<p>This report describes the fabrication and testing of a lens antenna that is designed to have wideband scanning capabilities for wide angle scanning in any plane. The lens has a 30 by 40 wavelength aperture. Far field patterns were measured in both the azimuth and elevation planes over an eleven percent bandwidth. The azimuth scan angles were 0°, 15°, 30° and 45° and the elevation angles 0° and 15°.</p> <p>The quality of the patterns is fairly good with the average power level from + 50° to -50° close to 44 dB in the sidelobe region (excluding the 7 or 8 close in sidelobes). These lobes have peak values about 30 dB.</p>

SECTION I

INTRODUCTION

1.1 GENERAL

A cylindrical-lens phased-array antenna offers the capability for electronically scanning a narrow pencil beam over wide angles in two dimensions, and for handling wide signal bandwidths without using variable time-delay devices.

An investigation of such a lens-array antenna has been conducted by Hazeltine for RADC/EEA. The first part of the program involves the study of the antenna and design of a specific configuration. The second part of the program included the fabrication and test of a lens-array antenna having an aperture of at least 40 x 30 wavelengths.

This final report presents the results obtained in the second part of the program. The results of the study have been documented in an interim report¹. The balance of this section will present a brief summary of the antenna concept, and design objectives. Section II presents an overview of the lens configuration which was selected for fabrication. It presents a description of the antenna system and calculated patterns of the antenna. Section III describes the detailed design of the component parts of the lens antenna, including the components for the lens and the line feed which illuminates the lens.

Section IV provides a physical description of the lens antenna and its components. Section V presents the measured array performance, including representative pattern and gain measurements. Sections VI and VII describe some refinements made to the lens in order to improve its sidelobe performance, and the result of tests performed after the modifications. Finally, Section VIII presents a summary and conclusions.

1.2 ANTENNA DESIGN OBJECTIVES

The purpose of the program was to study and demonstrate the feasibility of using a cylindrical constrained lens for wideband radar systems.

The constrained lens was to achieve the following performance objectives:

Scan:	$\pm 45^\circ$ Az. $\pm 25^\circ$ El.
Total Bandwidth:	5.0 to 5.6 GHz
Instantaneous Bandwidth:	400 MHz
Directive Gain:	38 dB minimum
Aperture Size:	40 λ Azimuth 30 λ Elevation
Sidelobes (El):	-28 dB peak
(Az):	-32 dB peak
	6 above -42dB
	4 above -37dB
	2 at -32 dB
	all others below -50 dB
Polarization:	Linear

The hardware to be constructed included the printed circuit lens (without phase shifters) and a single line feed. The line feed was to be scanned in elevation to a single angle (15°) by inserting fixed line lengths in the feed.

SECTION II

LENS-ARRAY ANTENNA OVERVIEW

2.1 THE BASIC ANTENNA

A fundamental approach for a constrained cylindrical-lens antenna has been derived by Rotman and Franchi (Refs 2, 3, 4). The three-dimensional cylindrical lens comprises a stacked set of identical two-dimensional lenses. Each two-dimensional lens consists of two arrays of radiators interconnected by transmission lines. This configuration is shown in figure 2-1.

There are four degrees of freedom in the design of such a lens: the inner contour, the outer contour, the relative location of the inner and outer array elements, and the lengths of the interconnecting transmission lines. Rotman and Franchi (refs 2, 3, 4) derive a lens design in which the first three of these degrees of freedom are used to provide three points of perfect focusing in the azimuth plane. At azimuth angles between these three directions the focusing may be imperfect but may still be quite satisfactory.

Figure 2-8. Azimuth Pattern of Lens Antenna at 5.3 GHz for $\theta = 0$

Figure 2-7. Line Feed Azimuth Pattern

Figure 2-6. Line Feed Array Configuration

The desired illumination of the lens was accomplished by using eight dipoles in azimuth on the line feed, with the dipole excitations adjusted to provide the required azimuth pattern. Figure 2-6 shows the configuration of the feed array. The eight dipoles are printed on a card along with their associated power divider. The dipoles radiate horizontal polarization, which was selected for the lens.

2.5 CALCULATED ANTENNA PERFORMANCE

The dipole excitation results in the computed feed pattern shown in figure 2-7. At the feed half-angle of 31.3° the feed pattern is quite weak, yielding an illumination of the lens that is almost completely tapered at the sides. The sidelobes of the computed feed pattern are low enough that their contribution to antenna pattern sidelobes is not substantial.

The performance of the array was calculated during the initial study effort for a variety of frequencies and scanned conditions. A few of the patterns presented in the interim report are repeated here in order to provide some indication of the antenna's theoretical performance. The patterns presented here do not include the effects of tolerances, mutual coupling or multiple reflections. These are considered in detail in the interim report.

A computed on-axis antenna azimuth pattern is shown for 5.3 GHz (midband) in figure 2-8. The sidelobes are at least 10 dB below the sidelobe envelope defined by RADC, leaving a reasonable margin for fabrication tolerance errors. The beamwidth is 2.3° .

The computed effects of operation at the ends of the 5.0 to 5.6 GHz frequency band are shown in figures 2-9 and 2-10. It is assumed that the feed excitation (figure 2-4) remains constant across the band. The beamwidth of the feed pattern changes with frequency but, because of the highly tapered lens illumination, this change has little effect on the azimuth sidelobes of the antenna.

Figure 2-5. Basic Antenna Configuration.

degraded by the spillover. The feed radiation must be confined within the sector $\pm\theta_f$, the half-angle subtended by the vertex and the edge of the lens. With an R-2R lens, it can be shown that:

$$\theta_f = \arcsin h_{\max}$$

$$\text{where } h_{\max} = \frac{D}{2F} = .52$$

$$\theta_f = 31.3^\circ$$

It can also be shown that with an R-2R lens, this half-angle remains invariant as the feed is moved around the feed arc.

2.2 LENS CONFIGURATION SELECTED FOR FABRICATION

The first phase of the program included a study of several different lens shapes which could be designed using the constrained lens concept. These were termed "dimpled, pointed, hybrid and R-2R". All had a minimum of three azimuth focal points, with the limiting case being the R-2R configuration, which had perfect focusing over the entire azimuth arc.

The R-2R configuration was selected for fabrication based upon:

1. The continuous focused feed arc.
2. The relatively simple geometry.
3. The lack of discontinuities at the center of the lens.
4. The symmetry of the lens.

