20. ABSTRACT (Continue on reverse side if necessary and identify by block number)

Infrared survey measurements obtained from two probeborne experiments flown in 1982 combined with extensive ground-based observations on AFGL sources are incorporated into a revised AFGL Four Color Infrared Survey catalog. Over 92 percent of the sky has been covered at 11 and 20 μm, 71 percent at 4 μm and 47 percent at high sensitivity at 27 μm. There are 2970 entries in the main catalog, most of which are multicolor observations. The 11- and 20-μm source counts show a distinct change of slope from 0.4 to 0.6 at about $m_{11} \cong -3.5$ and $m_{20} \cong 4.5$. The source counts are given by:

Preface

This revised infrared sky survey catalog includes the results of the extensive verification and photometric studies of AFGL sources performed since 1976 as well as recent survey measurements with larger instruments. These additions have broadened the photometric data base and, at least in the short term, the catalog contains the most comprehensive description of the infrared background brighter than 10^{-16} wcm$^{-2}\mu$m^{-1}. The three primary spectral bands at 11, 20, and 27 μm ($\Delta\lambda \simeq 5\ \mu$m) cover astrophysically interesting regions; the 11- and 20-μm bands span the silicate emission features, the 27-μm band is at the cross-over point in the spectral energy distribution for warm sources embedded in cold dust clouds. The effective wavelengths, intermediate spectral resolution, and photometric accuracy (20 to 30 percent) of the AFGL survey observations allows a quantitative analysis of the spectral energy distributions of the brightest sources in the 8- to 30-μm spectral regions.

Much of the computer programming necessary to reduce and analyze the data was done by Len Marcotte, including aspect determination. Photometric calibration was the responsibility of Paul LeVan.

The Revised AFGL Infrared Sky Survey Catalog

I. INTRODUCTION

Since the AFCRL and AFGL catalogs (Walker and Price[1] and Price and Walker[2]) were published a significant ground-based effort has been made to verify the AFGL sources not previously associated with known cataloged objects (Low et al;[3] Lebofsky et al;[4] Gehrz and Hackwell;[5] Allen et al;[6, 7] Joyce et al;[8] Lebofsky et al;[9] Kleinmann et al;[10] Gosnell et al;[11] Rudy et al;[12] Ney and Merrill;[13] Grasdalen et al[14]) and to analyze the contents of the catalogs (Harris and Rowan-Robinson;[15] Lebofsky et al;[9] Kleinmann et al;[16] Grasdalen et al[14]). The ground-based searches for the catalog objects have provided improved positions for many of the sources as well as more extensive photometry. The questions about the unconfirmed sources raised by the early investigations of the AFCRL catalog have, for the most part, been resolved. Some of these sources are indeed spurious (Price and Walker[17]), while others are too extended to be detected by ground-based telescopes (Lebofsky et al;[9] Price;[18] Price et al[19]). Many of the spurious sources were eliminated from the AFGL catalog in the reanalysis by including a rescan confirmation criterion in addition to the signal-to-noise gate used for the AFCRL catalog. Several real sources were also taken out but retained in a supplemental catalog (Price[20]) of potentially interesting objects.

(Received for publication 10 June 1983)

Because of the large number of references cited above, they will not be listed here. See References, page 29.

The "AFGL Four Color Infrared Sky Survey" catalog of Price and Walker[2] has been revised in this report to include more accurate information. The ground-based searches provide identification and improved positions for the unidentified AFGL sources. Associations of known objects with survey sources are upgraded to identifications based upon subjective judgment of the photometric agreement between the survey magnitudes and those listed in either the "Catalog of Infrared Observations" (CIO) compiled by Gezari, Schmitz, and Mead[21] or the list of Grasdalen et al.[14] If the source is considered "identified" then the best available position is substituted for the survey value. Photometry from the ground-based studies and the CIO is included, where possible, if no survey measurement was obtained at the wavelength in question or if the survey observation is deemed spurious. The major revision in the present catalog, however, is the inclusion of data from two more sensitive surveys flown in 1982.

2. THE NEW SURVEY EXPERIMENTS

The Far Infrared Sky Survey Experiment (FIRSSE) is a joint effort between AFGL and the Naval Research Laboratory (NRL) to survey the sky in five spectral bands spanning the spectral region between 8 and 120 μm. It was successfully flown from White Sands Missile Range, New Mexico (WSMR) on 22 January 1982 at $8^h00^m00.191$ UT. The ARIES guided rocket flew the 660-kg payload to a peak altitude of 379 km providing for 450 sec of data acquisition. The instrumental performance in the two long wavelength spectral bands (40 and 90 μm) is described in detail by Price, Murdock, and Shivanandan.[22] The measurements made in the two long wavelength bands are reported by Price et al[23] and Price, Murdock, and Shivanandan.[22] The present report includes only measurements in the two short wavelength bands at 20 and 27 μm.

A second experiment, the Survey Program of Infrared Celestial Experiments (SPICE) was flown from WSMR on 14 September 1982 at 4^h48^m 59.959 UT. A 363.5-km apogee was achieved and 455 sec of data taken. About 30 percent of the sky was surveyed in three broad spectral bands centered at 11, 20, and 27 μm.

A general description of the conduct of AFGL celestial experiments is given in a series of AFGL technical reports that detail the calibration (Price and

Walker[24]), the aspect determination (Price et al[25]), and the requirements with respect to particulate contamination (Price, Cunniff, and Walker[26]). Price and Marcotte[27] also briefly discuss the instrumentation used to gather the survey data; whereas Price, Murdock, and Shivanandan[28] describe the FIRSSE and SPICE instruments specifically. The pertinent features of these new experiments are summarized below.

Both the SPICE and FIRSSE telescopes use a doubly-folded Gregorian optical design with a 36-cm diameter primary mirror. The focal planes consist of linear staggered arrays of detectors in each spectral band. Each of the three SPICE arrays has 18 detectors with in-scan widths of 2.5 arc min and cross-scan lengths of 10.75 arc min for a 2.28×10^{-6} sr field-of-view. The 2.4-arc min overlap of adjacent detectors leads to a total cross scan extent of $2\overset{\circ}{.}5$ for the entire array. The FIRSSE 11-, 20-, and 27-μm detectors are 2.5 by 10 arc min and overlap by 1.75 arc min. The 13 elements in each 11- and 20-μm arrays have a cross-scan extent of $1\overset{\circ}{.}82$. The 27-μm array has 15 elements and covers $2\overset{\circ}{.}1$. The 11-, 20-, and 27-μm spectral filters were cut from the same samples for both instruments and only minor differences exist in the spectral response of the detectors between the two instruments. The adopted effective wavelengths are 11, 20, and 27 μm with effective bandwidths of 4.5, 5.5, and 5.0, respectively.

The telescope is yoke-mounted in a one-axis gimbal orthogonal to the longitudinal or roll axis of the payload. A star tracker is coaligned to the roll axis and the payload spin balanced about this axis during pre-flight preparations. During powered flight the star tracker looks aft. The payload and spent motor are separated by a double pneumatic bellows upon release of manacle clamps. A separation velocity of 9 m/sec was achieved on both flights, sufficient to escape the contamination from the spent motor seen on other ARIES-borne experiments (Price et al[29]). The payload is inverted after separation and the tracker is locked to a

pre-selected star. The star and launch time are chosen such that the star is near local zenith and meridian transit.

Once the star is acquired, control of the pitch and yaw jets is switched to the tracker. Error signals from the tracker are used to drive the star to a null and maintain that position to within a root mean square (rms) value of 30 arc sec while the payload rotates about that axis. This essentially established an alt-azimuth coordinate system with the pole of rotation fixed to the inertial coordinates of the star and the zenith angle set by the gimbal deployment angle of the telescope. The azimuth angle as a function of time is derived from stellar transits detected through an "N" slit retical mask at the focus of a small visual photometer. The vertical leg of the "N" is aligned to the deployment plane of the telescope.

