December 1985

Preface

The purpose of this study was to investigate the use of pseudo-color to enhance laser radar data for display to humans. Additional points of concern were the relevancy of synthetic laser radar data with respect to real data, and the benefits of designing a laser radar display format based on synthetic data alone.

My previous assignment at the Air Force Armament Laboratory was my introduction to active IR systems. I would like to thank Mr. Mack Gay, and Lt Col Larry Ankeney for all their help and assistance in "showing me the ropes".

During this thesis effort, I received great support from the Avionics Laboratory AAAT-3 Branch, and a special thanks to them, especially Lt Paul Blase. I also owe Capt Jim Riggins and Lt Mike Lankford a word of thanks for getting the laser radar data on time, and Mr. Dennis Garbo for being my "Vax expert on the phone".

Back here at AFIT, I would like to thank my thesis committee - Dr Kabrisky, Capt King, and Dr Lamont for all their help and assistance. Finally, I want to thank my wife Patricia for all her patience, and her help with the photographic work on this project. Keep the aspidistra flying.

Abstract

A pseudo-color representation of CO_2 laser radar data is developed. The pseudo-color scheme is based on the dilution of a set of baseline hues by white. The synthetic generation of laser radar scenes is used for display creation, and the results of analysis on synthetic scenes is applied to data collected by a CO_2 pulsed ladar system.

Chapter 1

1.1. General

The display of information to humans is a difficult task in the sense that few of the human processes that are involved are well understood. Modern combat aircraft systems present a large volume of information to the pilot. This is because of a number of reasons, not the least of which is the complexity of the weapon systems such aircraft are carrying, and are planned to carry. It is a cycle of increased cost, increased performance and increased complexity necessary to accomplish increasingly complex missions. Current technology is headed towards autonomous weapons which engage the enemy after launch from manned aircraft systems.

1.2. Background

In the interim before the arrival of totally autonomous systems, there will be the continued extension of the pilot's senses to the battlefield. Man-in-the-loop systems such as the GBU-15 and the laser guided bomb enable the weapon system operator to guide the weapon to the target while remaining in less hostile airspace. Until the arrival of totally autonomous systems, it is likely that such systems will continue to proliferate. Fecent advances in sensor technology have resulted in the development of infra-red laser radar(ladar) systems capable of producing high resolution range and angle measurements. The added dimension

of range may provide many capabilities to weapon systems carrying such sensors. Problems arise, however ,when these data are displayed to humans. This thesis attempts to deal with a number of these problems.

1.3. Objectives

This thesis has three objectives:

1) Verification of synthetic infra-red radar data for use in training humans and algorithms.

2 Design of a display format for representing the full dynamic range of 16 bit range imagery.

3) Investigate the advantages or possible benefit of color coding infra-red radar data.

Two common items in each of the objectives are the infra-red radar data, and the human visual system. The approach taken is the evaluation of real ladar data as compared to synthetic data created to mimic the real data in target signature only. By comparing the real data with the synthetic data, the data verification can be done before various target aspects and range parameters can be created synthetically in order to understand the problems involved with color coding range data. Any expected results can then be tested by color coding the real data.

1.4. Scope

This investigation contains:

1) An introduction of the human visual system in order to show the complexity of displaying information to humans.

2) A description of CO_2 ladar systems that illustrates the creation of data by such sensors. This will be

2

contrasted with the data that the human visual system usually collects.

3) The description of a simulation that creates ladar data, and a comparison between synthetic target signatures, and real ladar target signatures.

4) Analysis of geometry changes in data collection, and the effects that such changes have on various display schemes investigated.

5) Color coding of real data based on the analysis and color scheme developed by manipulating the synthetic data on an image processing system.

1.5. Summary

The basic conclusion of this thesis is that synthetic data may be used in place of real target signature data for training purposes, and color coding of the real or synthetic can be at least as acceptable as gray scale, and will be improved with further investigations.

Chapter 2
Human Visual System

The human visual system (**HVS**) is the pathway for an estimated 75% of the information that humans receive about the environment. Among the complexities of human vision is the overlap of various subsystems, which are not usually noticed by the individual. Vision in humans is actually a product of two visual fields. One field measures changes in brightness, while the other measures the average brightness. The effects of these two separate fields are rarely noticed by individuals because of the scanning behavior of the visual system. This chapter will present a brief description of the human visual system, and the rationale behind the utility of encoding sensor range data as color. It will be seen that color is a multi-dimensioned space that the HVS can quickly and randomly sample with sensitivity.

2.1. Eye as Camera Model

The eye as camera model is useful in understanding the optics of the eye; the parts of the eye have camera equivalents. The eye has all the essential components of any camera, a body, a lens, an aperture, and a recording or light sensitive system. The lens is made primarily of water and protein. The interface between the environment and the eye is the cornea. The cornea might be viewed as a lens cover of sorts, but it actually provides most of the

4

refractive power of the eye.
Fig. 2-1: Anatomy of the Human Eye(8:24)

The lens is a variable focus device. It can be flattened or curved to enable focusing of the image on the retina, or "film" of the eye. Between the lens and the cornea is the ciliary body. The ciliary body is where the cornea, and the sclera ,which is the outermost opaque layer of the eye, meet. In front of the ciliary body is the variable aperture or iris of the eye. The iris, by varying in diameter, can adjust light intensity on the retina. The iris can typically vary in diameter from 2 to 8 mm, this increases the dynamic range of the visual system by 24 dB. This is possible by the ability of the iris to constrict or relax according to the ambient light intensity. This adjustment is accomplished by a neural reflex.

2.2. Retina

The film of the eye is the retina, and it has the highest metabolic rate of any tissue in the human body. The

5

high metabolic rate is necessary to sustain many complex photochemical and biochemical processes that occur on the retina itself. This activity occurs in photoreceptors. The photoreceptors are commonly separated into two classes, rods and cones. The rods are 2 to 5 microns at the peripheral areas of the retina, while the cones are anywhere from 5 to 8 microns in diameter. In the fovea, or center of the retina, the cones are smaller than they are at the periphery and are about 1.5 microns in diameter.
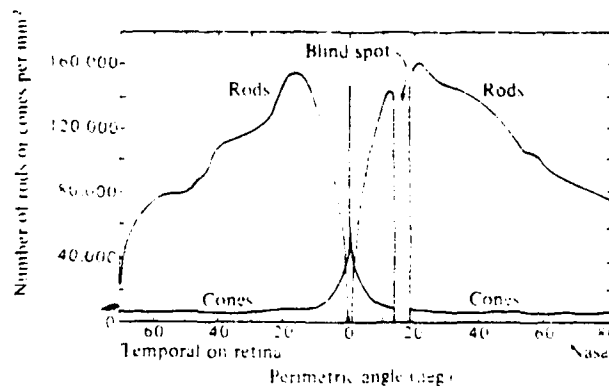

Fig. 2-2: Retinal Distribution of Rods and Cones(6:168)

Rods have the photochemical rhodopsin as their primary light sensitive material. Cones use a similar substance with a different protein structure that enables the cones to be sensitive to various frequencies of light in the visible band. The distribution of rods and cones in various regions of the retina is not uniform. The distribution varies drastically from the fovea, where the concentration of cones is high, and rods is extremely low, to the periphery where

6

the rods are more concentrated than cones. This non-uniformity in distribution of the respective photoreceptors should lead to a non-uniform response to color, depending on the area of the retina that the colored image falls upon. This is the case as colors are perceived as being somewhat different when placed in areas that cause the focus to vary over the retina(3:63). In everyday situations, this is rarely noticed by individuals, as they can simply orient their eyes and head in such a manner to insure that the image is centered on the foveal region of the retina. As the chart indicates, the field of regard of high resolution vision, as well as high resolution color, is quite small.

2.3. Spatial Sampling

Humans are able to compensate for the rather limited high resolution field of regard by scanning the high resolution region of the retina over the field of regard. Such movements of the eye are called saccadic movements. Saccadic movements are the result of several sophisticated reflex mechanisms that control the eye as it is scanned across the visual field of regard. One such reflex that is principally unnoticed is the suppression of information during scanning or movement of the eyes during a saccadic trajectory. This helps to stabilize the perceived image; it is done at a level in the HVS above the retinal level. The brain thus insures that the perceptual outside world is stabilized in matching its reality, and does not appear as a

blur, despite the movement of the retinal image.

2.4. Spectral Response

The visible band of light is named primarily due to the response of the photochemicals in the human visual system. The band is considered to lie between wavelengths of 350 nm and 780 nm. As mentioned earlier, the response of the rods and cones are different. The rods are responsible for scotopic vision. This is essentially, monochromatic or gray scale vision. Lower levels of ambient light are necessary to trigger signals from the rods, as compared to the response of the cones. This is the reason that low light, or night vision in humans is monochromatic. Night vision occurs when the light intensity for color or photopic vision is below the noise level for the photochemical processes that produce the sensations of color. The sensitivity to light of the rods is greater than that of the cones. The retina 'tself is capable of adjusting the sensitivity of the photoch.emical processes that occur on it. This adjustment has a longer time constant than the reflex which opens or closes the iris. The photochemical adjustment to light intensity has a dynamic range of 10^{100} (6:26). The primary means that enables the retina to set its overall sensitivity to light, or the gain of photochemical process is regulation of the concentration of rhodopsin, and the other photochemicals. High luminance in the environment will result in lower photochemical concentration, while low luminance levels

results in higher concentrations of these photochemicals.

Although the various chemical participants in human color vision have been isolated as various forms of rhodopsin in the cones, there are several models of human color vision. The differences in the absorption characteristics of these opsins, as they are called, are presumably the basis for color vision. Figure 2-3 shows the sensitivity of the various "color" receptive photochemicals found in the retina.
Fig. 2-3: Spectral Response of Photoreceptors(10:82)

It must be reiterated that these responses are not consistent across the retina. Even the sensitivities to various wavelengths of light varies as the light is focused on various parts of the retina.

2.5. Helmholtz Theory of Color Vision

The first theory of color vision in humans was proposed by Young and later expanded by Helmholtz. The Helmholtz-Young theory of color vision states that there are three

9

types of cones. Each cone is sensitive to light corresponding to the colors of red, green, and blue. The integration of these signals then results in a perceived color. The spectral responsivities of the three different types of cones have been measured(6:350). Models of color vision differ in the area of retinal-brain fusion of the various signals produced by the "color sensitive" photochemicals. The basis of the most workable theory of color vision is the three color theory. This is based on the fact that individuals with normal color vision can match any color presented to them with at least three colors. The three colors,or primaries used, have to differ in spectral characteristics, but the characteristics do not necessarily have to be separation of frequency content between the three colors used as primaries. The spectral distributions of the primaries have to vary. The primaries do not have to be pure tones, in fact the spectral content of the primaries can even overlap(12:327). Using appropriately different primaries, individuals can match any color by additively varying the amount of each primary added to the color patch in such a way as to produce a viewable copy of the target color. The net response of such a color matching scheme can be tested over a wide range of different target colors, and sizes of target colors. Difficulties arise when using color matching instruments that cover more than 4% of the visual field(3:61-64). In this circumstance, the three color theory

10

of color vision does have some problems. The problems may have basis in the differences in distributions of rods and cones in individuals. Von Kries has proposed that the tri-color theory is valid at the photoreceptor level only(7:32).

Several experiments have revealed that at least some fusion of the information must occur. If a red filter is placed over one eye, and a green filter over the other, most objects in the visual field will appear yellow. Clearly, the retinal sensations alone cannot explain the effect. Color models vary greatly with regard to how mucn fusion occurs between the retina and brain. Retinal level processes can be viewed as low level, and brain level processes can be regarded as high level.

