Far-Field Boundary Conditions in Numerical Solutions of the Navier-Stokes Equations

P.J. McKenna

Final Report AFSOR Grant 83-0330

Approved for public release; distribution unlimited.
The purpose of this project was to investigate the artificial boundary conditions which must be imposed at the boundary of a numerical grid. Numerical experiments were performed which evaluated various boundary conditions of this type. Of particular interest was the question of whether linearization around the flow at infinity provides an adequate choice of boundary condition for the fully nonlinear equations. Inflow-outflow conditions as well as several choices of periodic boundary conditions were considered. The inflow-outflow conditions worked reasonably well for two dimensional problems. For the periodic conditions, results were mixed. Concerns about over specification when using pure periodic conditions proved to be groundless. However, the method failed when attempting to use periodicity in the two sideways traveling periodic waves.
I INTRODUCTION

With the advent of high speed computers, new approaches to the solution of engineering problems have arisen. One such field is Computational Fluid Dynamics, in which numerical techniques such as finite differences are used to numerically integrate partial differential equations governing the physical phenomena. One problem with this approach is that on the boundary of the numerical grid, artificial boundary conditions must be imposed. Usually, these conditions are based on a linearization around the flow at infinity, and are thus non-physical. In this paper, we perform a series of numerical experiments, in which we evaluate various boundary conditions of this type, and investigate whether the linear model is an accurate representation of the fully non-linear equations.

The flow of fluid around obstacles in two dimensions is described by the compressible Navier-Stokes equations

\[
\begin{align*}
\frac{3U}{3t} + \frac{3E}{3x} + \frac{3F}{3y} &= 0
\end{align*}
\]

where

\[
U = \begin{bmatrix} 
\rho \\
\rho u \\
\rho v \\
\rho e \\
\end{bmatrix} \quad \quad E = \begin{bmatrix} 
\rho u \\
\rho u^2 - \sigma_{xx} \\
\rho uv - \tau_{xy} \\
\rho ve - u\sigma_{xx} - v\tau_{xy} - q_x \\
\end{bmatrix}
\]
\[ F = \begin{bmatrix} \rho v \\ \rho uv - z_{xy} \\ \rho v^2 - \sigma_{yy} \\ \rho ve - \sigma_{yy} - uz_{yx} - q_y \end{bmatrix} \]

\[ \sigma_{xx} = -\rho - \left(\frac{5}{3}\right) \mu \mathbf{i} \cdot \mathbf{j} + 2\mu \frac{\partial u}{\partial x} \]

\[ z_{xy} = \mu \left(\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x}\right) \]

\[ \sigma_{yy} = -\rho - \left(\frac{5}{3}\right) \mu \mathbf{i} \cdot \mathbf{j} + 2\mu \frac{\partial v}{\partial y} \]

\[ q_x = k \frac{\partial T}{\partial x} \quad q_y = k \frac{\partial T}{\partial y} \]

\[ p = \rho RT \quad \mu = \mu(T) \]

\[ e = c_v T + (u^2 + v^2)/2. \]

Here, the four variables \( \rho, u, v, e \) represent the physical quantities of density, \( x \)- and \( y \)- components of velocity, and internal energy.

This nonlinear system of mixed parabolic-hyperbolic type in two space dimensions and time, with four independent variables must be solved in an exterior region in \( \mathbb{R}^2 \). The geometry will depend on the particular physical situation that one is attempting to model.

The situation we shall be interested in occurs in modelling...
flight conditions, in which the conditions at infinity are prescribed with a large u-velocity and v-velocity zero and prescribed $p_\infty$ and $e_\infty$. Fluid flows around an obstacle in x-y space.

Usually, this equation is solved numerically using a finite difference scheme of the Lax-Wendroff type, such as the MacCormack ADE method. Since these calculations can only be made on a finite grid of points in xy space, an artificial far-field boundary is created. This boundary ought be sufficiently far away from the object around which the fluid is flowing so that local phenomena are not neglected by omitting part of the region of fluid flow. On the other hand, the farther away the region is, the more grid-points need to be included and thus the more expensive and time-consuming the computations become.

One then has the problem of deciding what effect this new boundary has on the solution of the problem. Because of the viscosity terms in (1) and the additional artificial viscosity introduced by the finite difference schemes, some boundary conditions must be imposed.