2.3 LENS CONFIGURATION

The antenna configuration selected for fabrication consists of the lens and a single line feed. Figure 2-5 shows the basic antenna configuration comprising the cylindrical lens and its on-axis feed. An h_{\max} of 0.52 was selected, corresponding to an $F/D = 0.96$.

The horizontal aperture dimension D was chosen as 40 wavelengths at 5.3GHz, or about 7.4 feet. The vertical length of the line feed L_f is about 35 wavelengths or 6.5 feet, and the lens vertical dimension is 38 wavelengths, or 7 feet.

The lens contains 62 layers of microstrip circuits, each layer containing printed dipoles and interconnecting transmission lines.

2.4 LINE FEED

The horizontal aperture of the line feed must be designed to provide a lens illumination shaped to attain low azimuth sidelobes. Also, the illumination must be very weak beyond the sides of the lens so that the overall antenna sidelobes are not

Figure 2-4. Cylindrical Lens Antenna for Wideband Wide-Angle Electronic Scanning

The cylindrical lens antenna has the capability for providing a wideband beam at the center of each sub-region. Each beam in a different azimuth direction requires a line feed that is appropriately displaced in azimuth, as indicated in figure 2-4(a). Each beam in a different elevation direction requires a line feed having collimated radiation that is steered by fixed time delays to the appropriate elevation angle, as indicated in figure 2-4(b). An electronic switch connects in sequence to each of the $M \times N$ line feeds, to provide the coarse steering from one sub-region to another. Electronic phase shifters located in the cylindrical lens provide the fine steering over each sub-region.

Each coarse beam position provides wide signal bandwidth because the lens antenna with multiple line feeds provides true time-delay steering and focusing. The phased array located in the lens uses simple phase shifters for finesteering the beam, but achieves wide signal bandwidth because of the relatively small size of the sub-region compared with the full scan coverage of the antenna.

ANTENNA SCAN COVERAGE:

PHASED-ARRAY COVERAGE:

Figure 2-3. Approach for Wideband Wide-Angle Electronic Scanning

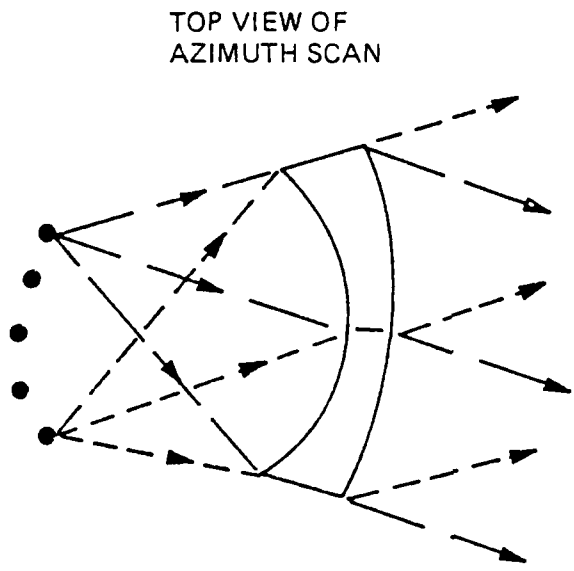

Figure 2-2. Scanning With a Cylindrical Lens Antenna

The fourth degree of freedom, namely, the lengths of the interconnecting transmission lines, is used to control the change of azimuth focusing that may occur with the three-dimensional lens when elevation angle is varied. In particular, Rotman and Franchi show that if the lengths of the interconnecting transmission lines are constant throughout the lens, the three points of perfect azimuth focusing are retained independent of elevation angle. Furthermore, at intermediate azimuth angles the azimuth aberration at any elevation angle is no greater than the azimuth aberration of the two-dimensional lens.

The significance of this result is that a cylindrical lens designed in this way can, when combined with an appropriate line-feed system, provide wide-angle scanning of a narrow pencil beam in both azimuth and elevation. For azimuth scanning the line feed is displaced in azimuth, while for elevation scanning the line feed aperture is phase steered. This is illustrated in figure 2-2.

The ability of this constant-line-length cylindrical lens to permit elevation scanning without aberration is analogous to the similar ability of the widely used cylindrical reflector. However, the azimuth-scanning capability of the cylindrical reflector is severely limited by its coma aberration and by the aperture-blocking effect of any centrally-located feed system. The cylindrical lens avoids these limitations.

A phased-array antenna that is electronically scanned can rapidly steer a narrow pencil beam over wide angles. However, if the signal bandwidth (instantaneous bandwidth) is not large, then a phased-array antenna can degrade the signal when the array scans over wide angles. One approach to this problem employs variable time-delay devices in the antenna, but these have some disadvantages. An alternate approach (refs 1, 2, 3, 4) employs the cylindrical-lens antenna as the feeding system for a standard electronically scanned phased array.

Suppose that the scan coverage of an antenna is $\pm \sin \theta_h$ horizontally and $\pm \sin \theta_v$ vertically. This coverage can be divided into M by N equal-size sub-regions, so that each sub-region covers only $\pm(1/M) \sin \theta_h$ by $\pm (1/N) \sin \theta_v$ as indicated in figure 2-3. If the feeding system for the phased-array antenna can provide a wideband beam that can be electronically switched from the center of one-sub-region to another, then the phased array needs to scan over only the relatively small sub-region rather than over the full coverage of the antenna. This will permit a much wider signal bandwidth to be handled without substantial degradation of the signal.

2.6 ELEVATION PATTERNS

The elevation pattern of the cylindrical lens antenna is similar to the elevation pattern of the line feed. Therefore the line feed should be designed to radiate a low-sidelobe, far-field elevation pattern. However, an additional factor affecting the antenna elevation pattern is the diffraction caused by the top and bottom edge of the cylindrical lens.

This diffraction effect could be made small by having a lens vertical dimension much larger than the line-feed vertical dimension. The diffraction effect can also be reduced by using a well-tapered vertical excitation of the line feed. We have chosen the modified $\sin u/u$ distribution (refs 8, 9) for the line feed because it is well tapered and can provide low sidelobes. The lens was made a small amount larger than the line feed.

The nominal vertical-excitation amplitude of the line feed was chosen for a nominal first-sidelobe level of -45 dB. The vertical excitation is provided by a microstrip power-divider network (discussed in a later section) and a set of interconnecting cables. The cable lengths were chosen so as to provide constant path length to the elements of the line feed for radiation at 0° elevation. A second set of cables will provide a time-delay-steered elevation angle of radiation.

The line-feed array was previously shown in figure 2-6. There are 58 elements along the 35 wavelength line feed, giving a vertical spacing between elements of about 0.6 wavelengths. The computed elevation pattern of this line feed array is shown in figure 2-11 for a beam at 0° elevation.