2.6. Dimensions of the HVS

The HVS is capable of resolving the world in four dimensions:

1) Motion (Time varying intensity)

2) Background Intensity (Average intensity)

3) Color (Photopic vision)

4) Luminance (Scotopic vision)

Presentation of information to humans may involve one or any number of these dimensions. Practical limitations occur in displaying information only as motion (such as a blinking light or alpha-numeric display), background intensity, and luminance or gray scale. The HVS is limited in the number of

11

simultaneous gray shades it can differentiate. This is due largely to the mechanisms that increase the dynamic range of the amount of luminance intensity that the eye responds to. If the dark-light adaptation mechanism of the retina is viewed as an automatic gain control circuit, the available dynamic range at any time is limited unless the gain control is reset. This mechanism drastically limits the number of gray scales that the HVS can discriminate at any particular AGC setting. The HVS performs as a contrast limited system with respect to gray scale detection and discrimination. The color domain, however, is much more flexible as long as there exists enough ambient light to enable the HVS to view the world photopically.

2.7. Colorimetry

Colorimetry is the science of measuring color, and defining colors scientifically. Truly color blind, or monochromat, individuals make up less than .0033% of the population(12:335). For a true monochromat, the world is a series of darkness and brightness, and nothing which could even be construed as variation among objects of the same brightness. For trichromats, the world presents a different set of data entirely. Light is able to acquire particular qualities other than merely brightness, or darkness, and varying degrees between. These qualities, to be measured and explained, have been enumerated through color science. The

12

essential problem is that measurable physical differences such as luminance and frequency of the light, do not often lead to complete characterizations of the psycho-physical effect that the viewed light has on humans. There exist a number of measurements in color science that are purely physical and there are also such measurements that are purely psycho-physical. Confusion often arises when the essential physical and psycho-physical definitions of terms and measurements are confused. An additional complication is the simple fact that humans tend to believe all what their eyes present to them.

The Committee on Colorimetry of the Optical Society of America has defined color: "Color consists of the characteristics of light other than spatial and temporal inhomogeneities." (4)

2.8. Color Measurement Principles

2.8.1. Subtractive Systems

Confusion usually occurs when describing color systems because there are several ways of characterizing a color. The approaches are those of additive and subtractive systems. Those who are painters are probably at least familiar with the problem of mixing paints to arrive at new colors on the palette; this is a subtractive color system. Simply stated, the white piece of paper that the painter is working with reflects all (or most) of the white light

13

source in the room, from the paper to the eyes of the painter. Now, the purpose of the paint pigment is to remove some section of the white light source, and reflect the rest of the white-filtered light. Yellow paint removes blue from the white light and leaves green and red parts of the spectrum unaffected. The net appearance to the painter is "yellow". It is clear from the onset that the original source of the "white light", in this case probably some form of incandescent light if the painter was indoors, has significant effect on the color balance of the painted scene. The HVS has the ability to normalize the color content towards an acceptable white. This is quite noticeable during the day when lamps in the house appear more yellow or green with respect to the sunlight outdoors. The brain accommodates such shifts in white in an attempt to make objects appear the same color when viewed under different sources of white light.

2.8.2. Additive Systems

Television displays use the principle of additive color. This differs from subtractive color in one essential way. The electron beam of the CRT on the television cannot deposit the equivalent of a paint-like substance which then subtracts a selected portion of the spectrum from the ambient white light source in the room. This is not physically possible. It is possible, however, for the

14

electron beam to deposit energy in such a manner as to excite a phosphor which emits light energy of a particular spectral distribution. Then, if three differing phosphors can be found, the tri-color theory can be applied and the three spectral distributions can be combined to form colors. Red, green, and blue are the usual primary colors for additive colorimetry. The addition of red and green light fluxes in suitable proportions to produce a new color-"yellow".

Since the coloring schemes investigated in this thesis are concerned with television display of information which is color coded, it is worthwhile to expand on the additive system as well as some standard color representation systems, and nomenclatures for describing colors if physical, and not psycho-physical terms.

Light can be measured as electromagnetic radiation, for that is the exact nature of the phenomenon. The chart on the following page illustrates the differences between radiometric or physical attributes of light and photometric or psycho-physical attributes of light that is viewed by a standard human observer.

15

Radiometric and photometric units*

Radiometry (Physical units)			Photometry (Psychophysical units)		
Symbol	Definition	SI unit	Symbol	Definition	SI unit
Q	Radiant energy	joule	Q	Luminous energy	lumen second (talbot)
w	Radiant density	joules per cubic meter	w	Luminous density	lumen seconds per cubic meter (talbot m³)
P	Radiant flux or power	watt	P	Luminous flux or power	lumen
M	Radiant emittance	watts per square meter	M	Luminous emittance	lumens per square meter (lux)
E	Irradiance	watts per square meter	E	Illuminance	lumens per square meter (lux)
I	Radiant intensity	watts per steradian	I	Luminous intensity	candela (lumens per steradian)
N	Radiance	watts per steradian and square meter	B	Luminance	lumens per steradian and square meter (nit)
$\rho(\lambda)$	Spectral reflectance		$r(\lambda)$	Luminous reflectance	
$\tau(\lambda)$	Spectral transmittance		$t(\lambda)$	Luminous transmittance	
$\alpha(\lambda)$	Spectral absorptance		$a(\lambda)$	Luminous absorptance	

*Ratio of photometric quantity to corresponding radiometric quantity (standard units) is luminosity or luminous efficiency K (l/W) or special luminous efficacy $K(\lambda)$ (l/W). Luminous efficiency is the ratio of the spectral luminous efficacy to its maximum value and thus is a numerical quantity.

Fig. 2-4: Radiometric and Photometric Units(8:13)

2.9. Standard Observer

The standard observer is an international standard under the CIE or Commission Internationale de l'Eclairge (International Commission on Illumination). The original basis for all photometric measurements was the candle, since it was the only form of illumination at the time that photometric standards were originated. After the establishment of psycho-physically based photometric standards, the metric system established several measurements concerning electromagnetic energy. These standards comprise the physical or radiometric units of the charts. The comparisons and conversions between the two systems can be quite easily done, as the processes , such as energy from a candle (radiant energy) has been measured and the conversion between the two systems is thus possible. It

16

is necessary to understand the distinction and use of both the radiometric and photometric systems, as color standards are usually expressed in photometric units.

2.10. CIE Color Standard

The CIE sought to establish a two-dimensional color standard that was accurate enough to specify any color with particular accuracies. This was essentially done by establishing a chromaticity diagram, on which any set of primaries could be plotted and then aligned to any reference white. The addition of the flexibilty of aligning to any reference white was necessary if the viewing conditions of the particular color was to be properly considered. Chromaticity is defined as being the color quality of the stimulus. The main difficulty in establishing such a chromaticity diagram is the definition of saturated colors. The difficulty is inherent in the nature of the relationship between primaries and their complements. The complement of every primary color is a combination of the other two remaining primaries, by definition. Then all three primary colors are actually half complements of each other. Any additive mixture of the primaries will then have an unsaturated effect. Here unsaturated is related to the amount of energy that corresponds to a single frequency in the electromagnetic spectrum. If pure laser light is used to produce the psycho-physical color, cross-talk between the cones causes the laser generated primary to appear

17

unsaturated. The problem is due to the response of the photo-receptors themselves. The CIE then extrapolated the existence of all saturated colors to lie on the locus as shown in figure 2-5 around three primaries, say red, green and blue. In order to contain all possible colors, the existence of super primaries was postulated, and X, Y, and Z were placed around the locus of saturated colors.
Fig. 2-5: Derivation of CIE Chromaticity Chart

This postulation was based on data collected by various groups concerning the color matching by human subjects on test colors that were made of large amounts of primaries in various combinations. It was found that all colors tested could be diluted by adding one or more primaries to the test

18

sample and that the test sample could then be compared with great accuracy to the standard colors they tested against. Hence the hypothesis of super-saturated colors would enable any color to be described. The triangle of the super-saturated colors would then encompass all physically realizable colors. In the final preparation of the chromaticity diagram, it was decided that the spectral energy distribution of the Y component primary should match the luminosity function curve. The luminosity function curve is essentially the response of the HVS to green light. It was then decided to place the X and Z primaries lie on a hypothetical line called the alychne. The alychne is a line of theoretical limits. It is the line where the subtractive color-matching process is exhausted, the line where the colors have zero luminance. The combined effect of all this manipulation was a diagram that not only tabulates the total chromaticity of a color, but also its luminance.

The use of CIE system is useful in explaining color content. For this thesis it is easier to specify the color content by specification of red, green and blue components. This, by itself cannot specify the total effect unless the monitor characteristics are aligned, and the brightness control adjusted or somehow calibrated. CIE specification can be found given RGB values, and assumed constant luminance.

19

Chapter 3

Active Infra-Red Systems

Much current work in the Department of Defense(DOD) concerns the computer generation of imagery. Computer generation of imagery is quite often less expensive than collection by a real sensor. In many instances the actual imagery of the sensor or candidate sensor is simulated by computer program before the actual sensor is operational. The flexibility of such computer generated imagery is often a major factor contributing to the development of a "sensor simulation" capable of producing two dimensional data that have the proper characteristics with respect to the sensor being simulated.

Very often, sensor simulations begin with " first principles" models, or, the basic physics or mathematical model which dictates sensor function. In short, if the sensor is acquiring visible light data, then a first principles model would somehow involve an illumination model as well as a reflectivity model. The sensor model would then proceed to more refined physical models of the interaction of the received light energy with the receiving transducer.

3.1. Applications of Imaging Sensors

Imaging sensors in the DOD have a wide range of applications. Data collected by imaging sensors are used in reconnaissance, strike planning, and even terminal guidance

applications to name just a few applications. Any particular mission usually requires digital processing of the information after collection by the sensor, and the ability to predict the content of the signal collected by the sensor with respect to the anticipated sensor performance is crucial in the development of algorithms that further process the information after collection. Thus a sensor simulation of some sort is usually necessary in order to develop applications software that enable the sensor system (sensor plus associated digital hardware) to perform its desired function.

3.2. Types of Sensors

Many DOD imaging systems collect infra-red imagery. The bulk of the infra-red imaging systems in the inventory or in development within the DOD are passive sensors. Passive sensors measure the irradiance of the source, as well as reflectivity of other infra-red sources that may be illuminating objects that are in the field of regard of the sensor. Autonomous target recognition systems using current technology are usually passive infra-red systems. The only exceptions are those involving MMW(millimeter-wave), which is not infra-red, and active laser ranging systems (ladar). There are several inherent difficulties in using information provided by a passive infra-red sensor for automatic target recognition. By a first principles account, the environmental factors that

21

affect the signal stationarity are complex and variable according to seasonal, diurnal and target initial conditions. Target initial conditions refers to the state of the vehicle previous to collection of passive infra-red imagery on the target. These variables have to be normalized if target recognition of that vehicle is to be done. For these reasons alone, it is exceedingly difficult to predict the signature of a vehicle in the passive infra-red bands. Several DOD programs have attempted to model the physics of infra-red scene generation, as well as a sensors performance based on the mathematical prediction of the simulation.