As we shall show in this report on numerical experiments, considerable care must be exercised in the choice of the boundary conditions. If one is interested in steady state flow, then one starts off with an initial approximation, and hopes that the errors in the numerical solution propagate out of the region as transitory disturbances in the physical variables. One then expects to converge to the steady state flow.
We have previously shown that the incorrect choice of boundary conditions can give rise to some of the following phenomena: i) reflecting boundary conditions, in which the disturbances in the physical variables represented by the difference between the steady state flow and the initial conditions are not allowed to exit through the far-field boundary but instead continue echoing within the grid, and giving rise to spurious oscillatory solutions; ii) under-specified boundary conditions, in which large errors are introduced before convergence takes place.

In this paper, we first discuss the theory for simple linear hyperbolic systems in one and two space dimension. We then analyze several computational experiments in the light of this theory in two space dimensions.

II A REVIEW OF THE LINEAR CASE

The method used in the calculations which are the subject of this paper is the MacCormack alternating direction explicit
scheme. [6] [15]. This is a multistep efficient scheme which reduces in the linear case to the Lax-Wendroff scheme. For a diagonal \( N \times N \) matrix \( A \), this scheme approximates the equation \( U_t + AU_x = 0 \) by

\[
U_j^{n+1} = U_j^n - \frac{\Delta t}{\Delta x} (U_{j+1}^n - U_{j-1}^n).
\]

\[
+ A^2 \left( \frac{\Delta t}{\Delta x} \right)^2 (U_{j+1}^n - 2U_j^n + U_{j-1}^n)
\]

As usual, \( \{j_1 < j < J\} \) represents the space step and \( n \) represents the time step. If we are considering the equation

\[ U_t + AU_x = 0 \]

on the region \( \{(x,t), 0 < x < 1, t > 0\} \) then the analytic solution is determined by the initial conditions and boundary conditions at \( x = 0 \) and \( x = 1 \). If the first \( k \) eigenvalues are positive and the remaining \( N - k \) are negative then the quantities \( u_1 \ldots u_k \) must be prescribed at \( x = 0 \) and \( u_{k+1} \ldots u_N \) must be prescribed at \( x = 1 \).

Thus if \( W_I = (u_1, u_2, \ldots u_k, 0, 0, \ldots, 0) \) and \( W_{II} = (0, 0, \ldots, 0, u_{k+1} \ldots u_N) \) then for well-posedness, the boundary conditions must be

\[
W_I = f(t) + B_0 W_{II} \quad \text{at } x = 0
\]

\[
W_{II} = g(t) + B_1 W_I \quad \text{at } x = 1.
\]
This gives a total of \( N \) boundary conditions. If either
\[ k \times (n-k) \text{ matrix } B_1 \] and the \((n-k) \times k \text{ matrix } B_0 \) are non-zero, then
the boundaries are reflecting, that is a wave in \( W_I \) travelling
left to right will be reflected as a wave in \( W_{II} \) running right to
left.

If a boundary is supposed to be non-physical, then it should
not be reflecting, since the reflections would depend on the
location of the artificial or numerical boundary.

Now let us consider the difference scheme of (2). If the
grid points are given by \( \{x_j\}_{0}^{J} \) with \( x = 0 \) and \( x = 1 \), then it is
clear from (2) that \( 2N \) boundary conditions are required. Thus we
must prescribe boundary conditions in such a way as to least
affect the closeness of the numerical to the analytic solution.

This situation has been the subject of several papers. In
[3], Gustaffson and Kreiss point out the danger of over-
specification. By this is meant that all \( u_i' \) are specified at
both endpoints. This might be tempting because one might argue
that if the boundary conditions \( u_i'---u_k' \) are given constants at
\( x = 0 \), then eventually these same values will be assumed by these
variables at \( x = 1 \). However, in [4] it is pointed out that
convergence may or may not occur, depending on whether the number
of grid points is odd or even.

A method which works well, as pointed out in [3], is to
impose
\frac{\partial u_i}{\partial x} (1,t) = 0 \quad 1 < i < k.
\frac{\partial u_i}{\partial x} (0,t) = 0 \quad k+1 < i < n.

or in the numerical scheme

\begin{align*}
u_i, j &= u_i, j-1 \quad 1 < i < k. \\
u_i, 0 &= u_i, 1 \quad k+1 < i < n.
\end{align*}

This introduces small errors at the outflow but these errors do not propagate upstream. This is proved analytically by Parter [10].