Initial deployment of the telescope is to a zenith angle of about 40°. At the end of a $382.^{\circ}5$ roll maneuver the sensor deployment angle is increased. The roll rate is adjusted to maintain a constant linear scan rate across the focal plane. The deployment angle of the telescope is increased during the first half of the experiment, reaching maximum deployment near apogee. The sensor is stepped up during the down leg of the trajectory. This scan program produces the maximum celestial coverage without significantly "background limiting" the performance of the detectors with off-axis thermal radiation from the earth. Data acquisition is limited to altitudes higher than 130 km. The $22.^{\circ}5$ roll is included for stepping the sensor so that at least 360° of each roll is at a constant zenith angle.

A linear scan rate of 20°/sec and stepping increment of $2.^{\circ}144$ were employed for the FIRSSE flight. The SPICE flight used a 15°/sec scan rate with $4.^{\circ}288$ steps. Thus almost completely redundant coverage was obtained in the FIRSSE 27-μm band and 85 percent redundancy at 20 μm. Only 14 percent overlap was programmed for the three SPICE arrays. The redundancy factor and difference in linear scan rates reflect the difference in the objectives between the two experiments. A higher degree of redundancy for the FIRSSE long wavelength bands (27 through 120 μm) was important because of the pioneering nature of the experiment. FIRSSE was the first exo-atmospheric experiment to successfully use super-fluid helium as a cryogen under dynamic thermal loading. It also was the first experiment to use Ge:Ga photoconductors in a multi-element focal plane to survey a large fraction of the sky at wavelengths longer than 30 μm. A very large areal coverage was desired for SPICE in order to survey at wavelengths shorter than 30 μm as much of the galactic plane around the galactic center as possible. The low rescan confirmation opportunity was balanced against much improved mapping of the galactic plane. The galactic plane was surveyed from a longitude of 355°, through the center, out to 36°. This coverage provided 11-, 20-, and 27-μm maps over this region at high signal-to-noise.

A complete survey over the area covered by both experiments was not realized because: (1) about 10 percent of the data for each experiment contained optical contamination, (2) a bias short to ground in the FIRSSE 11-μm band made this band inoperative, and (3) a shorted MOSFET on one of the SPICE 20-μm channels made this channel inoperative. One other 20-μm SPICE channel was anomalously noisy. Aside from the problems mentioned above, the performance of the instruments was acceptable. The average noise equivalent flux density (NEFD) was measured in flight to be 10^{-16}, 4×10^{-17}, and 2.5×10^{-17} wcm^{-2} for the 11-, 20-, and 27-μm SPICE bands, respectively. The FIRSSE NEFD at 20 and 27 μm was 2×10^{-17} and 3.5×10^{-17} wcm^{-2}, respectively. Although this is about a factor of four lower than predicted by pre-flight calculations, it is emphasized that, with the above exceptions, the noise, detector response, and NEFDs were nearly constant resulting in a uniformly complete survey over the area covered. This is in marked contrast to the survey experiments that produced the AFGL catalog, which were background limited, leading to a variation in noise of roughly a factor of ten during the experiment.

3. DATA REDUCTION

The signals generated as the detectors are swept across the sky are amplified and band limited. The high frequencies are attenuated by a low-pass filter with a characteristic frequency set at the inverse of twice the "point source" transit time across a detector. The response rolls off at 12 dB per octave with a corner frequency at 250 Hz for the FIRSSE channels and at 180 Hz for SPICE. Low frequencies generated by 1/f noise and background modulation are filtered with a single RC network with characteristic frequencies set at 10 and 4 Hz for FIRSSE and SPICE, respectively. The signal is sampled 1600 times per second, digitized and telemetered to the ground, where it is recorded on high-speed analog tape. After flight the analog tape is read, decommutated, and converted back into a digital format for storage on computer compatible digital tapes. These tapes are subsequently processed to extract signals from the survey data and the star mapper. The azimuth solution is then determined in the form of cubic polynomials as a segmented function of time as described in detail by Price et al.[25] The rms error in the azimuth solution is less than an arc minute during a large part of both experiments. The noise and bias levels in blocks of the data stream 0.38 sec long are determined for each sensor channel. The averaging method used to determine these parameters excludes point source signatures. The data is filtered by subtracting the average output of the raw data 7 arc min ahead and behind the point in question. Potential sources are selected if the

signal peak exceeds three times the instantaneous noise in either the raw or filtered data. The signal rise time and cross-correlation coefficient are calculated for each potential source, using a filtered signal from an ideal point source for the cross correlation. These parameters recognize and reject impulse responses due to cosmic ray interactions. About 2.5 to 3 potential sources per second were accepted by the routine, roughly ten times that due to white noise alone.

Next, the coordinates of the potential sources are determined from the aspect solution and multicolor observations are combined into a single source. The results are compared to cataloged positions of known infrared objects: the "Two Micron Sky Survey" (TMSS) by Neugebauer and Leighton,[30] its southern extension (Neugebauer[31]), and the AFGL catalog. Measurements in one color only which are not associated with known infrared objects, are rejected if they are either detected during a time of anomalously high noise, for example, optical contamination, or are a point source with a filtered signal-to-noise less than three. About half the potential sources are eliminated in this manner. The TMSS associations are used to determine the tracker to sensor and gimbal offsets and any field rotation, thus improving the sensor aspect. Satellite and asteroid positions are calculated for the launch epoch in sensor coordinates, after which they are subsequently identified in the data and eliminated.

The published ground-based and aircraft borne measurements in the CIO and the photometry on AFGL sources by Grasdalen et al,[14] Ney and Merrill,[13] and Gosnell, Hudson, and Puetter[11] were used to calibrate the survey photometry. Sources which are known, or suspected to be, extended on the order of an arc minute were rejected. The reference irradiances were extrapolations of the listed measurements at or near the effective wavelength of the survey band by assuming a zero color difference. The zero magnitude spectral energy distribution was approximated by a $\lambda^{-3.95}$ power law over the wavelength range in question. Measurements between 10 and 12 μm were used for the 11-μm survey observations, between 18 and 22 μm for the 20-μm survey values, and between 20 and 35 μm for the 27.3-μm calibration. Multiple observations by different observers on a given source were averaged after subjectively eliminating the low quality values. The resulting list contains a number of late type variable stars. Price and Walker[2] confirmed that the differences due to variability between the adopted reference fluxes and the actual values at launch epoch for such stars averages out in the calibration.

30. Neugebauer, G., and Leighton, R. B. (1969) Two Micron Sky Survey - A Preliminary Catalog, NASA SP-3047.

31. Neugebauer, G. (1971) Two micron sky survey zones -47° to -40° and -40° to -33°, private communication.

The sources with published measurements are associated with the survey observations by positional agreement, within 3 arc min in azimuth and 9 arc min in zenith. A linear weighted least-squares regression of irradiance as a function of signal is calculated with a fixed zero intercept for each individual detector. The weights were subjective judgments of the quality of the published measurement. Sources with irradiance values greater than one standard deviation from the fit were rejected and the regression repeated. The discordant values of irradiance are possibly due to large amplitude source variability, beam size effects due to extended emission or source transit at the edge of a detector.

About 160 sources provided the 193 observations for calibration of the 11-μm SPICE detectors. The smallest number of calibration sources per detector was four, the maximum number was 24, and the average was 10. The mean standard deviation of the differences between the reference and calculated irradiances was 1.3×10^{-16} wcm$^{-2}\mu$m^{-1} for the 193 sources. On the average this is equivalent to a source with a signal-to-noise of 5. The 11-μm calibration accuracy is estimated to be about 15 percent.

The 20-μm calibration for SPICE used 118 measurements, an average of seven per detector with as few as three and as many as 11. About 60 objects provided 107 measurements to calibrate the FIRSSE 20-μm survey photometry. The standard deviations averaged over the focal plane between the reference and calibrated values are 8 and 3×10^{-17} wcm$^{-2}\mu$m^{-1} for the SPICE and FIRSSE arrays. These values again correspond on the average to a source with a signal-to-noise of about 5. The accuracy of the 20-μm calibration is estimated to be about 20 percent.