Ref 8 - H. Jasik, "Antenna Engineering Handbook", McGraw-Hill, pp. 2.27-2.28; 1961.

Ref 9 - R. C. Hansen, "Microwave Scanning Antennas", Academic Press, Vol. 1, pp. 58-60; 1964.

In order to determine the effect of lens diffraction on the elevation pattern sidelobes, a pattern computation was performed that included the truncation by the lens of the near-field radiation of the line feed. Figure 2-12 shows the line feed and the inner surface of the lens. Also indicated are rays emanating from the top and bottom of the line feed; the intersection of these rays with the inner surface of the lens is shown by lines drawn across the inner surface. For this case of no elevation scan, these "ray illumination boundary" lines are straight. Of course, the actual illumination of the lens surface is given by the near-field radiation of the line feed, which is only approximated by the ray viewpoint.

Figure 2-13 shows the antenna elevation pattern computed from the actual lens illumination, ie, the near field of the line feed, when the vertical dimension of the lens is 37 wavelengths. Comparison with figure 2-11 shows that the sidelobes are slightly affected by the lens truncation action.

SECTION III

DESCRIPTION OF ANTENNA

3.1. LENS MICROSTRIP LAYERS

The wideband lens array consists of two principal components; the line feed and the lens. Both are constructed of lightweight microstrip transmission lines and components.

The lens layers have been designed on the Calma GDS II graphics system. Associated photo-artworks for etching were fabricated on a Gerber photo plotter from Calma generated data tapes. A typical layer is shown in Figure 3-1.

Through the versatility of the Calma system in the layout design, it was possible to fabricate one-half of a lens layer on a standard 24" by 36" panel. Figure 3.2 shows how the layer was broken up to realize these dimensions. This layout approach reduced the amount of excess material required to fabricate a layer and, thus, the cost of the lens. In addition, acceptable tolerance values associated with both the photo artwork reproductions and etching process are difficult to attain in fabricating panels longer than 36 inches.

Because the electrical length of the lines in each lens layer is several thousand degrees, the phase of each layer is highly dependent on the dielectric constant of the material each layer is etched on. To compensate for material variations, different linelengths were used on materials with different dielectric constants.

Five different artworks were generated for the lens layer. Each individual artwork contained equal phase lines for the 53 transmission paths. Between artworks, the physical length of each transmission path was adjusted to provide an absolute phase equality between layers manufactured from material with slight dielectric constant variations. Our fiberglass material has been manufactured to a ± 0.02 dielectric constant and measured to an average value within ± 0.01 .

Figure 3-1. Typical Lens Layer

Figure 3-2. Typical Lens Artwork

Dimensional information, for drilling and cutting the lens sections from the etched panels, was also Calma generated.

3.2 LENS STRUCTURE

Figure 3-3 shows the detailed construction of the lens layers, each containing 106 printed microstrip lines and associated radiating elements. Each layer is fabricated in 4 pieces, which are trimmed, drilled and mounted on an aluminum backing plate. The dipoles project beyond the metal ground-plane by approximately one-quarter wave. A vertical aluminum ground-plane, supported by the standoffs which space the layers of microstrip, is positioned behind the dipoles. A gap between the dipole feed lines and the ground plane is maintained to prevent short circuiting of the feed lines. The ground-plane controls the radiation pattern of the dipole and also provides limited shielding for the microstrip transmission lines.

A photo of the lens, without radomes, is in Figure 3-4. It consists of 62 layers of printed microstrip. The lens structure is supported by a half-inch thick aluminum plate at the base, and two channeled vertical side-wall structures. The base-plate also serves to position the lens on the antenna support structure (figure 3-5) which is used to align and focus the lens line-feed assembly. Every ninth lens layer, the microstrip aluminum backing plates are attached to the vertical wall structures. The lens antenna is offset approximately one foot from the base-plate to eliminate ground effects.

The complete lens structure, assembled with radomes to weather-protect the microstrip layers, is presented in the photos of Figures 3-6 and 3-7. The radome material and construction is essentially invisible to the lens. A teflon material was selected for its durability and good electrical characteristics. The radome panels are joined with a thin teflon tape which introduces negligible transmission phase variation in the areas used. As depicted in the photos, the radome material easily conforms to the inner and outer lens contours.

Figure 3-16. Support Structure Layout

3.6 ANTENNA SUPPORT STRUCTURE

The antenna support structure is designed to align and test the feed in four azimuth scan locations, namely 0° , 15° , 30° , and 45° . The feed structure and associated plates interface at each scan location through four alignment holes on the antenna support structure. A layout of the support structure and assembly locations for the lens at various feed positions is in Figure 3-16. Also indicated on the layout is a plate-interface for aligning and holding the structure to our antenna mount during testing.

Figure 3-15. Line-Feed And Structure
With Protective Radome

Figure 3-14. Line-Feed And Housing Structure Without Radome

3.5 LINE FEED STRUCTURE

The radiating layers and elevation power divider are enclosed in a sheet metal cabinet with a thin radome on the front, to protect the microstrip from weather. Figures 3-14 and 3-15 are photos of the final structure, with and without the radome.

The line feed assembly is positioned on the antenna support structure via a base assembly which enables adjustment of the feed position. The feed structure sits directly on an offset plate which has been designed to compensate for the change in location of the feed phase center. Next, a spacer is assembled to vertically offset the feed to the same position as the assembled lens. The spacer sits upon two adjustable sheet-metal plates. The first plate provides an azimuth tilting capability to optimize the lens illumination. The second plate allows fine adjustments to be made in focusing the feed relative to the lens along a straight line directed at the lens center for each feed focal position.

A larger spacer has also been designed for the feed structure. This spacer is used during elevation scanning. Cables are placed in the feed elevation network to scan the elevation beam down 15° . The larger offset spacer is utilized to focus this scanned beam at the lens center, without increasing diffraction effects significantly from the unscanned case.

Figure 3-13. Assembled Line-Feed Unit

Figure 3-12. Line-Feed Elevation Power Divider

3.4 LINE FEED ELEVATION POWER DIVIDER

The line feed elevation power divider (Figure 3-12) provides the vertical illumination for the line feed layers. Connectors at the network outputs interface it to the corresponding azimuth layers through semi-ridged cable. Each cable was phase-trimmed to provide equal phase lengths from the elevation input to the cable output over the 5.0 to 5.6 GHz band.