In [12], many different numerical boundary conditions are given. The conclusion is that upwind differencing at the point of outflow

\begin{align*}
u_j^{n+1} &= \nu_j^n + \lambda_i \frac{\Delta t}{\Delta x} (u_{j-1}^n - u_j^n) \\
u_1 &= \nu_1
\end{align*}

is most accurate, although it converges with the same speed as the previously discussed \( u^x = 0 \).

The most serious error which one could make would be to prescribe conditions at the wrong end. In other words, since \( u_1 \) is right running, this would involve prescribing \( u_1 \) at \( x = 1 \) and imposing \( u_1^x = 1 \) at \( x = 0 \). This would result in convergence to a
steady state which depends on the initial conditions.

III THE NAVIER-STOKES EQUATIONS AND CHARACTERISTIC VARIABLES:

We now begin our discussion of the equations of gas dynamics. We will neglect viscosity for the purposes of this analysis. We will assume that the flow is one-dimensional and subsonic and that the deviations from free-stream solutions are small. This will allow us to neglect second order terms.

There are many forms of this equation, but the one most suitable for the present discussion is

\[
\frac{\partial \mathbf{U}}{\partial t} + \mathbf{A} \frac{\partial \mathbf{U}}{\partial x} = 0
\]

where

\[
\mathbf{A} = \begin{pmatrix}
0 & 1 & 0 \\
\frac{(\gamma-3)u^2}{2} & (3-\gamma)u & \gamma - 1 \\
(\gamma-1)u - \frac{\gamma e}{\rho} & \frac{\gamma e}{\rho} - \frac{3}{2}(\gamma-1)u^2 & \gamma u
\end{pmatrix}
\]

and

\[
\mathbf{U} = \begin{pmatrix}
\rho \\
\rho u \\
e
\end{pmatrix}
\]

or in terms of physical variable

(3) \[ \frac{\partial \mathbf{U}}{\partial t} + \hat{\mathbf{A}} \frac{\partial \mathbf{U}}{\partial x} = 0 \]
where
\[ \hat{A} = M^{-1} AM \]

and
\[ M^{-1} = \begin{pmatrix} 1 & 0 & 0 \\ -u/p & 1/p & u \\ (\gamma^{-1})u^2 & (1-\gamma)u & (\gamma-1) \end{pmatrix} \]
\[ \tilde{U} = \begin{bmatrix} \rho \\ u \\ \rho \end{bmatrix} \]

Here we make the key assumption that deviations from the free stream are going to be sufficiently small that we can treat the entries in the matrix A as being approximately constant (at least locally). Denote these frozen variables by \(^{0}\text{-subscript}.\)

We then make the substitution

\[ (4) \quad \begin{pmatrix} W_1 \\ W_2 \\ W_3 \end{pmatrix} = \begin{pmatrix} 1 & 0 & -1/c_0^2 \\ 0 & 1 & 1/\rho_0^2 \gamma_0 \\ 0 & -1 & 1/\rho_0^2 \gamma_0 \end{pmatrix} \begin{pmatrix} \rho \\ u \\ p \end{pmatrix} \]

and when this is substituted into ( ) we obtain

\[ (5) \quad \frac{\partial W_1}{\partial t} + u_0 \frac{\partial W_1}{\partial x} = 0 \quad W_1 = \rho - \frac{1}{c_0^2} \]
\[ \frac{\partial W_2}{\partial t} + (u_0+c_0) \frac{\partial W_2}{\partial x} = 0 \quad W_2 = u + \frac{1}{\rho_0 c_0} \]
\[ \frac{\partial W_3}{\partial t} + (u_0-c_0) \frac{\partial W_3}{\partial x} = 0 \quad W_3 = -u + \frac{1}{\rho_0 c_0} \]
Notice now how this breaks down into two separate cases. On the one hand, if flow is supersonic then all wave motion is in the left to right direction. In this case all analytic boundary conditions should be prescribed at the left hand side and only numerical boundary conditions prescribed at the right hand side.

Since the substitution (4) is equivalent to

\[
\rho = K_1 + (\rho_0/2c_0)(K_2+K_3) \\
u = 1/2(K_2-K_3) \\
p = \rho_0 c_0/2(K_2+K_3)
\]

it follows that prescribing all physical variables at the inflow and prescribing \( \partial \rho/\partial x = \partial u/\partial x = \partial p/\partial x = 0 \) at the outflow is legitimate in terms of analytical and numerical requirements in the supersonic case.

