable. This is probably due to oxidation occurring in the environment which was not reproduced in the lab. Under the prolonged influence of sunlight and oxygen, it is likely that certain components of the oil (such as the asphaltenes) oxidize and form surface active compounds which reduce the interfacial tensions.

In general, the model provides a satisfactory predictive capability. The accuracy could be improved by selection of better equations and incorporation of more experimental data; but the significant advance in this work has been to establish for the first time the predictive framework and obtain reasonable parameter values.

6.0 CONCLUSIONS

An oil spill model has been developed, described, and provided to the Coast Guard R&D Center, Groton, CT. The model as originally developed includes calculation of rate of spreading, drift, evaporation, dispersion and water-in-oil emulsion formation. It also calculates the oil physical properties (density, viscosity, pour point, aqueous solubility, flash point, fire point, and interfacial tension) as a function of these weathering processes.

The focus of this study was to develop and calibrate a simplified version of this model which predicts volume fraction evaporated and physical properties based on evaporation alone for three types of oil under arctic conditions. The simplified evaporation model was calibrated using data obtained in simulated weathering (air-bubbling evaporation) experiments in the laboratory. The accuracy of the model was then judged by comparing the predicted values to experimental data obtained from outdoor weathering experiments at the R&D Center during the winters of 1979/80 and 1980/81. The results indicate that the model predicts oil density, viscosity, pour point, and aqueous solubility with a reasonable degree of accuracy. Attempts to predict flash and fire points, and interfacial tensions were not satisfactory. In view of this, the simplified model represents a significant contribution to predicting oil behavior and properties under arctic marine environmental conditions.

APPENDIX A
OIL SPILL BEHAVIOR MODEL

INTRODUCTION

This Appendix gives a brief description of the model and instructions for input data. The program could be modified to become interactive by insertion of suitable statements.

The oil parameters used here are purely illustrative and do not reflect the properties of a given oil.

The input data are grouped into:

- (a) Computing parameters
- (b) Spill quantities
- (c) Environmental conditions
- (d) Oil properties
- (e) Process constants

(a) Computing Parameters

The following quantities must be defined:

- DTIM - time increment (usually 100 s)
- TCOMP - total time to be computed (e.g., 24 hours)
- POFH - print out frequency in hours (e.g., every 0.1 hours)

(b) Spill Quantities

- VOLTS - total volume spilled in m³ (eg. 100)
- TIMSP - duration of spill in seconds. This should be a multiple of DTIM. For an instantaneous spill set TIMSP to DTIM.
- TTK - initial oil slick thickness (m) usually set at 0.02 m (2.0 cm)
- TTN - thickness of sheen (m) usually 0.000005 m (5 x 10⁻⁶ m)

(c) Environmental Conditions

- TC - temperature °C (eg. 15°C). Note that °F is printed out also.
- WSKH - windspeed in km/h (eg. 20 km/h). Note that speeds in m/s and knots are also printed out.
- FDR - oil drift factor (usually 0.035 or 3.5% of wind speed)

(d) Oil Properties

Note that all values must be inserted at 25°C. A correction is then made to the ambient temperature for density, viscosity and vapor pressure.

FMAX - maximum fraction evaporated (usually 0.4 but possibly lower)

ST - oil-water interfacial tension (usually 24 dynes/cm)

DEN25 - fresh oil density at 25°C (approximately 850 kg/m³)

VIS25 - fresh oil viscosity at 25°C (approximately 10 cPoise)

SOLO - fresh oil solubility (approximately 30 g/m³)

SENT, VIST - constants relating density and viscosity to temperature

DENK, VISK, SOLK - constants relating the change in density, viscosity and solubility to weathering. Typical values are 100, 4.0 and 12 respectively. The values of density viscosity and solubility (DENX, VISX, SOLX) at 10% weathering are calculated and printed out as a check.