The divider is fabricated on one microstrip board. A sheet-metal backing supports the microstrip and connectors. The fully assembled unit is located mid-way vertically behind the stacked-azimuth layers. The power divider is structurally supported through horizontal stand-offs which attach the power divider to the bent-sheetmetal supports in the column. The assembled layers, interconnecting cables, and elevation power divider are shown in Figure 3-13.

Figure 3-11. Lined-Feed Printed Layers

Figure 3-10. Microstrip Layer Construction For Antenna Feed

Top

Bottom

Figure 3-9. Feed Layer Design

3.3 LINE FEED MICROSTRIP LAYERS

The line feed consists of 58 identical microstrip layers. The layer design is shown in Figure 3-9. It contains a horizontal row of 8 dipoles excited by a microstrip power divider. The resulting current distribution across the dipole row provides the azimuth feed pattern needed for low antenna azimuth sidelobes.

Drill holes are located within the layer to provide points for aligning the layers during assembly of the line feed. The layers are stacked, aligned and supported by a bent sheetmetal structure whose design also provides a ground-backing for the printed dipoles. Figures 3-10 and 3-11 show the microstrip feed layer construction.

Figure 3-8. Lens Assembly With Absorber Panels

A solution to eliminate unwanted feed radiation spillover is to provide absorber panels beyond the lens structure. Upon measurements of the radiation patterns of the final feed design, the absorber requirement was confirmed necessary. Absorber panels were constructed and attached to the lens structure's vertical walls. The interface was accomplished with a hinge design to allow for adjustment of the panel angles. The photo in Figure 3-8 shows the absorber panels on the lens structure. The panels provide 30 dB attenuation at normal incidence for our frequency band. They have been made eight feet wide by 8 feet high to sufficiently cover the spillover sectors.

Each absorber panel is constructed with 16 two foot by two foot absorber sections glued to a plywood support and reinforced with an aluminum angle structure. The hinges are attached to the aluminum angle structure, and mating hinges are located on the vertical lens walls. A slide tube support has been designed which connects the absorber panel to the lens support structure. It is used to adjust and maintain the desired absorber position for various feed locations. The assembly is covered with plastic to keep the absorber dry.

SECTION IV

BREADBOARD DESIGNS

4.1 LENS BENT DIPOLES

To obtain low-sidelobe azimuth patterns when employing electronic phase shifters for beam scanning required a well-matched array element in both frequency and scan domains. This is because multiple reflections create discrete, high sidelobes. The bent dipole was developed to provide such an element for the array. A dipole feed and matching technique were selected that double-tuned the bent dipole design. The breadboard dipole and feed/matching are illustrated in Figure 4-1. The dipole is fed by a balun. The patch is used to single-tune the element and the stubs provide the double-tuning.

A waveguide simulator was designed to provide an array environment for the breadboard elements during impedance matching. A realizable waveguide cross section was chosen. It simulated a near broadside scan angle of 0° E-Plane and 8° H-Plane. Six breadboard elements are located in the waveguide cross-section as shown in Figure 4-2. For the simulator design to operate properly, the waveguide must propagate only the fundamental TE-10 mode. A smooth transition, from a standard waveguide operating in the TE-10 mode to the larger cross-section required for the simulator, was built to obtain the proper mode propagation. The transition built (Figure 4-3) is over seven feet long. The gradual taper was chosen to avoid higher mode propagations and to minimize phase curvature of the incident wave on the breadboard elements. Also shown in the figure are the breadboard elements mounted in a support structure that mates with the transition. In addition, the photograph displays a short circuit plate which provided a reference during impedance matching. The six elements were terminated in their design impedance and adjusted to provide the lowest reflection in the 5.0 to 5.6 GHz band. Slotted line measurements were used at the input of the taper to measure the element reflections. The resulting impedance loci of the matched-breadboard elements is given in Figure 4-4.

4.2 LENS MEANDERING LINES

In designing the microstrip layers for the lens, meandering lines were used to achieve the equal line-length connections between the dipoles on the inner and outer lens contours. Meandering the lines served two purposes. First, it simplified the development of the lens layout. Secondly, it kept the microstrip layers within realizable dimensions for manufacturing.

A direct layout approach for interconnecting elements allowed for .4 of available design space. The meandering line impedance was chosen to provide a reasonable line width for the layout. To minimize reflections caused by bending of the meandering lines, it was necessary to provide quarter-wave spacing between 90° bends. A section of the line is shown in Figure 4-5.

Breadboard lines were evaluated for successive numbers of meandering bends. Each was tested for VSWR performance, transmission amplitude and transmission phase. A typical bend was characterized in terms of mid-band transmission phase, and dispersion deviation from an equivalent straight microstrip line. The lens-layer was then developed using these measured characteristics. The basic design is shown in Figure 4-6. Note the number of meandering lines successively decreases out to the lens edge. The number of dispersive stubs increase as the number of meandering lines decrease. Their purpose is to provide the same dispersion as the straight line, thus equalizing the insertion phase of all lines over the operating band.