At 27 μm there are 36 reference values for calibrating the SPICE array, an average of two per detector. At least one, and as many as four, sources were detected on each channel. Thirty-three measurements were available for calibration of the FIRSSE 27-μm detectors. These included five asteroids (2 Pallas, 8 Flora, 15 Eunomia, 54 Alexandra, and 704 Internamnia). These asteroids were detected at signal-to-noise greater than 5 and also have published ground-based 10- and 20-μm photometry. A color temperature is derived from the best available 10- and 20-μm photometry in the literature and scaled by $T_c \propto R^{-1/2}$ to the correct sun-asteroid distance. The 27-μm flux is extrapolated along a greybody distribution at this temperature and then scaled to account for the difference in earth-asteroid distances. No systematic difference was found between the individual system responsivities derived from stars and those calculated asteroid values. Even with the asteroid measurements three 27-μm FIRSSE channels had no associated calibration sources. The calibration for these detectors was obtained by scaling the relative responsitivities for the filter-detector combination derived from extensive preflight laboratory testing to an average of the 33

reference fluxes weighted by the number of observations on a channel. The calibration error in the 27-μm band is estimated to be 25 percent for SPICE and 30 percent for FIRSSE.

The calibration was performed in terms of irradiance ($wcm^{-2}\mu m^{-1}$) and is therefore independent of the bandwidth of the survey photometry and ground-base instrumentation in the first approximation. The calibration reflects the energy distribution for the bulk of the calibration of objects, late type stars with some excess dust radiation longward of 10 μm. Color corrections are small for the 11-, 20-, and 27-μm bands.

Note that although the absolute calibration accuracy is estimated to be 15, 20, and 30 percent at 11, 20, and 27 μm, the relative photometry is much better. The relative photometric error is estimated to be 5 to 10 percent as determined by redundant measurements on overlapping scans within a flight and by the consistency of the confirming observations between the two experiments.

After calibration of the photometry, the measurements of the same source on adjacent detectors are combined as are the rescan observations during the $22.^{\circ}5$ overlap at the end of each roll during which the sensor is stepped. Then, confirming measurements on the overlapping coverage between the up and down legs of the experiment are combined. If a source is not confirmed but lies in an area that was rescanned the data stream for the confirming scan is examined. The source is appropriately flagged if lack of confirmation results from optical contamination, an edge detection at the end of the array, or high noise level in the data stream. The sensor steps were chosen such that the overlapping coverage was offset by about one half the height of a detector. Detections on adjacent detectors and rescan confirmation are used to improve the position accuracy in the cross scan direction. The rms accuracy is about 1 arc min in azimuth, 4 arc min in zenith for an uncombined detection, and 1.5 arc min for a confirmed measurement.

The overlap on the SPICE and FIRSSE flights was searched for confirming observations. Measurements of a source on both experiments were combined and, as before, unconfirmed sources appropriately flagged. All sources that were not confirmed but in coverage within a flight or on the two experiments are eliminated from further consideration. Also rejected are sources not associated with a known infrared object that have a filtered signal-to-noise less than five or that were detected with anomalously high noise. The resulting list is then compared to the "AFGL Four Color Infrared Sky Survey" and the Supplement.

4. THE CATALOGS

The AFGL and supplemental catalogs were revised based upon information obtained from the ground-based searches and the CIO. About 30 sources in the main catalog and 360 in the supplement, which were not labeled as extended and were away from the galactic plane or HII regions, were eliminated for lack of ground-based confirmation. Next, where available, improved positions were adopted if the AFGL source was considered identified. The identification resulted from a subjective judgment based upon agreement between the survey photometry and that published in the literature. Photometric agreement was considered as additional confirmation of the survey observations and 74 entries in the supplement were included in the main catalog on that basis. The ground-based photometry was selected on the same basis as for the survey calibration previously discussed: 4.2 μm was an average of observations made at 3.6 and 5.0, 11 μm adopted the published magnitude between 10 and 12.5 μm, and 20 μm adopted the published magnitude between 18 and 22 μm. The most common false entry in the AFGL catalog is the so-called "spurious color" - a valid measurement is coupled with a spurious one at another (usually longer) wavelength when the multicolor observations are combined. The ground-based values were substituted for those believed to be spurious or included when no survey measurement was made at that wavelength.

The resulting lists were combined with the SPICE and FIRSSE measurements. For the AFGL sources detected by SPICE/FIRSSE the irradiances at a given wavelength were averaged providing they agreed within a factor of 2, otherwise the SPICE/FIRSSE values were adopted. A source in the supplement was upgraded to the main catalog if (1) the SPICE/FIRSSE measurement had a signal-to-noise greater than 5, (2) it was confirmed, either within a flight or from flight-to-flight, or (3) the SPICE/FIRSSE observations had a common color with the AFGL entry and the two agreed to within 50 percent. A SPICE or FIRSSE measurement not associated with an AFGL source was incorporated into the main catalog if the signal-to-noise was greater than 5 and it satisfied at least one of the following confirmation criteria: the source is either seen twice on the same experiment or detected on both experiments, or that it is associated with an object known or suspected to be bright in the infrared, or that it is not associated with a cataloged object but it is a two-color measurement in adjacent bands, that is 11 and 20 μm and/or 20 and 27 μm. Although the last two criteria are weak, they were included to eliminate some of the spurious signals that satisfied the signal-to-noise selection criterion but which were not rescanned or flagged as not detectable during rescan. These criteria would not eliminate optical contamination that would show up as a cluster of predominately extended, unconfirmed and

unassociated sources. The SPICE/FIRSSE measurements that fail these criteria are relegated to the current supplemental catalog as are those observations with a signal-to-noise of less than 5 and associated with either an AFGL supplement source, a TMSS star, or have a rescan combination.

5. DISCUSSION

There are now 2970 entries in the main catalog, 624 of which are new objects detected on the SPICE and FIRSSE flights. The remaining 2345 are listed in the AFCRL, AFGL, and AFGL Supplement catalogs. About 110 Supplement sources are included, having been confirmed by SPICE, FIRSSE, or ground-based searches. The catalog contents are plotted on Aitoff equal area projections in Figures 1, 2, 3, and 4 for the 4.2-, 11-, 20-, and 27-μm bands, respectively. The plots show that the distributions are more concentrated in the galactic plane at the longer wavelengths and the source density along the plane is quite non-uniform. The greater sensitivity of the SPICE and FIRSSE measurements is graphically depicted in the 20-μm plot (Figure 3) where the stippling of fainter sources define the scan coverage of these experiments. The areal coverage at each wavelength is listed in Table 1 along with the corresponding number of sources in the revised main catalog compared to that in the AFGL catalog. The second entry for 27 μm refers only the SPICE and FIRSSE measurements as all the fainter sources are from these flights because of the factor of 10 higher sensitivity at this wavelength.

Table 1. Area Surveyed in Each Color and Number of Sources Detected

Color	Total Area Surveyed		No. of Sources Revised Cat.	AFGL Cat.
	sq. deg	percent		
4.2	32170	71	2053	1982
11	38159	92.5	1741	1151