(e) Process Constants

Evaporation

None are inputted but CE1, the evaporation mass transfer coefficient is calculated from wind speed. It is generally about 0.005 to 0.01 m/s. CE2 and CE3 are A and B respectively taken from the distillation curves for each oil (See Figure 4.4).

Dispersion

Three constants are inserted, CD1, CD2, and CD3 with values 0.00005, 2.0 and 1.0 respectively.

Emulsion Formation

Three constants are inserted, CM1 with value of 0.65, CM2 with value of 2×10^{-6} , and CM3 with value of 0.6 for PBC, 0.25 for HH, and 0.7 for FO.

Spreading

Four constants are inserted, CS1, CS2, CS3, and CS4 with values 1.0, 150, 5.0, and 8.0 respectively.

Note

In some cases, the values of these constants are oil dependent.

Shut-Off Factors

Five factors are read in with a value of 1.0 if the processes of evaporation, disperison, emulsion formation, spreading, and drifting are to proceed as normal. A value of zero stops the process and thus permits the impact of that process on overall spill behavior to be assessed.

COMPUTING PROCEDURE

- 1 - the program initializes a number of variables then proceeds to calculate the initial disposition of the slick and the oil properties.
- 2 - a print-out is then made of the spill conditions
- 3 - the oil spill behavior is then calculated as follows for the thick slick and the sheen
- 4 - time change is calculated
- 5 - evaporation amounts and rates are calculated
- 6 - dispersion amounts and rates are calculated
- 7 - emulsion formation amounts and viscosity are calculated
- 8 - spreading is calculated
- 9 - the new oil volumes, areas, composition and properties are calculated, any "new" spilled oil being added
- 10 - the slick position and shape is calculated
- 11 - the condition of the slick is then printed out if requested
- 12 - the program then returns to step 4, checking to determine if the program should stop.

C
VOLTS IS TOTAL VOLUME SPILLED (CUBIC METERS)
VSPL IS VOLUME SPILLED TO GIVEN TIME (CUBIC METERS)
TIM, TIMP, TIME ARE TIME (SECONDS, MINUTES, HOURS, DAYS)
DTIM IS TIME INCREMENT (SECONDS)
TIMP IS SPILL DURATION (SECONDS) (MUST EXCEED TIM)
DVOL IS SPILL VOLUME INCREMENT
FMAX IS MAXIMUM FRACTION OF THE OIL WHICH CAN EVAPORATE
WSKM, WSP3 AND WSKN ARE WIND SPEEDS IN KM/H, M/S AND KNOTS
FOR IS DRIFT FACTOR
TTN, TTK, TTD ARE ARE THIN, THICK AND AVERAGE SPILL THICKNESSES
ATN, ATK, ATC ARE THIN, THICK, AND TOTAL SPILL AREAS
(SQUARE METERS)
VTN, VTK, VTC ARE THIN, THICK AND TOTAL SPILL VOLUMES
(CUBIC METERS)
PTN, PTK AND PT ARE THIN, THICK AND TOTAL FRACTIONS EVAPORATED
ST, STK, AND STK ARE INITIAL, AND THIN AND THICK SLICK INTERFACIAL
TENSIONS
DENS, VISC AND SOLU ARE INITIAL DENSITY, VISCOSITY, AND SOLUBILITY
OF THE OIL
CENT, VIST, VPRT ARE CONSTANTS RELATING DENSITY, VISCOSITY AND
VAPOR PRESSURE TO TEMPERATURE
DENS2, VISC2, VPRT2 ARE FRESH OIL DENSITY, VISCOSITY AND
VAPOR PRESSURE AT 23 DEGREES C
DENS3, VISC3, SOLU3 ARE VALUES OF DENSITY, VISCOSITY AND
VAPOR PRESSURE AT ICK WEATHERING
INITIAL RAT INDICATES RATES OF PROCESSES
ZL, ZB ARE LENGTH AND BIRTH OF SLICK
ZDL IS DRIFT LENGTH OF THE SPILL SLICE POINT
ZDD IS DRIFT LENGTH FROM LAST SPILL POINT
TEMP IS EXPOSURE TIME (SECONDS)