Figure 4-5. Meandering Line Section

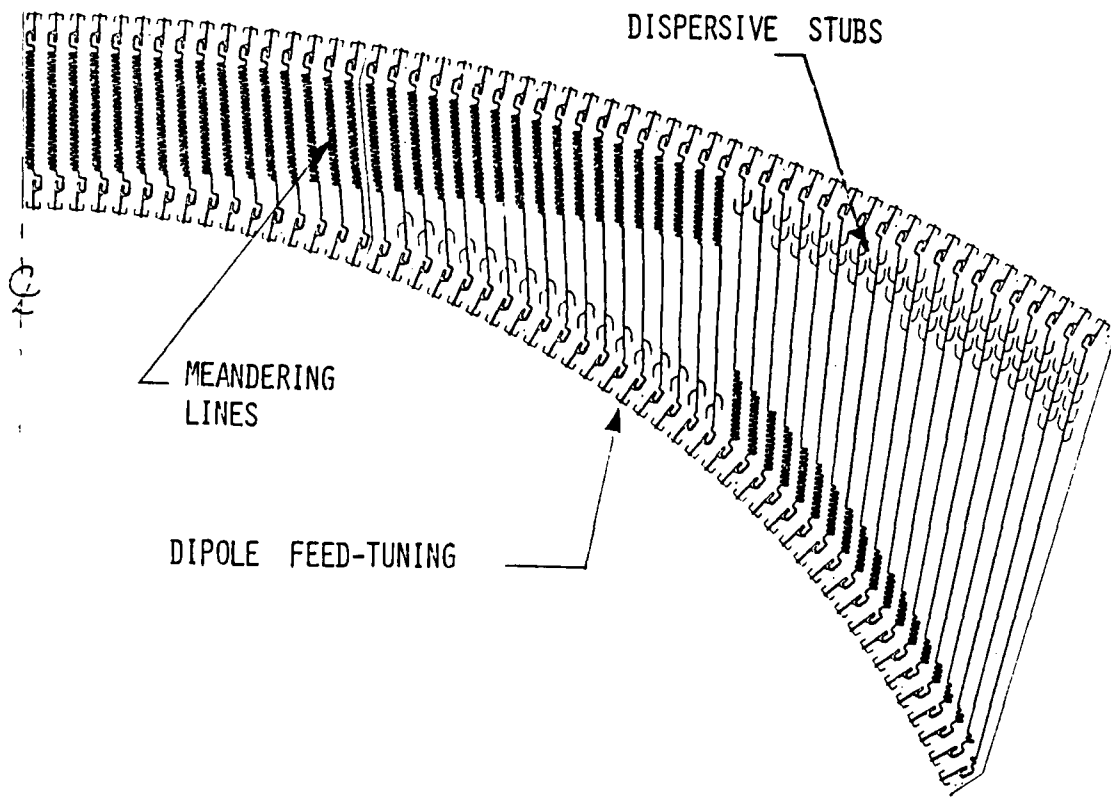

Figure 4-6. Basic Lens Layer Design

4.3 LENS LAYER

Utilizing the phase and dispersion characteristics of the measured breadboard meandering lines, an entire half-lens layer was designed on the Calma system, photo-plotted and fabricated. The dipoles on this test piece were replaced with impedance transformer sections and 50 ohm connectors to simplify testing. A section of the layout is shown in Figure 4-7.

Each line was measured for relative transmission phase over the 5.0 to 5.6 GHz band. Corrections were then made to the basic Calma layout for the final layer design.

4.4 LINE FEED DIPOLE

A simple straight-arm dipole design was adequate for use in the line feed since wide-angle scanning was not necessary. The element and feed-tuning layout is shown in Figure 4-8. The parallel plate construction, sketched in Figure 4-9, provided a semi-infinite array simulation of the feed for impedance matching of the elements. Although this simulator requires a feeding network for the dipoles, the measurement of impedance of an element at its feed point was quite simple. Results of the final dipole tuning over the 5.0 to 5.6 GHz band are in Figure 4-10.

4.5 LINE FEED SMALL ARRAY

A small array was built to empiracally optimize the horizontal excitation of the line feed. The theoretical far field azimuth pattern needed for generation of low-sidelobe lens patterns, set the design criteria for the illumination. This empirical final design includes the effects of dipole coupling and dipole feed stem coupling in finalizing the amplitude and phase settings for the array's columns.

Figure 4-7. Breadboard Lens Layer Section

Figure 4-8. Dipole For Feed Array

Figure 4-9. Simulator For Matching Line Feed Element

Figure 4-10. Impedance Locus of Matched Feed Dipole in Parallel-Plate Simulator

Figure 4-11 is a sketch of the small array and network. The array size was chosen eight elements wide by eight elements high. Those dimensions were selected to match the actual line feed in width, and to be adequately high so that mutual coupling effects are similar to the full height line feed. The eight outputs from each column are combined through eight-way power dividers equal in amplitude and phase. The column outputs are equally combined in symmetrical pairs through two-way power dividers. Each of these four outputs have individual in line attenuators and phase trimmers. The four adjustable outputs are combined through a final four way power divider. Initially, the system was phase-trimmed such that the total transmission phase from the network input to any individual dipole was equal. The theoretical excitation for the array was used as the starting point for setting the amplitude attenuators.

Patterns of the small array were evaluated as fine adjustments in amplitude and phase were made until acceptable azimuth patterns were obtained over the 5.0 to 5.6 frequency band. The relative amplitude and phase setting were then measured for the final feed design. The breadboard small array is shown in figure 4-12.

4.6 LINE FEED AZIMUTH POWER DIVIDER

A number of coupler-types were integrated together to form the Azimuth power divider. The breadboard shown in Figure 4-13 was fabricated, tested and phase trimmed to the output amplitude and phase settings of the breadboard small array. The spacing between the divider outputs was chosen to correspond to the required spacing of the horizontal elements in the line feed. This simplifies integrating the printed-circuit dipoles into the design for the line feed layers.

Results of these measurements are shown in Figures 5-5, 5-6, and 5-7 for frequencies of 5.0, 5.3 and 5.6. As might be expected, the performance is best at 5.3 GHz, the frequency at which the trimming was done. The elevation pattern sidelobes are somewhat worse at the band edges. The peak sidelobes are marginally above the design goal of -28 dB, but exceed them by no more than measurement error. However, it is likely that few sidelobes exceed -28 dB, principally due to variations in phase which could not be trimmed out.

Azimuth patterns of the feed were also measured. Although the patterns could have been evaluated by comparing them to theoretical feed patterns, it would be difficult to define an acceptable variation. Thus we chose to evaluate the patterns by digitizing them and plugging the values into our computer analysis of the complete lens antenna.

Figures 5-8, 9 and 10 show measured azimuth patterns at 5.0, 5.3 and 5.6 GHz. The azimuth pattern was specifically designed to provide a shaped illumination across the lens, and sidelobes below -40 dB at angles beyond those subtended by the lens. The sidelobes were not as low as the theoretical design, but were still well below isotropic and were very good considering that they were achieved by an 8 element array.

Peak levels of -28 dB are shown in the three patterns. Because levels such as these would result in unacceptable sidelobe levels for the entire antenna, absorbing panels will be placed on each side of the lens to absorb feed radiation.

Figure 5-4. Simulated Elevation Feed Pattern From Measured Elevation Network Outputs

5.2 LINE FEED TESTS

The line feed was tested on the Smithtown antenna range before being installed with the lens. Both azimuth and elevation patterns were measured.

Considerable effort was devoted to achieving low sidelobe elevation patterns. The elevation illumination is determined by the microstrip power divider and its associated cables. Initial measurements of the line feed elevation pattern showed sidelobe levels significantly higher than those calculated from the measured output amplitudes of the microstrip network. Figure 5-4 shows the pattern calculated from the measured outputs, with resulting sidelobes of -37 dB.