27	30102	73	754	72
	*19732	47	663	---

*SPICE + FIRSSE coverage

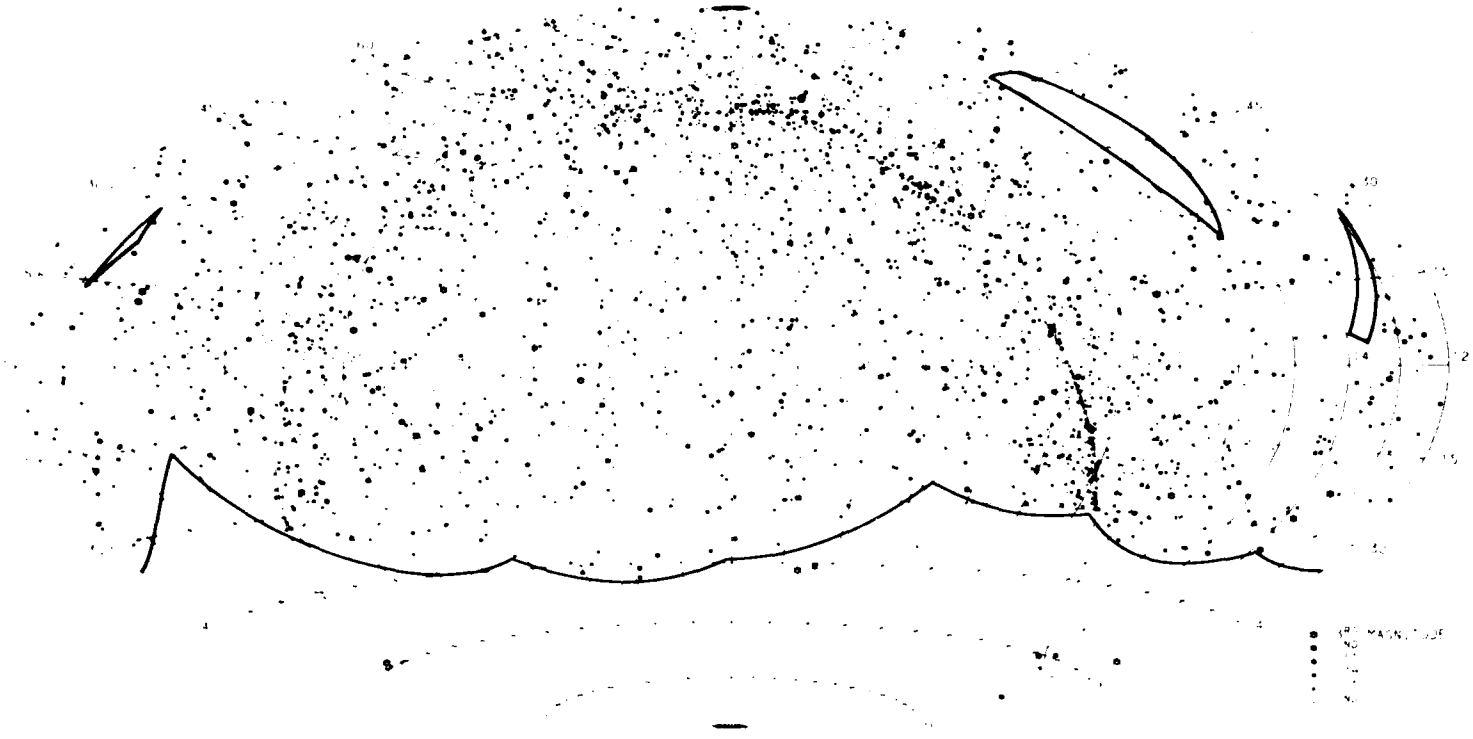

Figure 1. Distribution of 4.2-μm Sources in the Catalog on an Equal Area Projection in Equatorial Coordinates. The dashed line is the galactic plane; the heavy lines are the boundaries to the surveyed region. Sources outside survey region are CIO additions for objects detected at other wavelengths

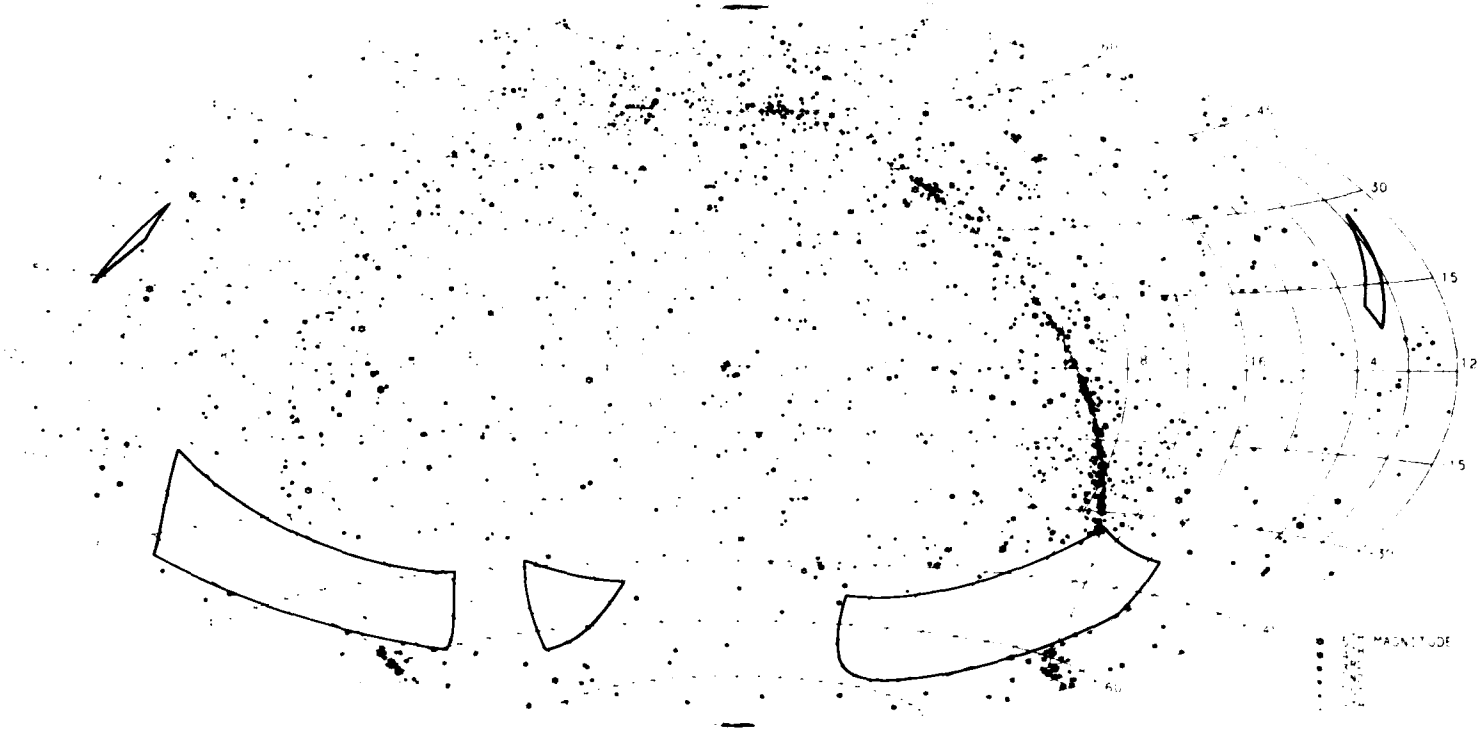

Figure 2. Distribution of the 11-μm Sources. See Figure 1 for definition of features