3.3. Disadvantages of Passive Infra-Red

Part of the difficulty in locating targets with a passive IR sensor autonomously is the complexity of the data set provided by such sensors. An actual infra-red sensor image of a non-moving target is constantly changing with such variables as sun angle between target and sensor, cloud cover between sun and target and atmospheric conditions between target and sensor. Consequently, any algorithm dedicated to finding targets in any realistic scenario has to compensate for the intrinsic variability of the sensor data. This is typically done by training the algorithm against any number of expected situations that may be encountered by the sensor-algorithm system. Due the extreme variability of passive IR scenes, the number of circumstances that an algorithm may have to be trained

22

against is enormous. In order to increase performance more sensor data must be collected , and the algorithms must be re-trained against the newly acquired data. By the time the process is complete, the performance of the sensor can be viewed as a mere characterization of the data-set generated by the sensor. This makes accurate predictions of the actual target signature generated by the vehicle difficult.

3.4. Active Infra-Red Sensor Development

The difficulties involved with working with passive IR data and more restrictive guidance requirements have caused several DOD agencies to investigate alternative sensor technologies. One such technology is active infra-red imaging. An active infra-red sensor is a sensor with a carrier frequency in the infra-red band. In short, an active IR sensor can be a radar or a radiometer. Early active laser systems merely measured the intensity of the reflected laser light returned to the sensor. More recent systems provide very high resolution range data spatially ordered in two angles, azimuth and elevation, on the sensed scene. Current ladar sensors have the angular resolution of passive infra-red sensors with range accuracies less than a meter. Such a sensor might have provide a data set capable of supporting many of the requirements of future autonomous attack vehicles.

Specifically, one such sensor under consideration for

23

future applications is the CO_2 laser radar. With advances in wave-guide lasers, it is possible to package compact high power, efficient sources at wavelengths of 10.6 microns. The wavelength corresponding to the P0 line of CO_2 is 10.6 microns, and this corresponds to an atmospheric window. Figure(3-1) shows the transmissivity through the atmosphere in the 8 to 12 micron band.
Fig. 3-1: Transmission of 8-12 micron band(16:5-90)

A CO_2 system will have adequate weather capability, and due to the fact that it will be a narrowbeam sensor, it will be a low probability of intercept system. Figure 3-2 (next page) illustrates a conceptual heterodyne CO_2 ladar system. The heterodyne system may be modulated in time or frequency. The principal difference between the continuous wave modulation format and the pulsed modulation format is the necessity of the pulsed system to have a separate local oscillator.

24
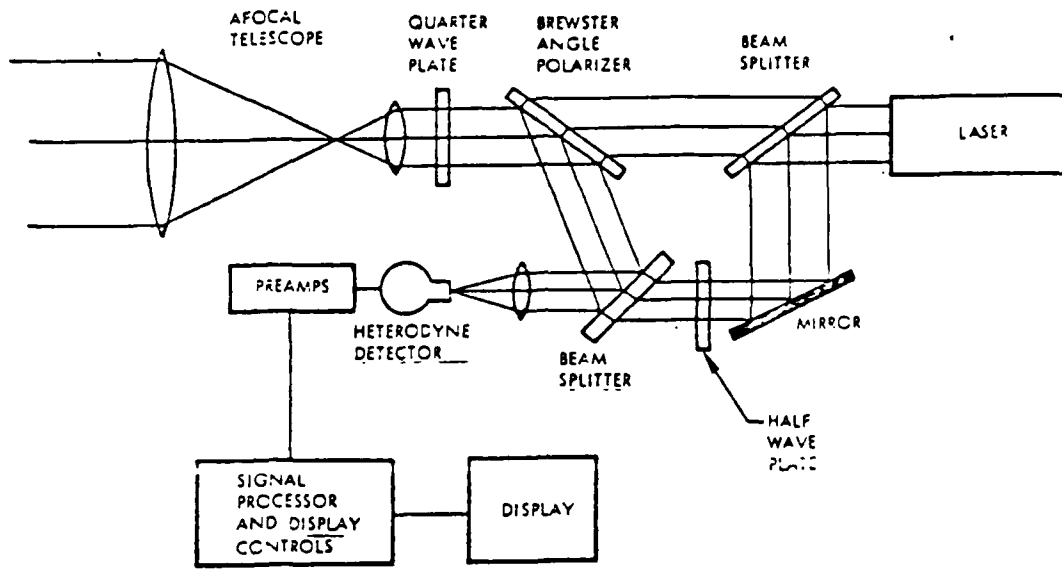

Fig. 3-2: Conceptual Heterodyne CO_2 Laser Radar(9)

3.5. Laser Radar Function

The laser energy is generated in the CO_2 waveguide laser. In a CW system the beam then leaves the laser cavity and proceeds through an optical beam splitter where the beam is split to form the local oscillator and the transmitted signal. The local oscillator beam then proceeds through a half wave plate. The half wave plate polarizes the light in such a manner to properly combine with the signal reflected

25

from the target. After the beam splitter, the transmitter beam proceeds through a quarter wave plate, and out the lens system to the far field . After reflection from the target, the returned signal is collected by the telescope, and due to the polarization change of reflection, is deflected by the Brewster angle polarizer, and sent to optically mix with the local oscillator on the detector. In current CO_2 systems, the detector used is a high bandwidth mercury-cadmium-telluride (HgCdTe) detector. Typical electrical bandwidth at the detector is on the order of 3-4 Ghz. It must be pointed out that the heterodyning of the returned signal and the local oscillator occurs physically at the detector. This improves the performance, and allows operation of the sensor to perform in a shot-noise limited capacity. The background noise of the environment at 10.6 microns does not limit sensor performance as the energy in band will not be in phase with the signal transmitted from the sensor. The heterodyne implementation also allows the usage of a lower powered transmitter for a particular probability of false alarm versus an incoherent system. (Similar to an RF radar system.) For pulse systems the path through the optics is identical with the exception of the beamsplitter that is placed at the exit of the laser cavity. Because the laser is not transmitting continuously during the time of flight of the pulse of laser light, it is necessary for a pulse system to have a separate local

26

oscillator in order to operate as a heterodyne system. Pulse systems also operate at the shot noise limit of the photovoltaic detector. Currently in the DOD, pulsed and CW ladar systems are being developed; each modulation format has its separate advantages depending on the particular application. Clearly, such an optical system as the conceptual design in Figure 3-2, will have significantly better spatial resolution than any RF system. Figure 3-3 illustrates the advantages of an active IR ranging system with 10 cm optics versus a MMW RF sensor with a 30 cm antenna at a range of 1500 meters. This high fidelity data will provide a geometric data set to the processors, as opposed to radiometric data that a passive IR system collects. Because the data collected by a ladar is geometric, target features can be based on the physical attributes of the target with respect to target geometry, and not on irradiance and emissivity of the target. No thermal model is necessary to properly model a target for an active ranging system simulation. A ladar produces data by calculating the time of flight of a pulse of laser energy, or by measuring a frequency offset between the returned signal and the local oscillator. This function is not unique to a ladar system. The resolution of the data as Figure 3-3 illustrated is finer than any RF system other than, perhaps, a synthetic aperture radar (SAR).

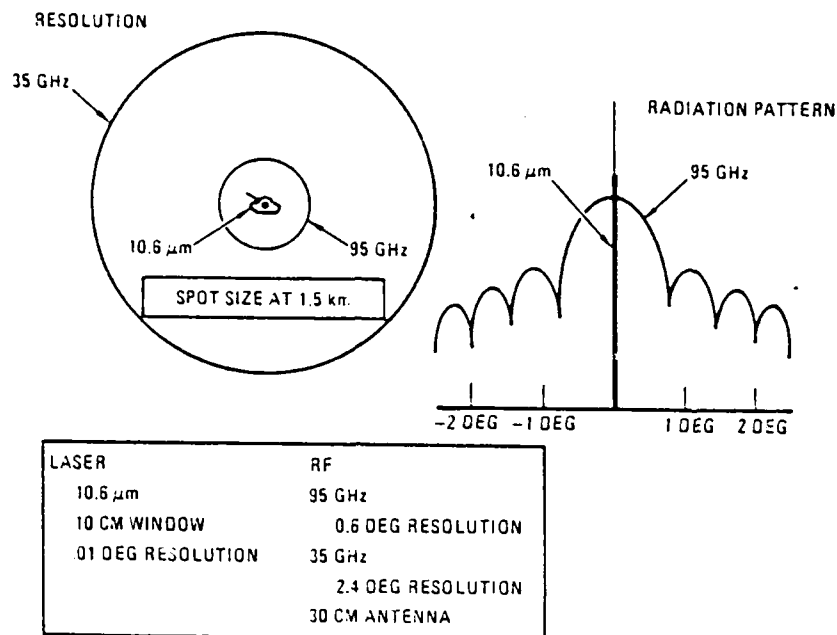

Fig. 3-3: Comparison of Ladar and MMW Spatial Resolution

The information provided by a ladar sensor is spatially arranged with respect to the environment . The sensor may scan the field of regard in any pattern that other optical sensors are capable of scanning. The two most common types of scanning are raster and line scanning. A raster scan covers two angles, azimuth and elevation, whereas a line scanner only scans in azimuth. The diagram on the following page illustrates both raster and line scanning patterns.

28

Raster Framing Scanning Geometry
Push Broom Scanning Geometry
Fig. 3-4: Raster and Line Scanning Geometries

The line scanning sensor would usually rely on the down track motion of the vehicle it is on to provide data as the vehicle moves. The line scanner then sweeps across the field of regard like someone pushing a broom, and hence the term "push-broom" line scanner is also used. Line scanners have an advantage over a raster framing sensor with respect to moving parts. Since the vehicular down track motion enables sampling down track, no motors or galvanometers are needed to scan the sensor in the downtrack direction. The following diagram illustrates the differences in the two scans.

As the sensor scans the field of regard, it is collecting data. Usually, in the case of electro-optic sensors, the position of the scan within the field of regard is time synchronized with information on the sensed instantaneous field of view. This information allows for the proper placement of the data. In an imaging system, this means that the spatial arrangement of the data is possible. In an active laser system the laser is modulated in time or frequency as the field of regard is being scanned.

3.6. Modulation Formats of Ladar Systems

Modulation formats of an active laser ranging system are as versatile and diverse as any RF radar. In fact, ladar systems under development employ many standard radar waveforms, as well as standard radar electronic circuitry and techniques to decode the waveform after heterodyning. The traditional radar parameters of interest, such as

30

antenna size, wavelength of the transmitter, bandwidth of the receiver transmitter, as well as power are all applicable to ladar systems. The high spatial resolution of ladar systems allows for meaningful geometric interpretation of the laser range data. This is not always the case for range data gathered by RF radars.

Even though an RF system is collecting range information, it is usually coarse in either range or angle. In fact, most RF radars trade off range resolution for angular resolution. The trade-off between angular resolution and range resolution occurs in RF systems because the target is usually smaller than the beamwidth. As long as the target is inside the beamwidth of the radar, range resolution and angular resolution can be traded off with one another. In narrowbeam sensors such as a CO_2 laser radar, the spot size of the sensor is small enough to insure that several resolution elements or samples of the target will be scanned. In this circumstance, the target is larger than several beamwidths of the sensor, and angular resolution, and range resolution are separate parameters. Applications that require several pixels across the minimum dimension of the target can be achieved as in any radar system. The issue in most ladar designs is the determination of exactly how many pixels are required to do the task. Target recognition requires finer spatial resolution than target detection does, and system requirements ultimately trace back to such

31

basic sensor parameters as the size of the optics, scan rates, and pointing accuracies to name a few. A laser radar system does not have to make the same system trades as it is a narrowbeam sensor and sidelobes are considerably narrower than on RF systems. The physics of the collection process of the antenna or optics of a laser radar system enables the data to be represented as a 2 dimensional surface mapping of the range to each point sampled in the scene. with the exception of a SAR system, RF radar data cannot easily and accurately be modeled this way.