Since the combined microstrip network and the semirigid cables (used to connect to the azimuth power divider) had been measured together and phase trimmed, we concluded that the microstrip azimuth power dividers were introducing significant phase errors. Although the azimuth power dividers were etched from material from a single batch of teflon-fiberglass boards to minimize variations in dielectric constant, the variation within the boards was great enough to introduce significant phase variations.

Measuring the phase through the azimuth power dividers represented a significant challenge because the output was not accessible to a network analyzer. A coupler was constructed which coupled to the microstrip line near one of the edge dipoles. Despite a weak coupling level (-20 dB), measurements were repeatable to within ± 3 degrees. Using this test setup, the insertion phase of the feed was measured from the network input to the coupler. Based on these phase measurements, the cables were retrimmed.

Elevation patterns of the line feed were measured on the Smithtown antenna range. The elevation patterns were measured using the elevation axis of the mount. This procedure was adequate because of the relatively high sidelobes (-28 dB) and low range reflections (-40 dB). Thus the sidelobes have a worst-case error of ± 2 dB.

Figure 5-3 Improved Antenna Test Setup

Figure 5-2 Antenna Being Positioned in Test Setup

71J1001

Figure 5-1 Antenna Test Facility

directed at or above the horizon. Thus the sidelobes measured are perturbed by a range reflection which is approximately 40 dB below the sidelobe level, resulting in a negligible error.

Pattern measurements were made on Scientific Atlanta equipment, using both manual and automated systems. The measurement equipment has a minimum dynamic range of 60 dB.

SECTION V

PRELIMINARY TESTS AND EVALUATIONS OF ANTENNA

5.1 INTRODUCTION AND DESCRIPTION TEST SETUP

This section describes the initial testing done on the line feed, and the combination of the lens and the line feed. It also describes diagnostic tests and adjustments to the lens performed prior to final testing.

All pattern testing was performed at Hazeltine's test range in Smithtown, N.Y. Figure 5-1 shows a photograph of the test facility. The building is used for assembly and checkout of antennas before they are installed on the roof for testing. The top of the building contains seven multi-axis mounts which are used for antenna testing.

The transmitting source building is located 1000 feet away across a shallow valley. The source frequency and polarization are controlled remotely from the main building.

The test setup was configured specifically for the measurement of low sidelobes. Because a range suitable for the measurement of sidelobes below -50 dB was required, special care was taken. The antenna was mounted on a three-axis positioner, with the upper azimuth and elevation axis located 10 feet above the lower azimuth positioner, as shown in Figure 5-2. The positioners are located on the upper roof of the building, so that there are no nearby reflecting obstacles in any direction.

The range was probed to measure the level of spurious reflections. Across a 10 foot square area, the peak measured amplitude ripple was ± 0.1 dB, corresponding to reflections of -40 dB. This reflection level is caused by scattering from the ground and objects which are illuminated by the source antenna. However, this level of range reflections, which is at the limit of our measurement capability, is not adequate to measure antenna sidelobes of -50 dB. It is adequate for measuring the elevation patterns of the array.

A more accurate means of measuring very low sidelobe levels is illustrated in Figure 5-3. Here, the pattern cuts may be taken so that the main beam of the antenna is always

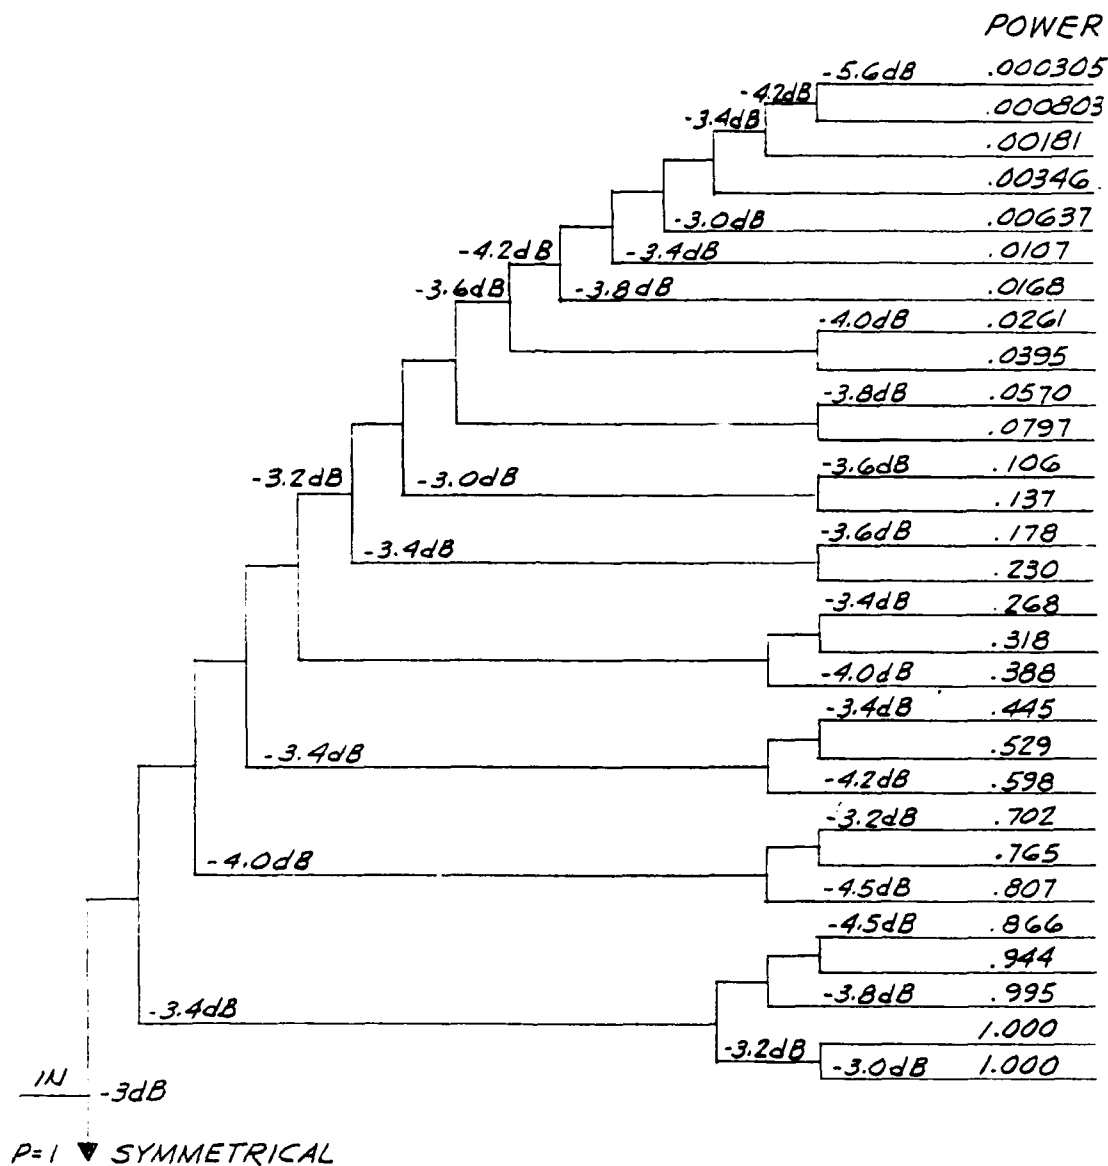

Figure 4-15. Quantized Coupler Layout

Figure 4-14. Theoretical Antenna Elevation Pattern With Quantized Coupler Elevation Network