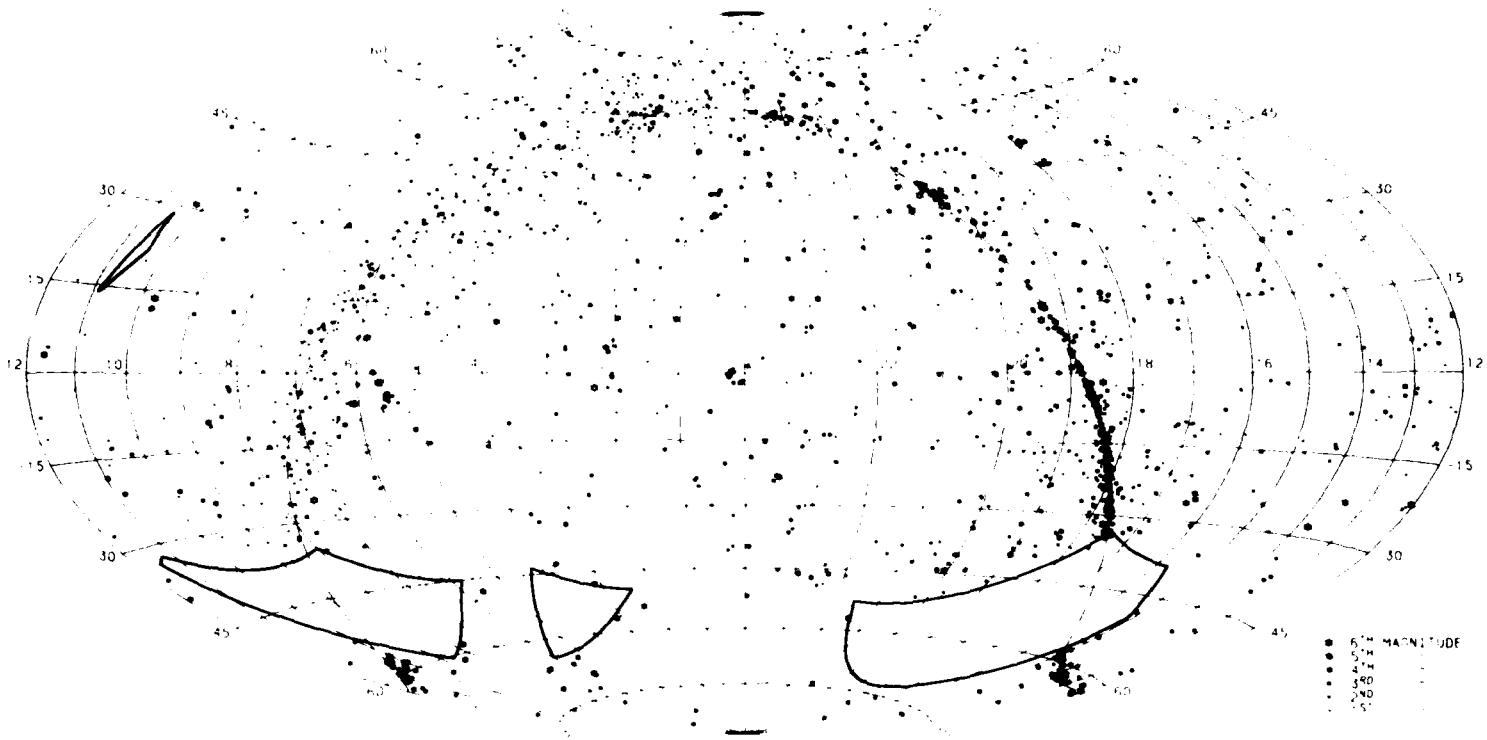

Figure 3. Distribution of the 20-μm Sources. See Figure 1 for definition of features

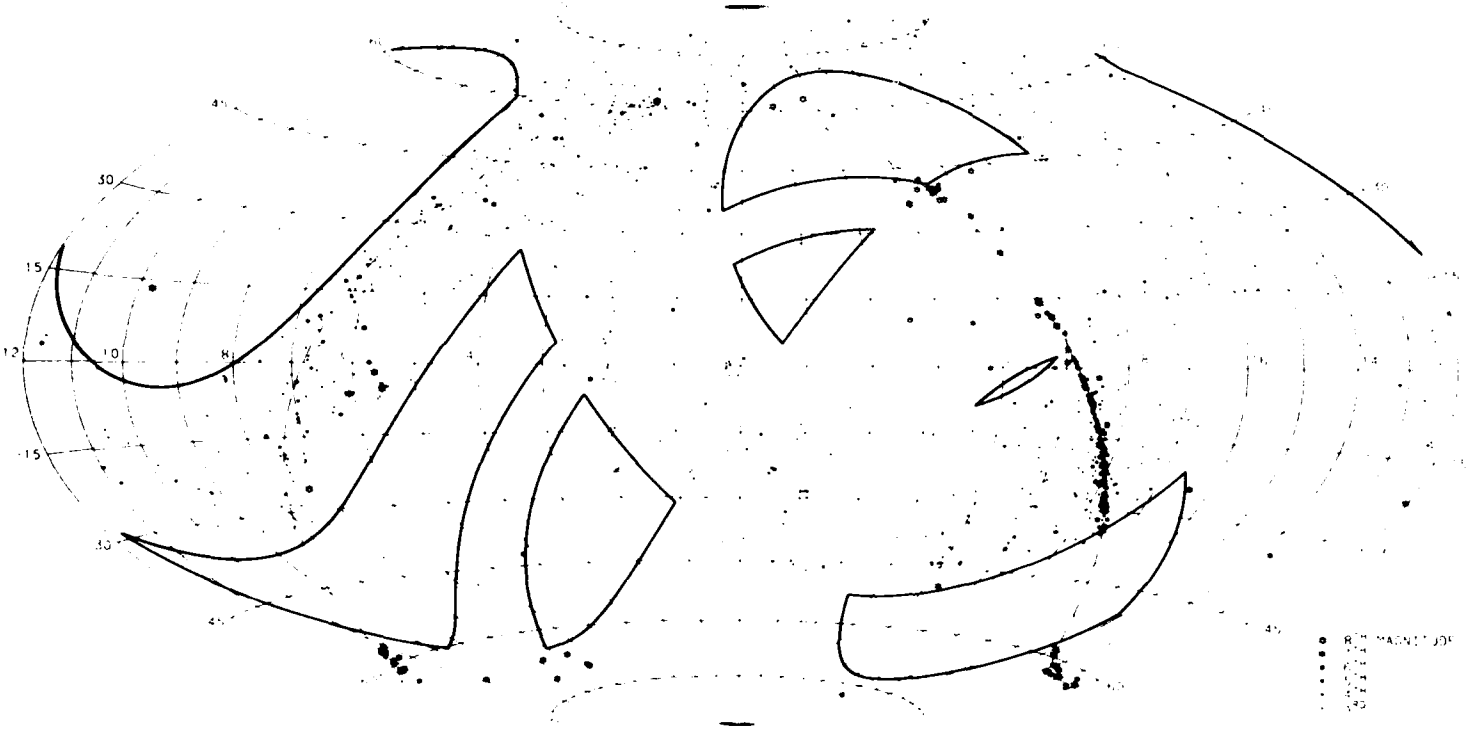

Figure 4. Distribution of the 27-μm Sources. See Figure 1 for definition of features

The logarithm of the number of sources brighter than a given magnitude as a function of magnitude for each wavelength is shown in Figure 5. The counts over the area surveyed are plotted as points. The FIRSSE and SPICE counts, normalized to the area covered at 20 μm, are denoted by other symbols. For reference the uniform disk and spherical distribution slopes of 0.4 and 0.6 are also included. The greater sensitivity of the FIRSSE and SPICE measurements is reflected in the proportionally larger source counts for the experiments at the fainter levels. The uniformity of these survey measurements is indicated by the manner in which the curves flatten at the fainter magnitudes. At 11 μm this occurs over a factor of 2 in brightness, which is the range in responsivities over the SPICE 11-μm array. The smoother turnover of 20 and 27 μm reflects the difference in sensitivity between flights in addition to the difference in detector responsivities.

The 11- and 20-μm source counts show a distinct change of slope from 0.4 to 0.6 at about $m_{11} \simeq -3.5$ and $m_{20} \simeq -4.5$. The 27-μm source count is consistent with a 0.4 slope over the entire coverage. Numerically, the source counts are well represented by the expressions:

$$N(4.2\ \mu m) = 10^{0.5\,(m_4 + 3.45)} \qquad m_4 \leq 1.3$$

$$N(11\ \mu m) = 10^{0.4\,(m_{11} + 7.55)} + 10^{0.6\,(m_{11} + 5.55)} \qquad m_{11} \leq -1.0$$

$$N(20\ \mu m) = 10^{0.4\,(m_{20} + 9.55)} + 10^{0.6\,(m_{20} + 6.55)} \qquad m_{20} \leq -2.5$$

$$N(27\ \mu m) = 10^{0.4\,(m_{27} + 10.45)} \qquad m_{27} \leq -3.5 \ .$$

Thus, the contents of the catalog can be resolved into two broad categories: a disk population with mean colors of $m_{11}-m_{20} = 2.0$ and $m_{20}-m_{27} = 0.9$ corresponding to color temperatures of 270K and 185K, and a spherical distribution of sources with a mean color difference of $m_{11}-m_{20} = 1.0$ corresponding to a 480K color temperature. The 0.5 slope for the 4-μm sources is not fully understood. Kleinmann, Gillett, and Joyce[16] found similar slopes for stars at 0.55 μm from the "Bright Star Catalog" (Hoffleit[32]), at 2.2 μm from the TMSS (Neugebauer and Leighton[30]), and at 4.2, 11, and 20 μm from the AFGL catalog. The SPICE plus FIRSSE measurements indicate that the AFGL survey at 11 and 20 μm was non-uniform at fainter magnitudes, which blurred the crossover point in the two distributions producing an "average" result. However, this explanation should not apply to the shorter wavelength measurements that are crossreferenced much more extensively.