3.7. Three Dimensional Nature of Ladar Data

Because of the nature of the two-dimensional surface mapping of the environment that a ladar is capable of producing, the ladar data is said to have a 3-D quality: often it is spoken as "3-D ladar". The fact thatan image collected by a ladar can be presented to a human viewer via a CRT, and the data appears as a low resolution television scene contributes to the usage of the term "3-D" with the term ladar. By properly interpreting the intensity of the two dimensional array as an encoded value of the range from the sensor to the particular ordered two dimensional point, the data may be viewed as have a three dimensional effect. Much can be learned of the sensed scene by looking at the laser data collected on the particular scene. Objects at the same range will appear as the same intensity, while those at other ranges will appear as different intensities, hues,

32

or whatever else is allowed to vary according to the viewing scheme, which is implemented.

3.8. Ladar Data and Modelling Simplicity

The important aspect of ladar imagery is that the first principles model dictating a target signature can be easily, and quite accurately extrapolated before any data are ever collected on that particular target. All that has to be known is the shape of the target, and its size. Since the ladar data are essentially two dimensional surface maps of the scene, it is relatively easy to construct the mapping of a known target.

In actuality, the first principles model of the ladar simulation is simpler than any similar model for a thermal imager. Noise models for a ladar receiver are more difficult than the purely geometric aspects of the sensor function.

Current work in robotics has a particular emphasis in the use of range data by robots to manipulate parts, inspect parts, or to simply identify parts. Many studies in this area have considered the problem of stereoscopically derived range images. In addition, work in this area has contributed to the computer representation of 3-d objects. Most of this work has dealt with the problem of simulating a particular scene as it would appear to a machine that viewed it with two separated cameras that operate passively in the

33

infra-red or visible bands.

There are many schemes that represent the data as a
collection of surfaces in three space. Depending on the
nomenclature, some schemes represent complete surfaces,
while others merely represent the boundaries of surfaces,
and assume a standard or set of surfaces that are between
each of the boundaries or edges. All schemes usually require
a large amount of data depending on the complexity of the
solid object represented.

Synthetic laser radar images can be easily
simulated with any set of data that represents a solid
object or a two dimensional surface of some sort. For
robotics applications, the generation of a synthetic
television scene is a difficult task with respect to
generating a synthetic laser radar scene. It is more
complicated to calculate the illuminance of an object with
respect to a source(or simulated source of light energy)
than it is to calculate the intersection of a line with a
surface of the object.

The benefit of using synthetic data for algorithm
training as opposed to real data collected by a sensor is a
complex issue. Arguments over the benefit of synthetic
training data are numerous. There is no argument with regard
to the simplicity of using computer generated imagery
provided the imagery generated is somewhat similar to data
that the real sensor would collect in the field. In any

34

final application the most meaningful test of a sensor with hardware for making decisions on the data is obtained with the sensor system operating on real data collected in an environment as similar as possible to the operational environment of the system.

Current work in the development of CO_2 ladar and the applications of that technology has relied primarily on the assumption that simulated ladar imagery is simple to create and that data produced by any of the numerous simulations are somewhat similar to the data that an active IR system would collect. The significant tests of the sensors that measure the angular and range separation of two dimensional objects such as flame sprayed aluminum plates have been conducted. For this investigation seeking the proper display format of ladar data for human viewing, most of the representation schemes investigated will use computer generated range , azimuth, elevation data. The next chapter will provide a verification that the usage of the synthetic data and the technique used to develop the imagery is valid for the first principles model of laser radar theory and function.

Chapter 4
Laser Radar Simulation

For the purposes of evaluating ladar display schemes for the display to humans the use of a synthetically generated range, angle, angle for display scheme was decided upon. The most important consideration for using synthetic data is simplicity of creation as well as cost. In addition the target and sampling parameters sought in the investigation of the various display formats, were readily obtainable by simulation.

The simulation used was developed at Eglin AFB in support of the Backbreaker/Optionbreaker Program. Full details of the simulation and proper documentation are available (15). For this effort, the simulation had to be rehosted on a Vax 11-780 computer. Access to a machine identical to the original host (CDC-Cyber) was limited. After rehosting, the simulation created several test scenes in order to verify that the software was performing properly. The test scenes were kept until they could be inspected on an image display system.

4.1. Synthetic Scene Simulation Routine

The scene generator creates synthetic laser radar imagery based on solution of a line-plane intersection. The target files were derived from an Army-Air Force munitions targets modelling standard. This enabled the creation of

36

metric range, angle, angle information on real targets. The target set includes many terrestial and airborne Soviet and Warsaw Pact vehicles, as well as some vehicles from NATO countries. The targets are described by a set of triangular facets that cover the surface of the target vehicle. The data on particular vehicles(e.g. T-72 tank) are derived by stereoscopic photographs of an actual vehicle. Facets are then laid out on the vehicle surface by a semi-automated process. Target file preparation is a labor intensive operation, so the compatability of the simulation with a rich data base was the deciding factor in using the triangular facet format in the simulation.

The simulation is capable of generating any resolution spatially and any range and apparent target aspect. This is done primarily by treating the coordinate system of the target in a relative manner with respect to the "scanner geometry". The "scanner geometry is actually the reference image plane. All perspective transformations are done with respect to what a sensor would collect given a set of sampling parameters in two angles(azimuth,and elevation) and an along boresight or line-of sight to the target. This is a spherical coordinate system. The target facet information is then oriented with respect to the required viewing angles and ranges to the target with respect to the sensor's spherical coordinate system.

Such a simulation is rather straight forward. The

complexities arise when the extent of the target files is considered. A typical number of triangular facets on a Shotgen target file is on the order of 20,000. This makes the creation of a synthetic image on that large a number of facets more difficult. Calculations must be performed in order to limit the number of candidate facets. Not all facets can be viewable at one time, and this simple fact eliminates a large number of candidate facets. The simulation calculates such items before any attempt is made to find the intersection of any line drawn from the sensor to the ground plane.

After the target facets have been oriented and screened with respect to the desired collection parameters, the sensor scans the extent of the target file in its entirety by placing a box around the extent of the target file as projected on the image plane or sensor location. The format of the sampling of the image plane projected target file can be controlled to the extent of scanning the target file as if it had been scanned and sampled by a raster framing scanner, or a linescanner. Both scanning techniques differ from each other in complexity. It requires an equal amount of time to collect data from either format.

4.2. Verification of Synthetic Range Data

The synthetic data used in the investigation of various coloring and display schemes for presenting ladar data to humans was contrasted in several areas with real data

collected from a ladar sensor. Real data were collected on a target fabricated from plywood sheets specifically for the validation of the synthetic scene generator. Plywood was assembled to form four boxes of various dimensions, the boxes were stacked to form a series of 4 steps. The following diagram and schematic illustrates target dimensions.
Fig. 4-1: Plywood Stair Step Model

Previous analyses of the signals returned from imaging ladars have dealt with the single measurement of sensor resolution and accuracy figures of merit. This is usually accomplished by placing plates of relative high reflectivity at 10.6 microns at varying distances along the

Z-axis of the sensor. (the term Z-axis here refers to the distance along the line of sight at the particular angular orientation) Analogously, the spatial resolution of the sensor is measured by placing two calibration plates side by side at the same range and separating them in angle. By using combinations of these two techniques, it is possible to determine all critical performance parameters of the sensor. These parameters include spatial resolution, range resolution, range accuracy, and angular accuracy. What was done for the validation of the simulation, was to compare directly, the data collected by a CO_2 ladar on the stair step target with the data produced by the simulation. The critical issue in determining the relev.nce of modelling laser radar data as range and two angles was the ground truth of the data collected. The data were collected on the stair step target at various ranges and depression angles as well as target orientations.

For the data validation of this project several modifications of the simulation were required. One involved the creation of a synthetic target model identical in metric proportions to the original plywood model, and the other modifications involved rewriting parts of the simulation to accommodate the collection parameters that were specific to the test set up at Eglin Air Force Base.

4.3. Synthetic Plywood Model Generation

Once the drawings of the stair step model and the dimensions of the stair step model were received, this information was coded into the appropriate triangular facet representation. After the model was generated, several test runs were performed on the simulation to insure that the format of the stair step target data was correct. The data created on the target file were subsequently validated at Eglin by a program which plots the projected outlines of the triangular faceted target file at various orientations. Below is the output of the target verification.
"View from X,Y" means X = azimuth, Y = elevation
Fig. 4-2: Computer Drawings of Plywood Stair Step Model

41

After the synthetic model of the stair step model was created and verified for accuracy, the simulation itself had to be modified in order to accommodate the geometry of the test range at Eglin AFB. The driving reason behind modifying the simulation was the tower height at the test range. The tower is 11 meters high. The plywood model was to be placed at distances of 500 meters and 800 meters from the base of the tower. At the 500 meter range the slant range to the target is 500.12 meters and, more importantly, the depression angle along the line of sight to the target is 1.26 degrees. The depression angle from the horizontal is .78 degrees shallower at the 800 meter range. Figure 4-3 shows the collection geometry of the plywood stair step range data.
RANGE GEOMETRY

Fig. 4-3: Range Geometry for Ladar Collection

The depression angles of the collected imagery were closer to the horizontal than the simulation was

originally written to support. The main problem occurred in the generating and scanning of the scene so that the depression angle did not approach the horizontal. As initially written, the software driver for the raster framer would, by default, place the center of the raster frame directly the target origin. In this configuration, the sampling of the synthetic scene is then done by specifying the number of scan lines and pixels desired. Since the dimension of the line which emanates from the simulated sensor is a purely one dimensional entity, the exact location of where the line intersects the target is controlled only by specifying the angular constraints on the particular sample. The line is dithered randomly inside the prescribed cone . This simplifies the calculation of range, and also allows for using relatively simple target files. The random dither within specified constraints of angle allows the usage of large triangles with long edges . The synthetic stair step model has edges between facets that account for , in some instances, 50% of the distance in that dimension of the target file. If a uniform approach to sampling at every angle as determined by the accuracy of the host computer were employed, several pixel dropouts would occur as a result of the projected ray from the simulated sensor striking an edge of two facets. Because the sensor calculates the intersection of a plane with a line, the line which forms the intersection of two planes is treated as a

43

line, which it is. The simulation cannot recognize the edge as belonging to either one of its facets. This becomes further complicated as several facets could, and many often do, intersect in a common point. Due to the random nature of creating the line target facet intercept , it was necessary to insure that no drop out occur on the synthetic data. Special code was written to insure that no pixel dropout occurred on a target pixel. The most accurate data possible was generated for the purposes of comparison with actual CO_2 laser radar data.

The simulation currently models no noise processes specific to a CO_2 system. The only noise that can be added to the collected pixels is random range noise. The simulation can provide Gaussian distributed or Rayleigh distributed noise globally across a simulated frame of data. Severe angular perturbations in the scanning process can be implemented on a pixel by pixel basis. This function was used to correct any "dropout" pixels if they occurred on the target.

4.4. Comparison of Synthetic and Real Data

Evaluating the applicability of using synthetic data in place of real ladar data, was done by directly comparing target signatures generated by the simulation and the real target signatures generated by a CO_2 ladar. Initially, target masks were created by the simulation of the plywood stair step target at the identical geometric parameters that

the real data was collected. The synthetic range data were generated as masks. Mask refers to the fact that only pixels that would occur on the stair step target were created. Normally, the simulation creates data on a flat earth ground plane if a pixel is not found to lie on a target facet. For this evaluation, only target masks were created. These masks are basically a matrix arranged with zeroes in locations that do not correspond to a target pixel location. The target signature, is then placed against a zero background.