However, we must now consider the case of subsonic flow. In this case the situation is completely different. Here, two of the variables \( W_1 \) and \( W_2 \) go left to right with velocities \( u_0 \) and \( u_0 + c_0 \) respectively, whereas one of the variables runs right to left with velocity \( c_0 - u_0 \). The variables \( W_2 \) and \( W_3 \) have no clear physical significance, yet it is only in considering these variables that the full wave structure of the equations (5) or (6) can be understood. Thus, one would be led to predict, for small deviations from free stream conditions, that the best boundary conditions would be, for an interval \((0,L)\)
\begin{align}
W_1 (0, t) &= K_1 \\
\frac{dW_1}{dx} (L, t) &= 0 \\
W_2 (0, t) &= K_2 \\
\frac{dW_2}{dx} (L, t) &= 0 \\
\frac{dW_3}{dx} (0, t) &= 0 \\
W_3 (L, t) &= K_3 
\end{align}

Note the curious aspect of these boundary conditions. In order to prescribe the numerical values \( K_1 \) and \( K_2 \), we need to know accurately all three physical variables at some distance to the left. However, only the two combinations \( K_1 \) and \( K_2 \) are prescribed. This can be summarized by saying that while we have used all three pieces of information upstream, we have done so in such a way that one degree of freedom remains, thus allowing the waves in \( W_3 \) to exit without reflections.

On the basis of the linearized model, various other combinations would be well-posed. For example, it is possible to prescribe \( K_3 \) in terms of either \( K_1 \) or \( K_2 \) at the outflow \( x = L \). Thus at the outflow one may prescribe

\[ W_2 (L, t) = F_3 (t) + c_1 W_1 (L, t) + c_2 W_2 (L, t) \]

For example if \( c_1 = 0, c_2 = 1 \), then this amounts to putting

\[ u (L, t) = 1/2 F_3 \]

(i.e., we prescribe velocity at the outflow).
Alternatively, we might take $c_1 = 0$, $c_2 = -1$ and we would get

$$p(L,t) = ((p_0 c_0)/2) F_3$$

(i.e. we prescribe pressure at the outflow).

Many other combinations are possible, but as remarked in section II, all these will cause errors in the initial data to be reflected back into the medium as waves running from right to left. For example, we would predict that an error in $W_3$ would be reflected back as an error in $W_1$ if we use boundary condition (8). As we shall see, this is exactly what happens.

At the inflow end, we may prescribe $W_1$ and $W_2$ in terms of $W_3$. Thus the following boundary conditions are well posed;

$$(9)(a) \quad W_1(0,t) = F_1 + c_1 W_3(0,t)$$

$$(b) \quad W_2(0,t) = F_2 + c_2 W_3(0,t)$$

For example, choosing $c_2 = +1$ in (9b) corresponds to

$$u(0,t) = (1/2) F_2$$

(i.e. prescribing $u$ at the inflow) and $c_2 = -1$ corresponds to

$$p(0,t) = (\rho_0 c_0/2) F_2$$

(i.e. prescribing $p$). One can prescribe the combination $(u,p)$ by first choosing $c_2 = 1$ (thereby prescribing $u$) and then choosing $c_1 = \rho_0 / c_0$, thereby prescribing $p$ in terms of a given $F$, and a
VI  TWO DIMENSIONAL RESULTS

Having now understood the phenomena which can occur when calculations are made with one space dimension, we now consider the more complicated situation of two space dimensions.

In this situation, we shall solve the Navier Stokes equation (1), again by the standard MacCormack A.D.E. scheme on a 20 x 20 grid, which is a very simplified model of a wind tunnel. We shall continue to consider flow close to the free stream flow ($M_a = 0.5$) previously studied in the one dimensional case. The physical values are given earlier. Figure 8 shows the geometry of the situation. The fluid is flowing in at the top right corner of the grid and flowing out at the bottom left.

We have three distinct types of boundaries to consider. We have the inflow and outflow boundaries (as before) and in addition, two sidewall boundaries, where the fluid is flowing parallel to the boundary.

We shall continue to impose one dimensional boundary conditions of the type given in the first section on the inflow and outflow, along with the additional condition $v = 0$. This says the fluid flow is one dimensional at the inflow and outflow, and could be physically reasonable.