4.7 COUPLERS FOR ELEVATION POWER DIVIDER

The layout of the elevation power divider was initially designed with realizable coupler values for microstrip fabrication. The coupler values were quantized to nine values to reduce breadboarding efforts. The calculated elevation pattern of the lens assuming the quantized coupler design is given in Figure 4-14. Figure 4-15 is the corresponding quantized coupler layout for the line feed. Each individual coupler was breadboarded and matched prior to fabricating the elevation network.

Figure 5-9. Measured Line-Feed Azimuth Patterns, 5.3 GHz For $\pm 90^\circ$ Sector

Figure 5-10. Measured Line-Feed Azimuth Patterns, 5.6 GHz For $\pm 90^\circ$ Sector

As described above, the shape of the illumination on the lens was evaluated by calculation. The calculation assumed that all the feed radiation outside of the lens is zero, and that the line feed phase center is that of the theoretical line feed.

Figure 5-11 shows the lens pattern calculated from the measured line feed azimuth pattern at 5.0 GHz. Table 5-1 summarizes the sidelobe performance of the calculated pattern compared to the design goal. The design goal is achieved or surpassed except for the sidelobes at -50 dB. This performance was deemed acceptable because these sidelobe levels were approaching the accuracy of the measurement. It should be noted that the calculation did not take into account tolerance errors in the lens, which may increase the low level sidelobes.

Figures 5-12 and 5-13 show the calculated patterns for 5.3 and 5.6 GHz, respectively. The calculated sidelobe levels are also summarized in Table 5-1. At these two frequencies, the calculated patterns satisfy the design goals.

These pattern tests completed the evaluation of the line feed prior to its integration with the lens.

5.3 MEASURED LENS AZIMUTH PATTERNS AND EVALUATION

Preliminary tests were performed on the antenna at broadside scan. The assembly of the lens, feed and support structure are in Figure 5-14. The absorber structures were not included in these tests, consequently, lens performance was evaluated only within the ± 30 degree sector off broadside. Sidelobe levels outside of this region include the effects of feed spillover, which results in significant degradation of the antenna sidelobes.

Results of these tests are shown in the measured antenna azimuth patterns presented in Figures 5-15 through 5-17. The extremely high sidelobe levels could not be reduced significantly during testing with any of the feed-adjustment techniques (i.e. feed tilting and re-focusing) available in the test setup. It was concluded that these results were caused by phase errors in the lens transmission lines. Tests were implemented to confirm that the errors were large enough to result in the measured antenna response.

A dipole coupler was designed to provide a means for measuring transmission phase of the microstrip lines in the lens layers. The coupler developed exhibited excellent electrical characteristics. The amplitude coupling varied between -5 and -7 dB over the 5.0 to 5.6 GHz band. The coupler match was within a 2:1 VSWR and did not significantly degrade the VSWR performance of the lens dipole when in use. Transmission Phase repeatability measurements were able to be made within 5 degrees of accuracy. Two such couplers were built and interfaced with the lens dipoles to measure and compare transmission phase between lines within a lens layer.

Figure 5-16. Preliminary Measured Antenna Azimuth Pattern 5.3 GHz

Figure 5-17. Preliminary Measured Antenna Azimuth Pattern 5.6 GHz

A spare microstrip lens-layer was tested. The relative transmission phase was measured between lines. A computed lens pattern was generated utilizing these measured phase errors. Figure 5-18 illustrates the resulting lens pattern. Comparing the relative sidelobe levels of this pattern to the preliminary measured azimuth pattern in Figure 5-16 confirms that the lens-layer phases were not held adequately to obtain the desired antenna performance.

The phase errors result principally from localized variations in the dielectric constant of each board. It is possible, although not certain, that a higher quality microfiberglass Teflon board would minimize the problem. The following section describes how they were corrected to improve the antenna.

Figure 5-18. Computed Azimuth Pattern of Lens With Measured Phase Errors of Lens Layer Included

5.4 LENS LINE PHASE CORRECTIONS

The lens layers were measured and phase corrections were inserted by placing a dielectric tape on each line to increase its insertion phase by a desired amount.

The test couplers were used in measuring and identifying the phase variations in the lens layers. The lens radomes were removed, along with the ground strip dipole backings. It was not necessary to fully disassemble the lens to perform the phase measurements or corrections.

Each lens layer was partially tested for phase variations within the layers transmission lines. Although the variations between all layers was not identical, implementation of an average correction of the lines was possible for layers manufactured from the same artwork. Care was taken to obtain more accurate phase information and not to use average correction values in the lens's central region where the feed illumination is highly concentrated.

A central element was used as a reference in each layer for relative transmission phase measurements. The largest normalized errors were on the order of 80 degrees. Typically, they were less than 60 degrees. Following the identification of the phase variation in a lens layer, each of the lines were adjusted to the electrically longest line apparent in the layer.

Teflon tape was used to trim the lines in the microstrip layers. Lengths of tape were chosen to provide phase corrections in 5 degree increments, to a maximum correction of 60 degrees when placed appropriately on the microstrip lines. The technique was breadboarded to assure the VSWR and transmission amplitude of the microstrip line were not significantly affected by the addition of the tape over a portion of the line.

Figure 5-19 is a list of phase corrections used in one lens layer. Each layer is not identically phase corrected. A correction scheme was developed independently for each layer utilizing measured phase variations in that particular layer.