32. Hoffleit, D. (1964) Catalog of Bright Stars, Third Revised Edition, Yale U. Obs.

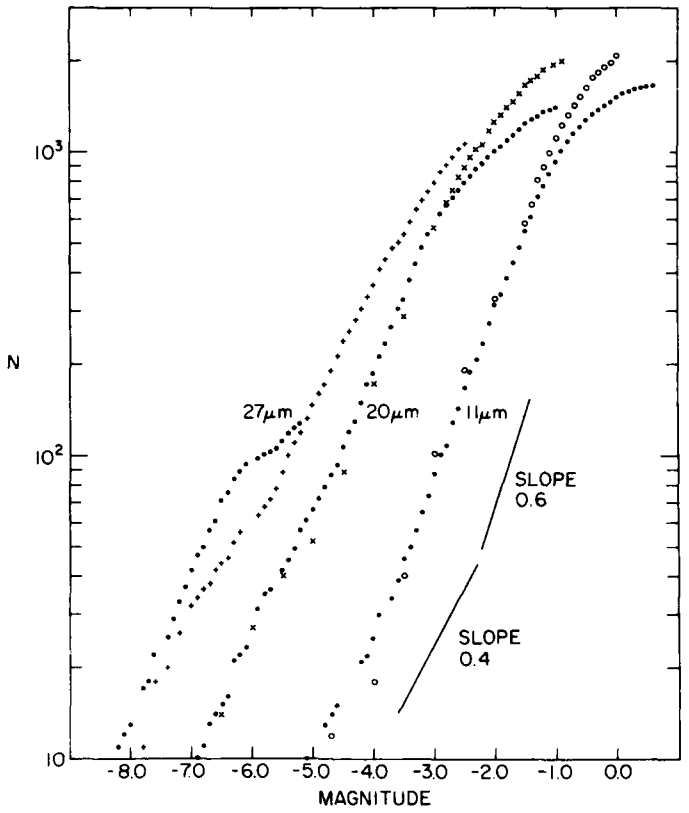

Figure 5. Number of Sources Brighter Than a Given Magnitude as a Function of Magnitude for the 11-, 20-, and 27-μm Sources in the Revised Catalog. Points are values for the entire catalog; (o) denotes the 11-μm source counts for SPICE multiplied by 3, (x) and (+) designate the 20 and 27 μm, respectively, source counts for SPICE and FIRSSE multiplied by 2. Also shown is a slope 0.4 characteristic of a uniform disk distribution and slope 0.6 a uniform spherical distribution

The limits in the numerical expressions for the source count are the magnitudes at which the SPICE plus FIRSSE source counts begin to diverge from a slope of 0.6 at 11 and 20 μm and 0.4 at 27 μm. These limits roughly correspond to the signal-to-noise criterion for inclusion in the main catalog. We adopt these values as the completeness level of the catalog at least over the area covered by the recent experiments.

This statistical approach to derive completeness of the survey and the use of source parameters to describe the overall background have been strongly criticized by Grasdalen et al.[14] They state that "until the AFGL sources are verified

from ground based observations statistical analyses based solely on the AFGL catalog are highly suspect". Also, referring to the conclusions reached by Kleinmann et al,[16] "since they have not made ground based observations to verify existence of these sources as a function of magnitude their completeness limit has no physical meaning. It is entirely conceivable that all the sources at their limit are spurious".

While it is true that some of the sources in the catalog are suspect, notably the cluster of objects near 0^h15^m, $+0^o$ and $0^h30^m + 35^o$, possibly for reasons of particulate contamination, these sources are a small percentage of the total. The slopes of 0.4 and 0.6 in the log N vs m have a physical rational. Highly contrived spatial, spectral, and amplitude distribution of spurious sources would be required in order not to distort the log N vs m plots if these false entries constituted a significant portion of the catalog. Also, about 85 percent of the sources in the catalog are either confirmed by rescan or have plausible associations, and some of those with plausible associations have measurements consistent with the photometry in the CIO. Over half of the remainder lie either along the emission ridge in the galactic plane or the Orion Complex or have magnitudes below the completeness level. Bright infrared objects in the galactic plane and molecular clouds are likely to be heavily obscured stars. Thus, the revised catalog does constitute an adequate data base from which general parameters on the background character may be drawn. It is currently the only data base for HII regions and other extended sources that Grasdalen et al[14] preferentially excluded from their analysis.

The concentration toward the galactic plane that defines the disk population is shown in Figure 6 as a histogram of the number of sources brighter than the statistical limits at each wavelength in increments of 0.1 in sin b. Equal areas are encompassed in the bins and the plots are roughly proportional to the areal density. The concentration to the galactic plane becomes greater with increasing wavelength; 26 percent of the 4.2-μm sources, 45 percent of the 11-μm, 50 percent of the 20-μm, and 73 percent of the 27-μm sources are within $5^o.74$ of galactic plane.

The longitude distributions of the 11- and 20-μm sources brighter than the completeness limits and within $5^o.74$ of the galactic plane are shown in Figure 7. Hatched area represents the number of non-stellar or unidentified objects in each region. On the average 60 percent of the 11 μm and 80 percent of the 20-μm sources fall into this category. The prominent peaks at 25^o and 310^o longitude lie in the direction of a tangent to the spiral arms defined by the HII regions studied by Georgelin et al[33] as does the smaller peak at 45^o. Other peaks at 80^o,

33. Georgelin, Y.M., Georgelin, Y.P., and Sivan, J.-P. (1979) Optical IR regions, IAU Symposium 84, The Large Scale Structure of the Galaxy, W.B. Burton, Ed., D. Reidel Pub. Co., Dordrecht, Holland.

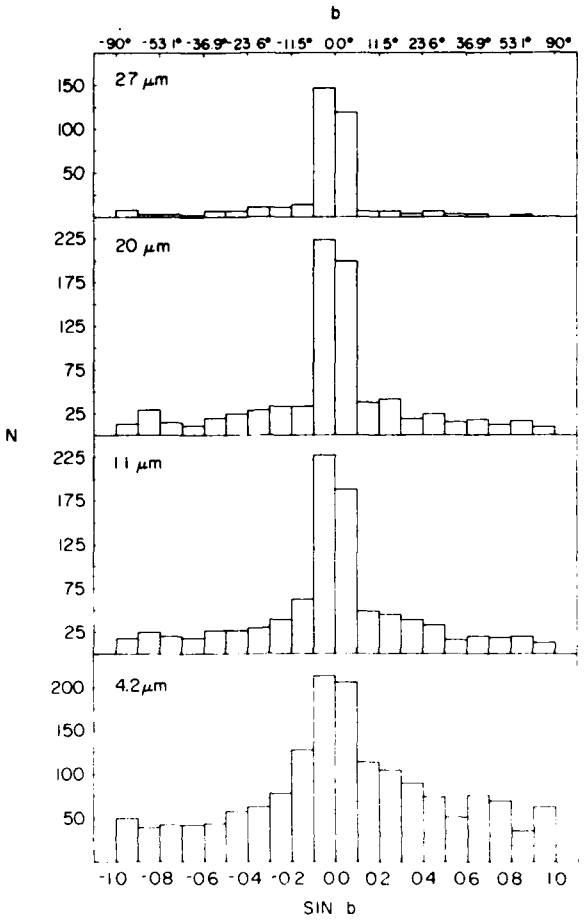

Figure 6. Latitude Distribution of the 4-, 11-, 20-, and 27-μm Sources. Bins are increments of 0.1 in sin b or equal areas for all sky coverage; counts are roughly proportional to areal density. Sources brighter than the completeness limits of 1.3 magnitudes at 4 μm, -1.0 at 11 μm, -2.5 at 20 μm, and -3.5 at 27 μm

110°, 135°, and 290° longitude correspond to peaks in the distribution of HII regions detected at optical wavelengths along the galactic plane (for example, the compilation of Marsalkova[34]). This indicates that the disk population in the galactic plane is dominated by HII regions or sources associated with them.