For evaluation purposes, the target signature of the plywood stair step model was then extracted from the real scenes collected by a CO_2 ladar system as described in appendix J. The target signature information from the real data was not extracted by use of an image processing system. Instead, it was extracted primarily by range gating the original data. The data as it arrived from the sponsor at Eglin AFB, was not in a form that could immediately be used as range,angle,angle data. The data, as received, came directly from the MULTI-BUS system which controls the laser radar. Figure 4-4 portrays the flow of data from the sponsor to a usable form as range angle, angle data, that can be manipulated as imagery. After an evaluation of a few scenes of real ladar data on an image processing system, it was determined that the data were being properly formatted as range image data.

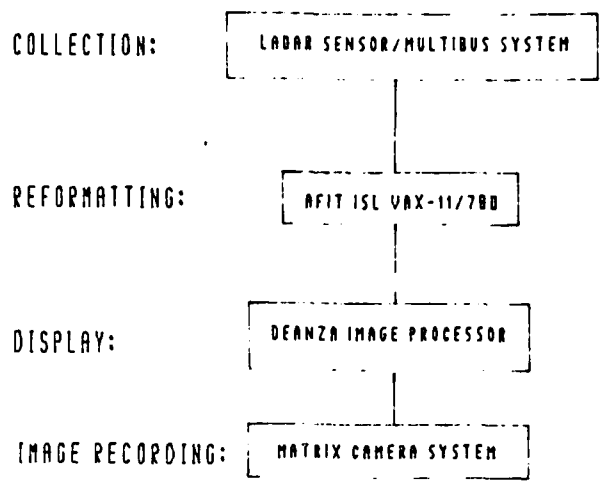

Fig. 4-4: Flow Diagram for Ladar Signal Processing

Target data of the plywood stair step at various locations
were range gated and displayed as a three dimensional plot
on a graphics terminal. These signatures appear on the next
page.

Compare these target signatures: notice the clear.
target mask signature created by the simulation. It can be
seen that the data as modelled by the simulation produce an
accurate simulation of the actual target data as collected
by an actual sensor. The image frames produced by Eglin AFB
are 128 lines by 256 pixels. For the initial comparison of
the data and the mask signatures, the data from the real
sensor were down sampled to produce an evenly sampled image
in elevation and azimuth. Masks were created accordingly:
this was easily implemented as two separate parameters,
namely the azimuthal quantization, and the elevation
quantization in angle of the created masks. On visual
inspection of the three dimensional plots of the two types

46

of data, it is apparent that similarities between the real data and the synthetic data do exist.
Fig. 4-5: Plywood Target Masks
Range 500m, aspect angle 90 deg
Real Data(top) Synthetic Data(bottom)

47

Note that no noise filtering or any processing of the real data collected by the sensor was attempted. The line of range pixels that extend in the azimuthal direction on the three dimensional plots is the ground plane upon which the plywood model is resting. This is easy to understand since the bottom of the target is at the same range as the ground upon which it rests. The remaining pixels to the left and right of the target on the ground plane are merely values of the ground plane that fall in to the selected range gate. Additional spikes that appear in the real data plots can be attributed to noise. The single spikes of range noise would be effectively removed with median filtering of the data. For the purposes of comparing the data generated by the simulation and real sensor data, it was more appropriate to use the data as they were collected with noise and any other distortion that might be present.

Chapter 5

Display of Range Imagery to Humans

The ability of humans to ascertain range to an object or area within their visual field is a complex learned task. The estimation of range is a complex computation on the environment. Because this information is valuable in everyday life the human brain computes it. Humans are capable of judging distances based on the information provided to them by the visual system and previous knowledge. Because the eyes are not capable of providing range information directly, the HVS must calculate it. This calculation is based on several pieces of information that the brain relates with range in the environment. One such item is scale. A large object has more spatial extent than a smaller object: the optical system of the HVS properly reports this. A large object farther away than a small object may not have the same spatial extent on the retina as the smaller. If the brain knows, a priori, the relative sizes of the two viewed objects, the information presented to the brain is scaled accordingly. Scale is one of the constant calculations that the HVS makes. It is a useful calculation to perform on the environment considering the sensors of the human visual system. Shading and texture are also other properties that the brain calculates on the environment. The lateral geniculate body fuses images from the two eyes. These measures on the environment extract information

49

pertaining to range, or information useful in the calculation of range. Calculating range is an important and inate ability, much of the everyday usage and calculation of range information by the human brain is done at an unconscious level. This may make the possibility of deriving a "natural" representation of laser radar information to humans a difficult task. Any representation of range data to the HVS will , at some level, be unnatural.

Displaying range as gray scale is more natural to the extent that bright things are closer than dark things if the two things happen to be of constant luminance and of different ranges. The color representation of range imagery is more complex, simply based on the fact that color space is multi-dimensional while gray scale space is not.

Much research has concerned the display of information to humans. Many of these studies have dealt with the display of alpha-numeric information to humans. These studies have investigated the optimum number of colors to use in the generation of alpha-numeric fonts, the size of the fonts, and the number of fonts that can be effectively used in a single display.

The use of the term alpha-numeric here also applies to symbols such as those found on stop signs and road-maps. Those symbols are alpha-numeric because they belong to the alphabet of "map language" or map symbology. Using the information and data collected by these previous studies, a

50

color code or set of symbols for range data were sought. The structure of the display is limited because the laser radar collects range. The spatial organization of the data is all that is in common with the data normally collected by the HVS. That part of the display scheme need not be derived. Difficulties arise when the presentation of the third dimension of the laser radar data is desired, namely that of metric range to the prescribed spatial location in an ordered two dimensional space. The HVS system is not acclimated to "viewing" range as a laser radar measures range.

It is quite possible that range information of the resolution and accuracy obtainable from a ladar may more benefit a man than a machine. This part of the thesis deals with the design of two color schemes, one scheme based on randomly selected colors, and another based on the concept of "warm" and "cool" colors as put forth by some artists. The utility of the warm and cool color display is based on the fact that a "favorite" color display would require a color display for every individual. If the display is to have some sort of intuitive meaning it should make sense; it seems natural for the display to represent the closer ranges as being "warmer" than the farther ranges. This is , at least, an apriori association of range with color.

5.1. Display Preparation

The system on which the color displays were created was

51

a Deanza IP-8500 Image Array Processor. The image array processor is hosted by a DEC Vax 11-780. Color image creation is possible by the use of three separate eight bit memory planes, each plane can be connected to an individual video output controller (VOC).

For pseudo-color images, it is possible to connect three image memory planes to a single VOC. Pseudo-color is possible by varying the transformation applied to the gray value resident in the image plane as the data flows through a look-up-table (LUT) for each of the three color guns. The color guns are driven by the VOC, which can be programmed in several ways.

The test scenes produced for this effort were true color images. A particular red, green, and blue value was calculated for every pixel. The look-up tables for the red green, and blue channels were merely used as an intensity transformation table. The host computer would transform an image into the appropriate red, green, and blue values for the display scheme implemented. An additional set of programs would then load the image data and the look-up table values into the image array processor for display to the operator. Figure 5-1, on the next page, shows the system configuration for the creation of the scenes used in the evaluation.
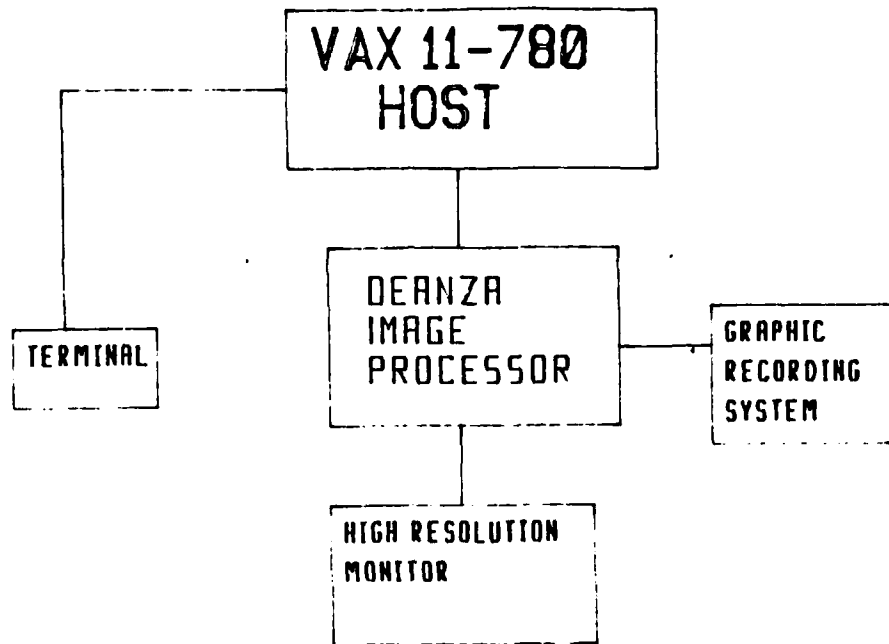

Fig. 5-1: Image Processing System Configuration

The following figure shows the flexibilty in assigning channels through the video output controllers.
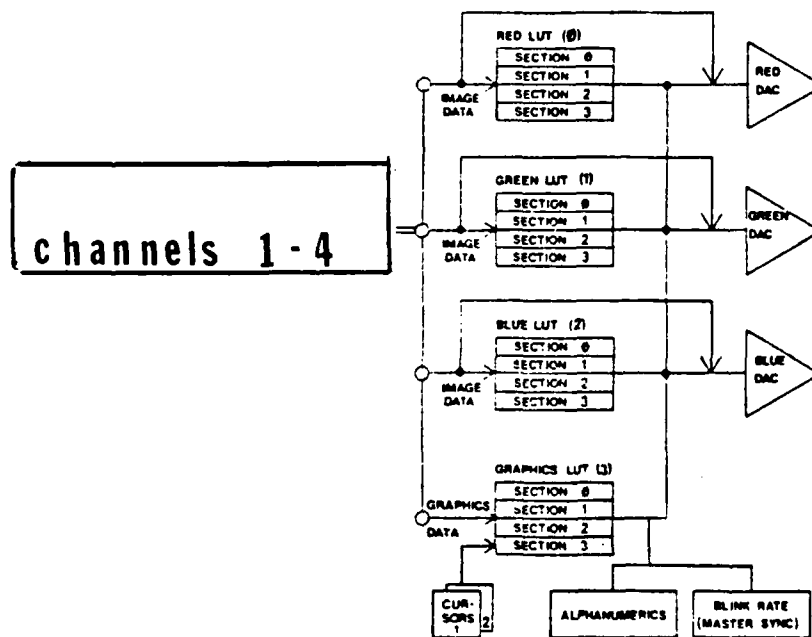

Fig. 5-2: Channel Assignments and Video Output Controllers

The image planes associated with the three channels portrayed in the diagram can be thought of as "red, green, and blue". This is not always the case, as reprogramming of the VOC can allow an assignment possibility:

```
Red=3
Green=2
Blue=1
```

But for the discussion here, it is assumed that channel one is associated with red, channel two with green and channel three with blue.

5.2. Image Format Specification

Each of the individual memory planes is 512 pixels by 512 lines, with each pixel represented by 8 bits, or a byte of memory. Since each byte has 256 possible values in three planes, and each gray level assignment may be mapped to one of an additional 256 values the number of possible color combinations with such a system is 256**3 or over 16 million combinations. Unique color representation is possible for range pixels of twenty four bits, but not all of the color representations possible are discernible to a normal (non-color blind) individual. In color systems, much effort has been placed in the determination of color discrimination of humans. This is of particular interest in the textile industry . Some particular color which is expensive to reproduce may give the same psychophysical effect as another color which is less expensive. Fortunately

54

a large amount of this data has been collected, and often this phenomenon has been discussed as minimal perceptual difference. Due to the fact that the image display system can produce a large number colors, it was essential that color schemes developed for the test at least allow for minimal perceptual differences in color perception by humans.