When we come to the sidewall conditions we must undertake another one-dimensional analysis. Thus, we assume all variables are constant in the $x$-direction and variation only takes place in the $y$-direction.
This leads to the set of equations

\[
(6) \quad V_t + AV_y = 0
\]

where

\[
\begin{bmatrix}
\dot{V} \\
u \\
v \\
e
\end{bmatrix} =
\begin{bmatrix}
p \\
u \\
\frac{u^2}{2}(\gamma - 1) - u(\gamma - 1) \\
e\gamma - \frac{u^2}{2}(\gamma - 1)
\end{bmatrix}
\begin{bmatrix}
0 \\
0 \\
u \\
0
\end{bmatrix}
\begin{bmatrix}
1 \\
0 \\
0 \\
0
\end{bmatrix}
\]

Freezing the coefficients of \( A \) in (6), we substitute

\[
T_1 = \rho + \frac{P}{c_0^2}
\]
\[
T_2 = v + \frac{1}{\rho_0 c_0^2} \rho
\]
\[
T_3 = -v + \frac{1}{\rho_0 c_0^2} \rho
\]
\[
T_4 = u
\]

Equation (6) is then transformed to
Thus, if we only consider deviations transverse to the free stream flow, we have on the basis of the linearized model, four non-physical variable $T_1$, $T_2$, $T_3$, $T_4$, two of which are $u$ and entropy. $T_1$ move with zero velocity in the $y$ direction, one of which, $T_2$, moves with speed $c_0$ in the positive $x$ direction, and one of which moves with speed $c_0$ in the negative $x$ direction.

Thus one dimensional theory predicts that at the sidewall, we should impose

\begin{align*}
    y &= 0 & y &= L;
    \quad T_{1y} = \text{const} & T_{1y} &= 0 \\
    T_{3y} &= 0 & T_3 &= \text{const} \\
    T_{4y} &= 0 & T_{4y} &= 0
\end{align*}

This, together with the inflow and outflow conditions gives the following set of boundary conditions
Inflow

\[ v_1 = v_* \]
\[ p_1 = \frac{1}{2} \left[ p_2 + \rho_0 c_0 (k_3 - u_2) \right] \]
\[ u_1 = \frac{1}{2} \left[ k_3 - \frac{p_2}{\rho_0 c_0} + u_2 \right] \]
\[ \rho_1 = k_1 + \frac{\rho_0}{2c_0} \left[ \frac{p_2}{\rho_0 c_0} + k_3 - u_2 \right] \]

where the free stream values are specified in the characteristic variables

\[ k_1 = \rho_* - \frac{p_*}{c_0^2}, \quad k_3 = u_* + \frac{p_*}{\rho_0 c_0} \]

and where the zero-subscript refers to frozen variables

Outflow

\[ v_n = v_{n-1} \]
\[ u_n = \frac{1}{2} \left[ u_{n-1} + p_{n-1}/(\rho_0 c_0) - k_4 \right] \]
\[ p_n = \frac{\rho_0 c_0}{2} \left[ k_4 + u_{n-1} + p_{n-1}/(\rho_0 c_0) \right] \]
\[ \rho_n = \rho_{n-1} - \frac{p_{n-1}}{c_0^2} + \frac{\rho_0}{2c_0} \left[ k_u + u_{n-1} + \frac{p_{n-1}}{\rho_0 c_0} \right] \]
Top wall

\[ p_j = \frac{\rho_0 c_0}{2} [v_{j-1} + \frac{p_{j-1}}{\rho_0 c_0} - k_3] \]

\[ v_j = \frac{1}{2}k_3 + \frac{1}{2}(v_{j-1} + p_{j-1}/\rho_0 c_0) \]

\[ \rho_j = \frac{\rho_0}{2c_0} (v_{j-1} + \frac{p_{j-1}}{\rho_0 c_0} - k_3) + \frac{p_{j-1} - \frac{1}{c_2} p_{j-1}}{2} \]

\[ u_j = u_\infty \]

Bottom wall

\[ u_1 = u_\infty \]

\[ v_1 = \frac{1}{2} [v_2 + k_2 - p_2/(\rho_0 c_0)] \]

\[ p_1 = \frac{\rho_0 c_0}{2} [-v_2 + k_2 + p_2/(\rho_0 c_0)] \]

\[ \rho_1 = \rho_2 + (\rho_0/2c_0) [-v_2 + k_2 - p_2/\rho_0 c_0] \]

where the free stream values are used to specify the characteristic combinations

\[ W_2 = v_\infty + \frac{p_\infty}{\rho_0 c_0} \quad W_3 = v_\infty - p_\infty/\rho_0 c_0. \]
The purpose of the present grant was two-fold: first to expand the previous work to situations where the flow was at an angle \( \alpha \) to the artificial boundary, but is primarily steady-state, and second, to see how the artificial boundary conditions apply in period situations where convergence to free stream is not expected.