Multicolor observations that have $m_{20} \leq -2.5$ are shown on two-color plots in Figures 8 through 10. The spectral class of the source in the [4.2-11 μm],

34. Marsalkova, P. (1974) A comparison catalogue of HII regions, Astrophys. Space Sci. 27:3.

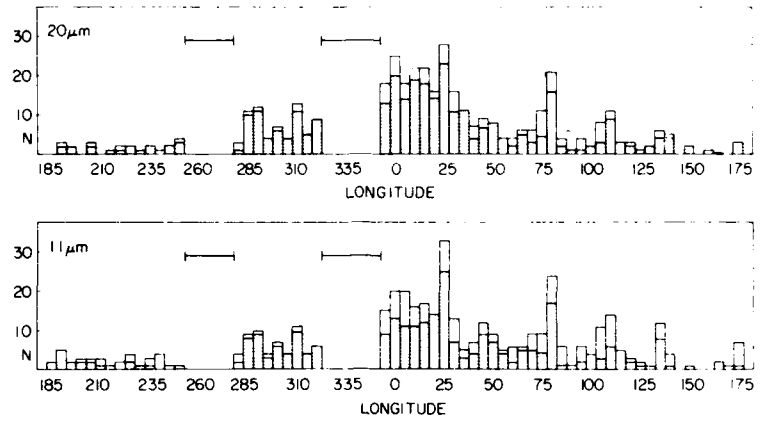

Figure 7. Longitude Distribution of the 11- and 20-μm Sources Within 5.74^{o} ($|\sin b| \leq 0.1$) of the Galactic Plane. Shaded area represents the number of non-stellar or unassociated sources in the region. Marked areas from 260^{o} to 280^{o} and 325^{o} to 355^{o} longitudes are not covered at these wavelengths. Histograms include sources brighter than -1.0 magnitudes at 11 μm and -2.5 at 20 μm

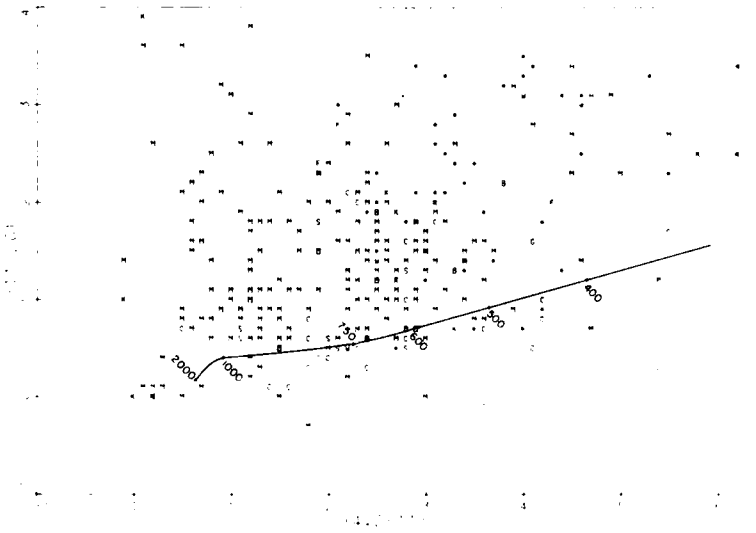

Figure 8. [4.2-11 μm] vs [11-20 μm] Color-color Plots for Sources Brighter Than -2.5 Magnitudes at 20 μm. Symbols denote major spectral class with asterisks representing unclassified objects. (P = peculiar object η Car, W = Wolf Rayet, H = HII region.) The F stars are T Taurii stars, the very red, very cold K source is M17. The band integrated blackbody color temperature curve is also shown and a few reference values designated

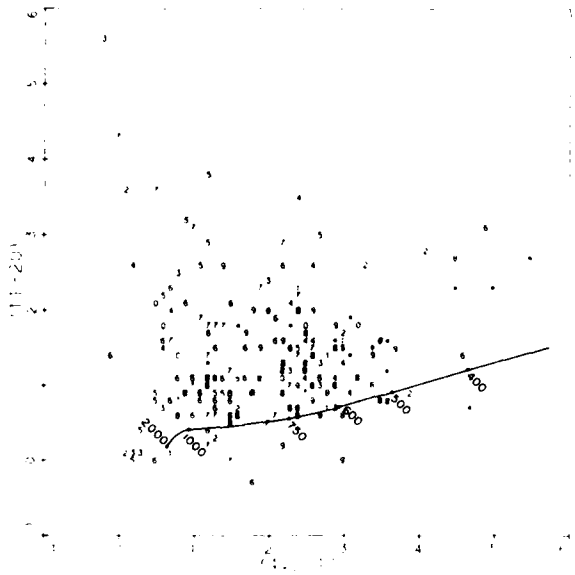

Figure 9. [4.2-11 μm] vs [11-20 μm] Color-color Plots for the M Stars Brighter Than $m_{20} \leq -2.5$. The plotted number denotes the M subclass assigned to the star. M stars without subtypes are designated by an asterisk. The curve for the band averaged blackbody color temperatures and reference values are also shown

[11-20 μm] is plotted in Figure 8 if it is known, an H denotes a known HII region and an asterisk (*) an undesignated source. The spectral type is given even if the source is embedded in dust with the majority of the infrared emission from the surroundings. The color temperature curve for [4.2-11 μm], [11-20 μm] is also plotted with reference values noted. Almost all the sources lie above the blackbody curve with cool color temperatures ranging from 2000K to 400K for the [4.2-11 μm] measurements and 1000K to 150K for the [11-20 μm] differences. The M stars are replotted in Figure 9 with the spectral subclass as the symbol; an asterisk denotes lack of a subclass. The large majority of stars have [11-20 μm] ≤ 2.0 in agreement with the conclusion of Harris and Rowan-Robinson.[15] Extinction or excess emission will cause the points to lie above the blackbody curve. Interstellar extinction has a negligible effect. For an $A_v \sim 30$ magnitudes, the extinction to the galactic center, [11-20 μm] is increased by less than half a magnitude if the interstellar grains have silicate absorption ($A_{4.2} = A_v/20$, $A_{11} = A_v/25$, and $A_{20} = A_v/37$; see Kleinmann, Gillett, and Joyce[16]). Emission from circumstellar dust shells would cause the large observed departures in the

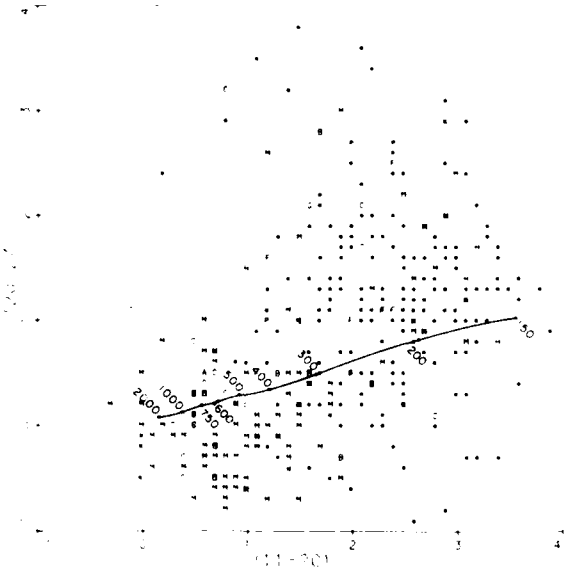

Figure 10. [11-20 μm] vs [20-27 μm] Plots for Sources With $m_{20} \leq -2.5$. Symbols have the same meaning as in Figure 8

colors from the blackbody curve. From Figure 8 it is apparent that circumstellar emission is a common feature of M stars which are bright in the infrared.

The [11-20 μm] vs [20-27 μm] colors are plotted in Figure 10 for sources brighter than $m_{20} \leq -2.5$. Most of the stars are in the region [11-20 μm] ≤ 1.5 and [20-27 μm] ≤ 0.5 and fall below the blackbody curve. The majority of these stars have circumstellar emission due to silicates. Band emission from silicates at 10 and 20 μm would enhance the 11- and 20-μm fluxes compared to that at 27 μm. The unassociated sources and HII regions populate the region [11-20 μm] ≥ 1.5 particularly for [20-27 μm] ≥ 0.5. The cool temperatures are characteristic of HII regions. The large [20-27 μm] color indicates the presences of a significantly cooler ($T_o < 100$ K) component of these sources.