5.3. Color Display Design Methodology

Due to the wealth of possible colors which can be generated, the display schemes developed could not have found potential color mappings of gray scale values completely randomly as this would have taken an inordinate amount of time. Additionally, there is no certainty that any two possible colors will be recognized due to minimal perceptual constraints. The only way to ascertain whether two color are differentiable is to view them side by side on the same background(3:62), The background against which a color is viewed does change the psychophysical effect of the individual color.

For these reasons, it was necessary to design an interface between operator and the color display system which could essentially, allow the operator to create colors on various background without regard to the spectral content or even the RGB (red,green,blue) values of the created colors. The interface was essentially a paint routine. This routine enabled the operator to interactively place a

55

particular color on a selected background, and view the color with respect to other colors.

5.4. Description of Color Routine

The coloring routine placed a selected gray value in channel one of the display. The look up tables for the red green, and blue channel were loaded with values used in normal color image display. A set of intensity squares were written into channel three of the display system. When a particular color was searched for, the squares resident in channel three were enabled by setting the appropriate registers for the VOC and squares of various hue, intensity and saturation would appear on the output monitor. The operator could then choose a particular color from the screen by manipulating the cursor. After the color was selected the operator could select the color as a foreground or background color. If the color was selected was placed in the foreground, it could be manipulated from the keyboard terminal. The keyboard manipulation was limited to varying the saturation, and intensity of the color. Once a particular color was saturated, it would not change hue. This coloring routine proved useful in manipulating colors, and viewing colors against various backgrounds. After a particular candidate color is selected to correspond to a particular gray scale value or number, the contents of that color with respect to red, green, and blue is written to a buffer, and after the "coloring" session, the buffer is

56

written to a file. Later, the operator may re-edit the file, and display the colors that correspond to gray values. If desired, any color previously created may be placed in the foreground or background of the display. With this option, it is possible to create color look-up tables based on the assumption that minimal perceptual differences are satisfied. A selection of a color "X" for gray level "Y" should not look like color "A" for gray level "Y+1". The interactive nature of this utility precluded the selection of indifferentiable colors for different numbers to be represented.

5.5. Display Color Scheme Generation

Using the coloring routine discussed in the previous section, the operator would select a color for the background. The background color would then fill the entire background. Next, a single color would be selected as a test color. The color would then be placed in the foreground as a single square. The operator could then color the background with the foreground color by moving the cursor or trackball. While the foreground was coloring the background, the intensity of the foreground could be varied by pressing keys on the keyboard. The red ,green and blue values of the chosen color were manipulated as long as the color would not become saturated. Once a color was saturated, pressing on the keys did not change its value unless the key for "less" intensity was being pressed. After the selected foreground

57

color had been displayed from less saturated to most saturated, the operator could, if desired, selected any location on the color line and assign a gray level number to it. After this was done, control was established to the extent that if color "x" was assigned to number "y", then the proper RGB components necessary to create "x" were known. This was the process used for coloring the gray value with pseudo-color.

5.6. Conclusion to Display Generation

A user friendly interface was developed that allowed the manipulation of colors on a CRT monitor. Colors could, with constraints of saturation, be generated and manipulated. The RGB constants of the particular color scheme could then be loaded in the look-up tables of the red green and blue channels. The RGB values could then be stored, re-edited, or displayed at a later time.

5.7. Preparation of Look-Up-Tables

The coloring utility served as the interface between the host computer, display system and the operator. Initially, the creation of the baseline hues was a time consuming and labor intensive effort. This was due to the design goal of presenting the colors as a spectrum which started at pure red and moved through orange, yellow, green, blue, and finally from dark blue to a neutral gray which

varied in luminance to dark. The design of the psycho-physical effect of the desired look up table was simple ,but manipulation of the color values was more difficult than expected. Difficulty often occurred in selecting an appropriate color which could be varied in intensity to a transition to another hue in a reasonable or "linear" fashion. Linear is not necessarily the correct term, orderly is more correct, but a seemingly orderly arrangement of the red green and blue values to be placed in the look up table often produces colors which are either indifferentiable, or seemingly unrelated to the color assignment of the previous gray number. Gray number here refers to the value of the one byte value that is to be placed on an image memory plane. Recall that the laser radar simulated imagery is in the Fortran Integer*2 format, which means that the value of the particular range pixel is represented by two bytes. In keeping with the limits of the display, any representation of the particular Integer*2 number will be a combination of three single bytes, each byte residing in an image memory plane of the display system. The warm-cool color scheme developed for the laser radar imagery proceeded along certain limitations in the ability to assign colors to range values.

5.8. Practical Limitations in Range Coloring

The wealth of possible color assignments to any of the possible 2**16 or 65636 possible values that can be

59

represented by a 16 bit pixel is rich. In principle, it is theoretically possible to generate a particular color for any 16 bit pixel value. The utility of such a representation would be questionable. Also the time required to generate the color mappings would be great. This coupled with the fact that no data are available on the exact number of differentiable colors can be displayed on such a system led to the simple solution of coding the information according to some scheme other than just color.

If laser radar scenes, either real or synthetic, are viewed on a CRT monitor, it is apparent that the information content of the high bits is less than that of the lower bits. This assumes that the quantization level of the data is at the sensor noise level, or above it. Randomly fluctuating lower bits provide no information. This argument can be further stressed by considering the geometry of the sensor scan. If the sensor is scanning a rather flat benign background, the range values will vary smoothly in accordance with the quantization of the sensor output in range. The CO_2 laser radar developed at the Air Force Armament Laboratory at Eglin AFB is typical of most state of the art CO_2 systems, and it has a range quantization of about .33m. Much more quantization is often not necessary in tactical applications, nor affordable.

Because the high byte of the range data varies slowly with respect to the lower byte, it makes sense that

60

not every value should have its own particular color. In
fact, color coding in conjunction with another display
scheme other than a color for each representable 16 bit
value makes sense with regard to any transmission scheme of
such data. Clearly if any data link system would attempt to
perform bandwidth compression on a transmitted laser radar
signal, any visual display system should also attempt to
"keep down the bandwidth".

Chapter 6

Analysis of Laser Radar Imagery

By interactively manipulating laser range data, several items could be discovered about the nature of an effective display of that information. Typical image processing techniques such as thresholding , cursor and trackball investigations of numerical values, and biasing and scaling of the data were found most useful in determining the visual effects of the particular operation on the range data. Thresholding, for instance, on range data is simply an act of "range gating" the data. Range gating is quite common in most radio-frequency radars, and applying a threshold operation on range data displayed as an image is analogous to presenting only the data that is present at a prescribed range from the sensor. The prescribed range is metric, and can varied by interacting with the display system.It is difficult to display the full resolution of a 16 bit pixel on the display simultaneously. This can only be accomplished by displaying two or more channels simultaneously if no 16 bit color mapping is present.

In preparing these displays the upper byte was loaded into one channel and the lower byte was loaded in another. Operations could be performed on the 16 bit pixel, but the channels had to be displayed simultaneously. This was accomplished by in one of two ways. The high byte was displayed through the red gun and the lower byte was

62

displayed through the green gun, or the two channels were split, that is , half of the red channel was displayed and half the green channel was displayed on the monitor. This was accomplished by manipulating the control register of the image array processor, and setting it so that the VOC would pass the particular channel (high or low byte) to the desired color gun for display on the CRT monitor. After performing several threshold comparisons of the data it became obvious that a viable display scheme for the range data could be accomplished by displaying both the high and low bytes simultaneously. The key was that the high byte and low byte for every pixel would not be displayed. This makes sense when the relative low frequency content of the high byte with respect to the lower byte is considered. The display scheme for the 16 bit range pixel evolved according to the a priori information known about the intrinsic nature of the data itself.

6.1. Pseudo 16 Bit Display

Since an occasional display of the information in the high byte was decided upon, the display scheme design now focused on the issue of determining how to present the high byte in an effective manner. Since this work is considering only static display of the imagery in non-real time, the consideration of having the VOC alternate between the channel containing the high byte and the channel containing the low byte was dismissed. This technique could be quite

63

effective. The advantage the alternating high byte - low byte display would have over a split scheme is that every range pixel would have its full 16 bits displayed, but not simultaneously. This technique would, in effect, be time multiplexing the display monitor between the two bytes of range information. Again, it must be pointed out that this discussion is concerned with the problem of displaying the full dynamic range of a 16 bit pixel without uniquely coloring each range pixel.

6.2. Full Dynamic Range Display Technique

The technique decided upon for the presentation of the full 16 bit range imagery works under two assumptions:

1) The full dynamic range of every single pixel need not be presented to the human.

2) It is not desirable to color each range value of a 16 bit pixel uniquely.

The first point is justified based on the low information content of the high byte. In scenarios where the range to the target is varying quickly or the quantization level of the range data is extremely low, the information content of the high byte will be high. For the application under consideration here, namely the usage of laser range data for the terminal guidance of a missile or glide bomb, the high byte, from pixel to pixel, will not vary as quickly as the low byte, and hence, it should not be as well presented to the human. Based on psychological and man-machine interface studies, it is unlikely that a human would

64

perform favorably with a suite of 65636 different colors. In addition there is the problem of not knowing how many distinguishable colors are physically realizable on current RGB display systems. The additional problem of aligning and calibrating a display monitor for a possible 65636 colors may preclude the unique representation of a 16 bit range pixel based on maintainability. This can be borne out by the difficulties encountered on this project in selecting only 256 colors, or coloring uniquely, a single byte. The non-linearities with the display as it heated and cooled during the day oftentimes caused a noticeable color drift during the creation of the look up tables developed under this effort. Any number of colors beyond 256 would add to the difficulty of maintaining constant color balance of the monitor. This problem may result into a need for fewer than 256 colors. There is also the problem that the HVS shifts, at least, its neutral white value, and that it is probably not stable with a large palette of colors.

For the previously mentioned reasons, a display scheme of pseudo-coloring the range information in conjunction with spatially multiplexing the data was decided upon. Spatial multiplexing means that the information in the high byte and low byte are presented on the same display screen. Although the information contained in either bytes may physically reside in separate memory planes. The test scenes developed for this project did, in fact, reside in separate

65

planes. After the color code was developed in a final form, an algorithm was written that decomposed a 16 bit number into its appropriate high byte and low byte representation. A unique representation of 256 colors for 256 values, and the simultaneous display of black and white requires using three memory planes. The following figures are the look-up-tables corresponding to the full 255 color look-up-table called 255Spec and the full 255 gray scale look-up-table called 255Gray. The top left entry in the table corresponds to the color assigned to the value 0, and the bottom left entry of the look-up-table corresponds to the value 255.