The first objective is clearly desirable, simply to save in additional computing time. The requirement that the grid not be rectangular with boundaries either parallel to or perpendicular to the free stream at infinity clearly can be used to remove a large number of points from the grid. The entire boundary can be chosen approximately equidistant from the object whose flow characteristics are being studied.

The second objective was chosen because of its importance in modelling flow in the compressors of turbines. If one is attempting to design turbine compressors, one must have knowledge of how the flow in the area between the stators and the rotors is behaving. This is almost impossible to measure.

On the other hand, to accurately model the entire inside of the compressor requires a computational capability far exceeding the largest of today's computers. Thus one models only the flow past two blades of the rotor, and uses periodicity to extend the calculations to the entire rotor. The flow coming in past the
stator is regarded as a periodic inflow term.

The following pages summarize the results of the research on these two projects.

Section I Flow at an angle of incidence $\alpha$.

The previously outlined boundary conditions were used. Computations were done on the basis of the inflow or outflow depending on the flow perpendicular to the surface. For computational simplicity, we chose a rectangular grid, but choose $u_0 = V_0 = 300$. This results in a $45^\circ$ angle of incidence or exit. We impose an initial 10% disturbance in $W_2$, the right running characteristic variable and observe what happens as it exits. Recall that this disturbance runs at an angle of $45^\circ$ to the flow. The following plots for $W_2$ at various iteration numbers show it exiting without any surprising phenomena, similar to the one-dimensional case. By the sixty-fifth iteration, the flow has almost converged to steady state. There appear to be some small reflections (as shown in the last plot) in $W_3$, but nothing to worry about.

Thus we can conclude that the inflow-outflow boundary conditions work reasonably well. Subject to a rotation of coordinates, they can work on any geometry – the only decision is whether we are at an inflow or outflow point.
II. The case of periodic BCs

We now consider some experiments on the case of periodic boundary conditions. We study flow parallel to the rectangular grid, perpendicular to the inflow and parallel to the side-walls.

The most obvious boundary condition is pure periodic: $S_i = S_{n-1}$, $S_n = S_2$ for all physical variables $S$. This, it was feared might lead to over specification, but these fears appeared groundless. A sight-traveling wave would exit to the right, and reappear at the left in a predictable and correct manner.

The next objective was to see if this could be done by only using periodicity in the two sideways traveling periodic waves. The reason for this was to minimize storage problems for the more complicated turbine problem already discussed.

Curiously, this method failed. Furthermore, the failure seems intrinsic to the whole idea, as we shall demonstrate.

First the $W_2$ wave appears in iteration 5 and proceeds to exit. Periodicity requires that it reappear, and this can be seen in iteration 20. However, already, a sharp spike (reminiscent of over specification is appearing in $W_3$ by iteration 20. As far as iteration 40 $W_2$ continues to progress from right to left, but at iteration 55, sharp spikes begin to develop in $W_2$ and $W_3$. This seems to suggest overspecification at the corners, but as far as we know, this is not the problem. Shortly afterwards the program crashes. The relevant portion of the program for the boundary condition implementation is included.

ITERATION NUMBER = 5
ITERATION NUMBER = 20
ITERATION NUMBER = 25
ITERATION NUMBER = 30
ITERATION NUMBER = 40
ITERATION NUMBER = 4.0

% ERROR IN W3
ITERATION NUMBER = 55
ITERATION NUMBER = 55
ITERATION NUMBER = 65
Finally, we attempted to run periodic characteristic B.C.s on a one-dimensional basis. We felt that since the problem manifested itself at the corners, if we removed the corners the problem should go away. We next show what happened in this situation.

First we see the one-dimensional wave in $W_2$ moving to the right, exiting and reappearing by the iteration 20. However, sharp spikes appear in $W_3$ by this time. $W_2$ appears to behave well until iteration 85, but either reflection or some non-linear instability lies caused $W_3$ to grow catastrophically. Clearly this represents failure of the boundary conditions, even in the one-dimensional case.

Various minor variations were tried, but all produced the same basic phenomena.
Conclusion

Non-reflecting characteristic boundary conditions work well so long as the flow is basically returning to steady state. This was seen in the first series of numerical experiments.

However, at this stage of development they cause strange instabilities which prevent efficient modelling of periodic phenomena. The reasons for this are not understood at the present.