SECTION VI

FINAL TEST OF ANTENNA

6.1 SETUP/TEST METHOD

The final antenna tests were made with the absorber structures included in the assembly as shown in Figure 6-1. With the antenna upright, as shown, azimuth patterns were taken over $\pm 90^\circ$, for all azimuth scan positions, relative to the on axis broadside scan angle of 0° . These measurements were made with the source horizontally polarized, using the upper azimuth mount for antenna rotation. Azimuth pattern measurements with the antenna tilted 90° were not made because of the weight of the antenna and structure.

Elevation patterns were also taken with the source vertically polarized. The patterns were taken over a range of $\pm 45^\circ$ for both the 0° and 15° elevation scan case relative to the broadside position. Full pattern measurements were restricted by the weight of the assembly. However, the pattern sector covered is sufficient to demonstrate the scan capability of the system.

Figure 6-1. Antenna Assembled for Final Test
at Smithtown Facility

6.2 MEASURED LENS PATTERNS AT 0° ELEVATION SCAN

Antenna patterns were taken for four azimuth scan locations, namely, 0°, 15°, 30° and 45°. Appendix A includes azimuth and elevation measured patterns for 5.0, 5.3 and 5.6 GHz for each feed position.

The feed tilting and focusing adjustments were made to optimize the respective patterns at midband (5.3 GHz) in each scan location.

6.3 15° ELEVATION SCAN TEST SETUP

Appropriate cable lengths were added to scan the elevation beam 15° down toward the lens base. The feed spacer size was increased to position this scanned beam to the lens center.

A removable panel was designed into the line feed structure for direct access to the network of cables which connect the azimuth layers and elevation power divider. Figure 6-2 is a view of the feed with the panel removed.

Azimuth patterns were taken $\pm 90^\circ$ relative to the azimuth broadside 0° scan through the 15° scanned elevation beam. Again, the source was horizontally polarized. The upper azimuth and elevation tables were adjusted to locate the beam peak, and azimuth patterns were taken using the upper azimuth table control.

Elevation patterns were taken for the same polarization with the elevation mount control. All elevation patterns were taken referenced to the 0° broadside elevation scan for the $\pm 45^\circ$ sector.

Figure 6-2. Line Feed With Access Panel Removed

6.4 MEASURED LENS PATTERNS AT 15° ELEVATION SCAN

Azimuth and elevation patterns were measured for the 15° elevation scan case at two azimuth scan locations of the line feed: 0° and 30°. Appendix B includes the final measured results. All line feed tilting and focusing was adjusted to optimize the antenna performance at 5.3 GHz. Measurements were also taken at 5.0 and 5.6 GHz.

A discussion of the final antenna performance is included in the next section.

**SECTION VII
SUMMARY AND CONCLUSIONS**

7.1 ANTENNA PERFORMANCE

The wideband, wide-angle scan capability of the lens is well demonstrated in the measured patterns included in Appendix A and B. The antenna has been tested to both 45° azimuth scan at 0° elevation, and 30° azimuth simultaneously with 15° elevation beam scanning.

Test results have demonstrated that the lens can be scanned to wide azimuth angles ($\pm 45^\circ$) without pattern degradation over a 5.0 - 5.6 GHz band. The patterns confirm the design of the R-2R lens which provides a circular focal line and allows the patterns to remain perfectly focused for all azimuth angles.

The pattern tests also showed that the array can be scanned in elevation by displacing the line feed and scanning the line feed beam. No significant degradation of the elevation patterns was noted with elevation scanning.

The table below summarizes the antenna performance in the azimuth scan sector of $\pm 60^\circ$ relative to the on axis broadside beam location.

Freq. GHz	Scan Angle (Deg.)		Peak Sidelobe Level - dB	No. Sidelobes Exceeding dB		
	Az.	Elev.		32	37	40
5.0	0	0	24.0	3	12	15
5.0	15	0	24.5	2	4	9
5.0	30	0	25.0	2	6	13
5.0	45	0	25.5	4	7	12
5.0	0	15	25.5	3	10	13
5.0	30	15	26.5	2	6	15
5.3	0	0	28.0	1	4	7
5.3	15	0	29.0	2	2	9
5.3	30	0	29.0	2	4	7
5.3	45	0	30.0	3	6	9
5.3	0	15	27.0	4	7	10
5.3	30	15	30.5	2	4	9
5.6	0	0	27.5	1	6	15
5.6	15	0	26.0	5	12	20

APPENDIX A

LENS MEASUREMENTS 0° ELEVATION SCAN

Feed spillover outside of this region is not well attenuated by the lens absorber panels.

Considering the magnitude of the encountered phase variations in the lens microstrip layers, and the averaging and quantization correction technique used to trim the lens microstrip lines, final antenna performance has demonstrated feasibility in attaining low sidelobe levels. Random phase errors are still present in the lens. Our best estimate is that the levels do not exceed $\pm 30^\circ$ peak and 10° RMS.

Since the low-range reflection test setup could not be used due to the weight of the assembled antenna, sidelobes below -40dB are known to be degraded by range reflections and are therefore not able to accurately measure. Although the previous table summary indicates a large number of sidelobes exceeding the 40 dB level, the measured patterns show most of them only exceed this level by a small margin.

Amplitude and phase assymetries in the feed contribute to slight degradation in antenna performance at the band edges. It was possible to reduce sidelobe levels at the band edges, with small feed-position adjustments. However, the results were higher sidelobes at mid-band. Final pattern data has been presented, therefore to optimize lens performance at mid-band, and accept the poorer performance at the band edges.

The antenna performance in elevation was consistent for all scan conditions. Variations in the absolute phase between lens layers is as large as $\pm 35^\circ$. These phase errors could not be corrected in the lens microstrip line trimming.

7.2 CONCLUSIONS

The microstrip lens array approach is a good choice for wideband, wide-angle scanning. The major difficulties in attaining the low-sidelobe levels are in the manufacturing of the lens layers. Present available materials are not adequate for a microstrip lens. Fabrication techniques must be carefully implemented to meet the goals of this contract. Hazeltine has demonstrated that trimming of the lens microstrip is necessary, and that low sidelobes can be attained with suitable phase corrections. The trimming on the lens was limited by budgetary and time constraints so that -50 dB sidelobes were not expected.

*MISSION
of
Rome Air Development Center*

RADC plans and executes research, development, test and selected acquisition programs in support of Command, Control, Communications and Intelligence (C³I) activities. Technical and engineering support within areas of competence is provided to ESD Program Offices (POs) and other ESD elements to perform effective acquisition of C³I systems. The areas of technical competence include communications, command and control, battle management, information processing, surveillance sensors, intelligence data collection and handling, solid state sciences, electromagnetics, and propagation, and electronic, maintainability, and compatibility.