Fig. 6-2: 255Gray Look-Up-Table
Top Left Corresponds to Value 0
Bottom Right Corresponds to Value 255

6.3. Laser Radar Range Display Format

In addition to the creation of a full 255 color look-up table which traversed the visible spectrum from red to violet, through an additional 16 neutral grays, two 32 level color look-up tables were created. This enabled the comparison between a look up table which was arranged according to some rule to be compared with a color scheme which was completely random in color assignment of values. Colors for the random look up table were created in the same manner as the 32 color scheme which varied according to the visible spectrum. The random color scheme shall henceforth

be referred to as "32Ran"(for 32-random), while the scheme which varies according to the visible spectrum will be referred to as "32Spec"(for 32-spectrum). The 32Spec look up table was created to have 8 separate hues, and each hue was to be diluted by neutral white 3 times. This makes 8 * 4, or 32 possible colors in this scheme. Since the baseline hue was diluted by white, in colorimetric terms this is corrupting the purity of that baseline hue. White light is a composite of all primaries in an additive system. The following two photographs of the monitor contrast the 32Ran and 32Spec color tables. A third table, that of a neutral gray look-up table is also included for comparison. The 32 gray scale scheme spans the entire dynamic range of gray from complete darkness, 0, to complete whiteness, 255. This is accomplished by a linear ramp of slope -8 which starts at 255 and proceeds to 0. A data entry of value zero would appear as white, and white is displayed by having the value of 255 loaded in the red, green, and blue channels simultaneously. Similarly, the three channels would be loaded with register values of 247 for a data entry of 2. This is the easiest way to visual the coloring process. It must be pointed out that the luminance display or gray scale is not biased or adjusted to provide maximum contrast on a step-wise basis, it does, however, use the entire available contrast that the display is capable of producing.

68
Fig. 6-3: 32Ran Color Scheme

Top Value is 1, Bottom Value is 32
Fig. 6-5: 32Gray Display Scheme
Top Value is 1, Bottom Value is 32

The following two scenes are illustrating the full
dynamic range of a 16 bit pixel as displayed through the
full dynamic range display scheme developed. The 32 pixel
wide bar at the left of the scene denotes the value of the
high byte for that particular scan line. If the value of the
high byte changes along a scan line, the value of the high
byte which is in the majority over the scan line is used to
fill the color bar value. Notice the compression of the
color bar as the scene is viewed from the bottom of the
scene to the top of the scene. This is due to the geometry
of the scene. As the depression angle of the sensor
approaches the horizon, the range to the ground plane

becomes infinite. The tan(90) is undefined, and the range value is resultingly large. The edge at the top of the scene is the horizon. This display provides much of the information present in an aircraft artificial horizon display. This is purely a function of the scene geometry. In an actual application, it would be possible to alpha-numerically list the range to the color bar at the left, and the additional range to the target or object of interest in the scene could be quickly calculated as an offset from the color bar range value. The target portrayed is a cone located at the 384th scan line and centered at the 128th pixel. The range to the cone along the bore-sight of the sensor is 971.2 meters. The cone itself is 18 meters high.
Fig. 6-6: Pseudo 16 Bit Display of Cone at 971 meters
Color Bar at Left Denotes Value of High Byte-32Ran Scheme
Lower Byte of Image Displayed Through 255Spec Color Table

6.4. Comparison of 5 Bit Data

Since $2^5=32$, 5 bit imagery was used to compare the differences between images colored by 32Ran, 32Spec, and the 32 gray schemes. Two target models were used. The target was the stair step model used in the evaluation of real sensor data in Chapter 3. The second synthetic target was a cone. These two targets were selected because they are relatively simple, and image creation is quick. The cone is particularly useful in that it has curvature which often results in shading differences under the display schemes. The flat surfaces of the stair step do not always provide the appropriate geometry for such shading to occur. The cone has an altitude of 4.5 meters, and is 3 meters in diameter at the base. These dimensions insure enough curvature under the sample geometry used.

6.5. Synthetic Data Creation Parameters

For the 5 bit evaluation, a sensor altitude of 60 meters above the ground plane, and the targets were placed at 160 meters downrange from the sensor. An additional downrange value of 320 meters was also used in order to create scenes of varying dynamic range along the sensor boresight. The two scene geometry produced data which were indicative of 8 and 9 bit scenes, with the quantization level of .33 meters(1 foot) in range. The scenes were produced at a greater dynamic range than 5 bits to insure that there would be several ambiguity intervals in the

72

image.

6.6. Range Ambiguity Function

The ambiguity function occurs as a result of the display scheme. Since there are 8 or 9 bits of dynamic range in the original image and only 5 bits in the display scheme, repetition will occur. Because the data was created with a quantization level of .33 meters, and the display is modulo 32, the ambiguity function is displaced every 32*.33 meters or 10.6 meters. This corresponds to 32 feet. Thus all points in the scene that are the same color are at the same range under modulo 32 arithmetic. It could be viewed that this data was created with a relative range sensor, say a radar that was amplitude modulated. The waveform has no ability to measure any phase delay over 360 degrees. Thus, any range value measured will be modulo 360 in phase. Any range scene encoded with less dynamic range in the coding scheme than the scene content will appear to have ambiguity intervals in it.

Compare the following scenes displayed in the various 32 entry look-up tables. The location of the target in Fig 6-7 is at the 128th pixel of the 128th scan line. The target is the stair step model at an apparent aspect of 135 degrees. Range to the target along the boresight is 178.64 meters. The 32Ran display scheme shows details across the target more clearly Than the 32Spec scheme does. The target stands out more apparently in the 32Spec scheme however.

73

This is due to two factors. The first is the geometry of this particular scene, and the second is the display schemes. The rapidly changing colors of the 32Ran scheme provide more visible detail across the target as each different color corresponds to a difference in range along the boresight of .33 meters. The silhouette of the target stands out more clearly in the 32Spec scheme as there are the same number of colors present as in the 32Ran scheme, but the background changes more slowly because the 32Spec scheme changes from one hue to another through 3 dilutions of the baseline hue.
Fig. 6-7: Scene 1 Viewed through 32Ran Scheme

74

Hence the 32Ran scheme varies, at first appearance four times faster than the 32Spec scheme does. Upon close scrutiny, it can be seen that the 32Spec display does indicate the changes in range across the target. Several of this type were developed, and the problem of determining the proper of colors to display frequently arose.

Fig. 6-8: Scene 1 Viewed through 32Spec Scheme

Any display scheme should support the detection of the target from the background as well as the recognition of the target.

The next set of images will attempt to illustrate the inherent problem with providing too much discernible

difference across a common target. To further compare the differences between the 32Ran and 32Spec schemes, Scene 2 illustrates a situation where detection of the target in either the 32Ran or 32Spec schemes is of the same difficulty. These scenes were created with the proper geometry for this comparison in mind.

Fig. 6-9: Scene 2 Viewed through 32Ran Scheme
Fig. 6-10: Scene 2 Viewed through 32Spec Scheme

The segmentation of the target i: the 32Ran scheme is a disadvantage. This scheme breaks up the target into too many sub-targets. The accuracy of the representation is not the issue; the recognizability of the object as opposed to its appearance in the 32Spec scheme is. For this scene, the target is located at about the 128th pixel of the 384th scan line. The target is 69.3 meters from the sensor. Apparent aspect to the target is 167 degrees. The 32Spec scheme keeps most of the pixels on the target in the same hue, namely blue, while the 32Ran scheme has colored several of the regions on the back part of the target. If such a scheme as

77

32Ran were used in a scene with range noise at an rms value of .33 meters, the color fluctuation across the target would be considerably more distracting to a human than display of the same noisy scene through the 32Spec scheme. For comparison, the 32Spec scheme could tolerate at least as much as 2 times the range noise as the 32Ran scheme and not have the pixels change hue. Thus the sensitivity to noise of a scheme like 32Ran would not be expected to be as robust as a scheme such as 32Spec.

In the first two sets of images, the differences between a totally random coloring scheme and one with an ordered progression of colors were investigated. Several color look up tables and test images were developed during the investigation, and these two selected compare the fundamental difference found with respect to locating targets in synthetic range imagery. For the investigation, target parameters were varied as well as sample geometries, the difficulty in finding targets with the 32Ran scheme compared to the 32Spec scheme quickly became apparent after several test scenes were displayed. The 32Ran scheme with a highly trained individual viewing the ladar data may have some advantages. The simple fact that each range difference is a totally different hue with respect to the previous hue may enable a trained individual to detect detail that may be imperceptible under the 32Spec scheme.

78

6.7. Difficulty with Gray Scale Display

Because the HVS can detect fewer number of gray scale changes than it can color changes, the limitation of a gray scale display is thus known. The relative effectiveness, of a gray scale display may not, however, detract from system performance. The exact nature of the particular scene displayed has a bearing on the effectiveness of any display scheme. For the most part, the limiting factor in a gray scale display is the uncertainty of where the target will be. This is significant when it is considered that a gray scale typically ranges from white to black. A black gray scale presentation of range data to humans will always result in a contrast limited situation. Contrast differences do not limit any color display of ladar data. Two colors may be of the same contrast level, but be viewably different. Recall from the discussion of the human visual system that contrast detection or perception is primarily a determination by the HVS of the luminance. Thus it is possible to have several different hues at the same luminance. This is an inherent benefit of encoding data in color. Figures 6-11 and 6-12 illustrate the difficulty in using any gray scale presentation scheme. Notice that the target might have easily occurred in a location that rendered its display largely in a dark region. The contrast between the target and the background in a gray scale display scheme will always be the limiting factor in the

display scheme. The fact is that humans cannot recognize more than about 50 levels of gray at any time. The possibility of a scenario that requires more than 50 different range numbers to be presented to the human is not unreasonable.
Fig. 6-11: Scene 3 Viewed through 32Gray Scheme

Fig. 6-12: Scene 3 Viewed through 32Spec Scheme

Clearly a total gray scale presentation of more than 50 levels of gray would not satisfy all display requirements. Color coding as opposed to gray scale coding of the data offers more flexibilty in the presentation of range values to the human.

6.8. Color Differencing and Contrast Limits

The final comparison of the benefit of a color scheme that advances through the visible spectrum of colors is shown in this section. The primary limitation of any monochrome display is due to the limited dynamic range of gray scales that may be simultaneously displayed to the

81

human. Although gray scale presentation is useful in the presence of high noise, it is inherently limited in dynamic range.

The full 255 color look-up table designed for this thesis was based on the same idea as the 32Spec look-up-table discussed earlier. The primary concept was to group the colors in some order, namely warm colors to cool colors, and include a decrease in purity from a baseline hue. This would enable various effects on the ladar data to be produced by simple multiplication and division of the absolute range values. All effects are "non-linear" with respect to the HVS, as the processed image appears differently from the original image as displayed through the 255Spec, or 255 color look-up-table which traverses the visible spectrum. All images are displayed through the 255Spec color table, and all operations are a result of 16bit scaling operations on the data.

Division of the full 16 bit range values will result in a decrease in the quantization level of the original data. This will also result in a decrease in range resolution of the original scene. Compare the original image of the plywood stair step model at 500m range displayed through the 255Spec look-up-table. The plywood stair step target is in the center of the frame and is at an apparent aspect of 90 degrees to the sensor. Details are rather difficult to discern.

82
Fig. 6-13: Plywood Model at 500m, 90 degree aze - 255Spec

The next scene is the same data in the previous scene displayed through the 255 gray scale look-up-table. The target stands out distinctly in the gray scale display. The dynamic range of the original scene is 4200.(1400 meters original dynamic range of the scene, but quantized at .3 meters/bit). Displaying a unique color for every value of the lower byte is simply too much information for the human. The gray scale presentation of the data is limiting the number of viewable values to about 50. The gray values seen are falling into differentiable grays as a function of the HVS. The net effect is a more understandable scene.
Fig. 6-14: Plywood Model at 500m, 90 degree aze - 255Gray

Panels at the low left of the scene are calibration panels
for the ladar sensor. They are viewably more distinct in the
gray scale presentation of the data. Due to the structure of
the 255Spec look-up-table, it is possible to scale the data
in such a manner as to vary the quantization level of the
data and achieve the appearance of having stretched the
colors over larger sections of the scene. This occurs
because the 255Spec display scheme is a composite of various
hues that are grouped together, and within each hue a trend
from the pure baseline hue to a more impure rendition of
that hue is accomplished.