INITIAL D MEANS DELTA CR DIFFERENCE
FINAL E INDICATES EVAPORATION
FINAL D INDICATES DISPERSION
FINAL P INDICATES EMULSION
FINAL S INDICATES SPREADING
FINAL W INDICATES DRIFT

```
C
VOLTS IS TOTAL VOLUME SPILLED (CUBIC METRES)
VSPL IS VOLUME SPILLED TO GIVEN TIME (CUBIC METRES)
TIMT, TIMP, TINC ARE TIME (SECONDS, HOURS, DAYS)
DTIM IS TIME INCREMENT (SECONDS)
TIMSP IS SPILL DURATION (SECONDS) (MAY EXCEED TIM)
CVOL IS SPILL VOLUME INCREMENT
PMAK IS MAXIMUM FRACTION OF THE OIL WHICH CAN EVAPORATE
WSM, WSM5 AND WSKN ARE WIND SPEEDS IN KM/H, M/S AND KNOTS
FOR IS WIND DIRECTION
TTN, TTK, TPC ARE THIN, THICK AND AVERAGE SPILL THICKNESSES
ATN, ATK, ATD ARE THIN, THICK, AND TOTAL SPILL AREAS
(SQUARE METRES)
VTN, VTK, VTC ARE THIN, THICK AND TOTAL SPILL VOLUMES
(CUBIC METRES)
FTN, FTK AND FTY ARE THIN, THICK AND TOTAL FRACTIONS EVAPORATED
ST, STX AND STK ARE INITIAL, AND TFIN AND TPIC SLICK INTERFACIAL
TENSIONS
DENC, VISC AND SCLD ARE INITIAL DENSITY, VISCOSITY, AND SOLUBILITY
OF THE OIL
DEAT, VIST, VPRY ARE CONSTANTS RELATING DENSITY, VISCOSITY AND
VAPOR PRESSURE TO TEMPERATURE
DEN2S, VIS2S, VPR2S ARE FRESH OIL DENSITY, VISCOSITY AND
VAPOR PRESSURE AT 25 DEGREES C
DENX, VISX, SOLX, VPRX ARE VALUES OF DENSITY, VISCOSITY AND
VAPOR PRESSURE AT 10X WEATHERING
INITIAL RAT INDICATES RATES OF PROCESSES
ZL, ZW ARE LENGTH AND WIDTH OF SLICK
ZDL IS DRIFT LENGTH OF THE SPILL SOURCE POINT
ZDD IS DRIFT LENGTH FROM LAST SPILL POINT
TEXP IS EXPOSURE TIME (SECONDS)

INITIAL D MEANS DELTA OR DIFFERENCE
FINAL E INDICATES EVAPORATION
FINAL C INDICATES DISPERSION
FINAL M INDICATES EMULSIFICATION
FINAL S INDICATES SPREADING
FINAL W INDICATES WIND DRIFT

C DEN2, VISC2, VPR2 ARE FRESH OIL DENSITY, VISCOSITY AND
C VAPOR PRESSURE AT 25 DEGREES C
C DENX, VISCX, SOLX, VPRX ARE VALUES OF DENSITY, VISCOSITY AND
C VAPOR PRESSURE AT 10% WEATHERING
C INITIAL RAT INDICATES RATES OF PROCESSES
C ZL, ZW ARE LENGTH AND WIDTH OF SLICK
C ZDL IS DRIFT LENGTH OF THE SPILL SOURCE POINT
C ZOD IS DRIFT LENGTH FROM LAST SPILL POINT
C TEXP IS EXPOSURE TIME (SECONDS)
C
C INITIAL D MEANS DELTA CR DIFFERENCE
C FINAL E INDICATES EVAPORATION
C FINAL D INDICATES DISPERSION
C FINAL W INDICATES WEATHERING
C FINAL S INDICATES SPREADING
C FINAL M INDICATES DRIFT
C