6. CONCLUSIONS

The AFGL catalog has been revised to include measurements from two recent high sensitivity surveys and ground-based searches for sources in the previous catalog. Source counts on the revised catalog show two distinct populations, a spherical component with a slope of 0.6 and a disk component with slope of 0.4. The density distributions and mean color temperatures indicate that, for the most part, the spherical component is made up of late type stars with infrared excesses while the disk is composed of HII regions and stars embedded in circumstellar dust shells with large infrared excesses.

Appendix A

Table of Observations

A1. COLUMNS 1, 2, AND 3 - POSITION

Coordinate information is given in these columns. The epoch 1950 right ascension and declination are given in columns 1 and 2, respectively. The three letter symbol in column 3 designates the reference for the position. In approximate order of increasing accuracy these reference positional accuracies are:

AFGL- AFGL catalog (Price and Walker;[A1] Price[A2]) - 1!3
FIR/SPC - FIRSSE and SPICE derived positions - 0!8
GVS - Kukarkin et al[A3-A5] - 0!8
IRC - Neugebauer and Leighton, [A6] Neugebauer[A7] - 0!5
LKV - Low et al[A8] - 30"
LKR - Lebofsky et al[A9] - 15 to 30"
LSK - Lebofsky et al[A10] - 1 to 30"
UCS - Gosnell, Hudson, and Puetter[A11] - 10"
GH - Gehrz and Hackwell[A12] - 5"
JCG - Joyce et al[A13] - < 5"
KLM - Kleinmann et al[A14] - < 5"
WYO - Grasdalen et al[A15] - < 5"
EIC - Sweeney et al[A16, A17] - < 5"

Because of the large number of references cited above, they will not be listed here. See References, page 163.

CIO - listed in Gezari, Schmitz, and Mead[A18] - $\leq 1''$

SAO - Smithsonian Astrophysical Observatory Star Catalog[A19] - $< 1''$

In general the SPICE and FIRSSE source positions were not improved even though many of the associations were plausible identifications. Better positions were substituted for a few of those SPICE or FIRSSE objects that had corroborative ground-based photometry.

A2. COLUMNS 4 THROUGH 7 - PHOTOMETRY

The 4-, 11-, 20-, and 27-μm photometry is listed in the next four columns, respectively, along with the estimated error or source reference if it is not a survey measurement. A magnitude derived from the CIO listing is designated by a C, one taken from Grasdalen et al[A15] by a W and a value from Ney and Merrill[A20] by M. These non-survey measurements are included in order to facilitate analyses of the catalog content. For example, Harris and Rowan-Robinson,[A21] Kleinmann, Gillett, and Joyce,[A22] and Grasdalen et al[A15] found it possible to divide the catalog content into broad but well-defined categories based upon the [4-11 μm] vs [11-20 μm] color differences.

The adopted zero magnitude irradiances are:

$$H(4.2) = 3.6 \times 10^{-15} \text{ wcm}^{-2}\mu\text{m}^{-1}$$

$$H(11) = 8.7 \times 10^{-17} \text{ wcm}^{-2}\mu\text{m}^{-1}$$

$$H(20) = 8.2 \times 10^{-18} \text{ wcm}^{-2}\mu\text{m}^{-1}$$

$$H(27) = 2.5 \times 10^{-18} \text{ wcm}^{-2}\mu\text{m}^{-1} \quad .$$

A22. Kleinmann, S.G., Gillett, F.C., and Joyce, R.R. (1981) Preliminary results of the Air Force infrared sky survey, Ann. Rev. Astron. Astrophys. 19:411.

A3. COLUMN 8 - SPECTRAL TYPE

The spectral type is listed in column 8. The large majority of the spectral types result from association of the survey source with an object in the TMSS. The compilation of Bidelman[A23] of the published spectral classifications for the TMSS and his own determinations of spectral type was used. Additional spectral types for AFGL sources come from Bidelman,[A24] Buscombe,[A25] the "General Catalog of Variable Stars (Kukarkin et al[A3-A5, A26]) and Kleinmann, Gillett, and Joyce.[A22]

A4. COLUMN 9 - AFGL NUMBER

The AFGL number is listed in this column. Numbers less than 3200 identify sources in the AFCRL and AFGL catalogs. An S appended to an AFGL number in the main table denotes a source originally in the supplemental catalog (Price[A2]). The 624 detections on the SPICE and FIRSSE flights are enumerated, beginning at 5001 by right ascension. The new entries in the "revised" supplemental catalog begins at 6001S.

A5. COLUMNS 10, 11, AND 12 - ASSOCIATIONS

Associations with sources in other catalogs are listed in these 3 columns: the Two Micron Sky Survey (Neugebauer and Leighton[A6]) and its extension (Neugebauer[A7]) in column 10, the Bright Star (Hoffleit[A27]) in column 11, and other designations in column 12. The entries in columns 11 and 12 are independent of the TMSS association. If the source has no Bayer, Flamstead, or variable star designations, column 11 contains associations with sources in the "Dearborn

A27. Hoffleit, D. (1964) Catalog of Bright Stars, Third Revised Edition, Yale U. Obs.

Catalog of Faint Red Stars" (Lee et al[A28-A30]) designated by DO, the Revised New General Catalog (Sulentic and Tifft[A31]) for NGC objects, Catalog of HII Regions (Sharpless[A32]), and the Index Catalog of Dryer. Additional associations are obtained from the CIO.

A6. COLUMN 13 - COMMENTS

Comments on the source are given in this column, including alternative names. The class of object is listed if the association is with an NGC source. If appropriate, the type of galaxy is also listed. Sources measured to be extended on the order of 5 arc min or greater are designated by EO, those of marginal extent by E?.

A7. COLUMN 14 - OBSERVATION LOG

This is a three-element code that outlines the observational record for the entry. The first character pertains only to previous AFGL sources. A "C" designates that the source was detected on a SPICE or FIRSSE flight in a common color. If this is not the case the maximum number of times the source was seen in a common color as listed in the AFGL catalog is given. The second character describes the observation within a SPICE or FIRSSE flight. A "2" means that the source was seen twice in a common color on the same flight, and a "0" denotes no common color confirmation. If the object was rescanned but was not confirmed an asterisk "*" designates that the rescan region contained optical contamination or has a calculated signal-to-noise less than 3; a question mark denotes that the calculated signal-to-noise was between 3 and 5 on rescan or the confirming detector was at the end of the array. An S or F means that the source was only scanned once on a SPICE or FIRSSE flight, respectively. Flight-to-flight obser-

---

A28. Lee, O.J., Baldwin, R.L., and Hamlin, D.W. (1943) Dearborn Catalog of Faint Red Stars Titanium Oxide Stars in Zones $-4.^{o}5$ to $+13.5^{o}$, Ann. Dearborn Obs. Northwestern U. V(Part 1A).

A29. Lee, O.J., and Bartlett, T.J. (1944) Dearborn Catalog of Faint Red Stars Titanium Oxide Stars in Zones $+13.5^{o}$ to $+40.5^{o}$, Ann. Dearborn Obs, Northwestern U. V(Part 1B).

A30. Lee, O.J., Gore, G.D., and Bartlett, T.J. (1947) Dearborn Catalog of Faint Red Stars Titanium Oxide Stars in Zones 40.5^{o} to $+90^{o}$, Ann. Dearborn Obs., Northwestern U. IV(Part 1C).

A31. Sulentic, J.W., and Tifft, W.G. (1972) The Revised New General Catalog of Non-Stellar Astronomical Objects, U. of Ariz., Tucson, Ariz.

A32. Sharpless, S. (1959) A catalog of HII regions, Astrophys. J. Suppl. IV:257.

vations are denoted by the last character. The asterisk and question mark have the same meaning as for the second character. A number means that the entry is a combination of a FIRSSE and SPICE measurement: "2" denotes a common color with values within 60 percent, "3" a common color with values greater than 60 percent of each other, and "4" no common color.

A8. COLUMNS 15 AND 16 - GALACTIC COORDINATES

The galactic longitude and latitude are listed in columns 15 and 16, respectively, to the nearest tenth of a degree.