The display of the data through the gray scale

presentation is best when there are rapid spatial variations of the contrast content of the scene. Recall that in every instance of traversing from white to black in the gray scale presentation, the data along the boresight of the sensor has moved 85 meters(255 feet). In the 255Spec display, this same 85 meters along the boresight of the sensor results in crossing the color spectrum from red to violet.

Because a color appears differently when viewed against different backgrounds, an improvement in the displayed scheme should result from varying the colors across the scene more slowly. This would serve to stretch the colors across a greater range variation, and hence a greater part of the scene. This is accomplished by simply multiplying the original 16 bit range data by a scaling factor. The result of scaling by a number less than one is to reduce the quantization of the original data. The dynamic range of the original scene is large enough to result in a full range of values from 0 to 255 in the low byte of the 16 bit range values. Note the effect of the reduced quantization on the gray scale presentation. The gray scale presentation may still be better than the 255Spec presentation. Transitions from one hue to the next can be more easily seen in the scaled data as opposed to the original data in the 255Spec presentation. The result of scaling the original data by .25 and displaying it through the 255Gray and 255Spec look-up-tables is shown in the next two photographs.

85
MICROCOPY RESOLUTION TEST CHART

ﾂ)ARDS-1963-A
Fig. 6-15: Scene Scaled by .25 - 255Spec

Fig. 6-16: Scene Scaled by .25 Displayed through 255Gray

The next set of two images is the original data scaled
by a factor of .125 . Notice how the gray scale presentation
is losing information due to the stretching of the contrast
function over a larger portion of the scene. The 255Spec
presentation is able to present more detail to the human as
a result of its not having the same contrast limit as the
gray scale look-up-table. Again, the low byte has a dynamic
range of a full 8 bits.
Fig. 6-17: Original Scene Scaled by .125 Displayed through 255Spec
Fig. 6-18: Original Scene Scaled by .125 Displayed through 255Gray

The final set of images illustrates the advantage of a color display over any gray scale display scheme. For this scene, the original 16 bit range data was scaled by .0625. Again, the dynamic range of the low byte was still a full 8 bits. The main point in comparing these images that have been scaled by various factors is the progression of the display from scaling factor to scaling factor. The color bands in the 255Spec displayed scenes varied from having color transitions that occurred at relatively short intervals in the original data, to bands that occurred at longer intervals. This rendered the data more intelligible, but not at the expense of reduced contrast. This particular scene geometry was more advantageous to the 255Gray display

88

scheme with the original data.
Fig. 6-19: Original Scene Scaled by .0625 Displayed through 255Spec

Fig. 6-20: Original Scene scaled by .0625 Displayed through 255Gray

89

Another scene geometry where the range values from pixel to pixel varied more slowly would have been less advantageous to the 255Gray scheme. The best that can be done for a gray scale presentation is to have the range values varying rapidly from pixel to pixel or scan line to scan line. Compare the differences between the original scene displayed through the 255Gray look-up-table, and the original scene after scaling by .0625 as displayed through the 255Spec look up table. It could be argued that the viewable quantization level of the original data viewed through the 255Gray look-up-table is not the original quantization level of .33 meters in range. The quantization level of the scene which has been scaled by .0625 and displayed through the 255Spec look-up-table has the same quantization viewable as unscaled scene viewed through 255Gray. The difference is the HVS limited the number of differentiable range values in the 255Gray look-up-table, whereas the 255Spec look-up-table controlled the number of differentiable range values. Actually, the range quantization of the original data at a value of .33 meters is accurately displayed by 255Spec in the original unscaled scene. Clearly, displaying the full dynamic range of the low byte may not be desirable under most circumstances. The power of a color presentation lies in the extended contrast range it provides over gray scale presentations. Additional complexities arise when the human may be required to do

90

different functions with the ladar data. Target recognition and target detection are two such functions that require different presentation schemes.(recall discussion earlier in this section). More research has to be conducted on the presentation of image data to humans via color versus gray scale; the objective of the presentation should be well structured into the display format. No single display scheme will provide the necessary information in the most effective manner under all circumstances. It is possible that multiple display schemes that can be manipulated by the operator will provide the necessary flexibilty to display the information in an effective manner.

Chapter 7

Recommendations and Conclusions

This thesis had three objectives:

1) Verification of synthetic ladar data.

2) Design of a display format for representing the full dynamic range of 16 bit range imagery.

3) Investigate the advantages or possible benefit of color coding ladar data.

It is clear that the use of synthetically created ladar data for the purposes of display to humans is acceptable when the target signatures are considered. Training humans to recognize target signatures generated by a simulation should pose no problems. Use of the synthetic data to simulate target signatures is confined by sensor noise only. Limitations arise due to the difficulty in predicting noise and clutter content of the scenes. Using simulated data for complete training of humans to recognize targets in realistic scenes has not been investigated. The simulation used in this effort could be modified to provide background clutter, but it is unlikely that such scenes would look much like data collected by a real sensor. The recommended approach to modelling a full complex scene involving both targets and clutter would be to deterministically create target information and stochastically model the background clutter. More analyses of actual CO_2 ladar data is necessary in order to compile

92

the necessary statistics for the stochastic noise and background generator. Any display schemes for the presentation of the data should, however, consider using the deterministic target signatures that are created by the current simulation, and then display real data through any scheme developed by using the synthetic data. Throughout the course of this thesis, it was found that the target signatures derived from the simulation were, with the exception of noise, compatible with the target signatures in the real sensor data. From a design standpoint, changes in the display scheme appeared as imagined, even before the display scheme was created and implemented on synthetic data. This was most helpful in determining what would work and what would fail with respect to the target signatures. The limitations of the synthetic data approach broke down when the background clutter was considered. Often a change in the look-up-table structure would produce the expected change in the target signature, but produced unexpected effects in the background clutter. Use of synthetic data was beneficial when the target signature alone was considered. No display scheme should be wholly based on the effects the display has on synthetic target signatures data alone.

7.1. Dynamic Range Presentations

For this thesis, the use of color only was investigated. The full dynamic range display was developed as a starting point only. For static image presentation,

this was about the most that could be done. The high byte displayed on an edge of the screen, with the low byte displayed on the screen provided all the information about the scene geometry in an understandable fashion. The investigation concerning how this display should be configured was most useful in uncovering the limiting factor in displaying range data to humans. This limitation is clearly the human. Color coding the information has the major advantage over gray scale in that more viewably different entities may be portrayed using color. The exact number of different color entities that may be displayed on a CRT should be investigated, or at least modelled. It is unlikely, however than any human would be able to perform reliably with a large number of differentiable colors presented on the CRT. It is more desirable to have a limited number of colors, and have the human operator scale the range values in order to vary the color content of the scene until a desirable effect is found. Many other schemes such as this may be developed and tested against each other if that is found to be necessary.

During the course of this investigation it was found that the context of what the human was expected to perform with the data was of primary importance. Some schemes that had distinct advantages over other schemes with regard to target detail, had severe disadvantages with respect to those same schemes when target detection was concerned. In

94

pattern recognition systems that attempt to find targets in real scenes a similar phenomena occurs when throughput of the processor is concerned. For example, target detection using sensor data is usually a throughput intensive operation. This means that every pixel that is collected by the sensor must be interrogated by some process in an attempt to limit the number of candidate pixels that might constitiute part of the target signature. The other aspect of the problem results when the regions of the scene that have been segmented as possible targets have been extracted from the scene. At this point, most of the pixels in the scene have been discarded and closer inspection of the regions segmented may reveal a target. The operation of processing the regions of interest is a comput tionally intensive operation. These effects were found with regard to the HVS. Target detection requires a different display scheme than does target recognition. Put another way, an optimal target detection display scheme for a human viewer may not be an optimal or even an acceptable display scheme for a human performing target identification. The trade-offs between these two functional requirements with ladar data, and the impact that this has on any display scheme needs to be investigated.

7.2. Possible Plans for Further Studies

    1) Continuation of low level studies

    2) Investigation of high-level processes

95

7.2.1 Low Level Studies

The continuation of low level studies would include an investigation concerning the number of entities that would be displayed to the human in an operational environment. The next issue would involve the creation of an n-dimensional color space that would be modelled as an n-dimensional orthogonal or maximum difference color space. The desired effect would be to create as many single colors that are required for the display, and place each of these single colors as far away from each of the colors in perceptual color space. This could then be thought of as an n-dimensional color space which is perceptually orthogonal. This would have several advantages over the color spectrum schemes used in this thesis, providing the colors can be sensibly grouped by the human operator in order. The perceptual differences would be satisfied in that each single color would be as different as possible from each of the remaining colors. This would be another low-level approach to enhancing the display of the ladar data.

7.2.2 High Level Process Enhancement

It has been shown in this thesis that there are some benefits to be found by displaying range data in color as opposed to gray scale. Since the schemes used in this thesis used only low-level approaches to the problem. A high level approach to displaying the ladar data would involve processing of the sensor data by a processor for the

96

purposes of ordering the data. By ordering the data, the processor would be adding information, and decreasing the entropy of the the image before it is displayed to the human. Due to the metric quality of the ladar data, the high level approach to enhancing ladar data may be of most benefit to a human operator. A proposed high level scheme that would reduce the computations by the human is as follows:

1) Segment the incoming sensor data into planar surfaces

2) Calculate the mean square range to the planar surfaces

3) Color the surfaces according to the mean square range

Such an approach would then allow the human to view the scene and connect the surfaces together to create objects. This would reduce the burden of having the human screen every pixel. The problems with any such scheme is that the processing algorithm will have sensitivities as well as a probability of false alarm and a probability of detection as all pattern recognition algorithms have. It will, in effect, be detecting planar surfaces in ladar data. Schemes of this sort will probably provide the most flexibilty and increase in performance of the man-in-the-loop. The current trend of ever rising complexity in the cockpit, and increased pilot workload, may require such a scheme, as the pilot or weapon systems operator may be performing in a time limited capacity.

7.3. Limit of Human Visual Capacity

Ultimately, the target recognition may be totally done by computer, and only confirmation of the target would be required of the pilot or weapon system operator. The time line may then require a quick response from the operator in order to launch a weapon to destroy the target. High level processes of the computer may assist in reducing pilot reaction time by properly displaying the ladar data to the pilot in a concise, quickly recognizable format. The only alternative to displaying the ladar data to the human would be to construct a world model in a cartoon or synthetic display format, and train the pilot on the world model that the computer is using to communicate with him. All this would involve a series of higher and higher level processes. This may lead to the total removal of the man-in-the-loop. When the system has to make progressively more complicated calculations in order to describe the world state to the human than it requires to internally ascertain the world state, then it is necessary to remove the man from the loop.

C. Source Listing for Synthetic Scene Generator

C.1. Main Program Listing

THIS IS THE FORTRAN SOURCE FOR THE SYNTHETIC SCENE GENERATOR
USED TO CREATE THE SYNTHETIC IMAGERY FOR THIS PROJECT
FULL DETAILS OF ALL ROUTINES CAN BE FOUND IN THE AIR FORCE
ARMAMENT LABORATORY (AFATL) TECHNICAL REPORT TR-83-37.
THIS VERSION LISTED IN THIS APPENDIX WILL RUN ON A DEC VAX
FAMILY COMPUTER

```

C

      SUBROUTINE TEXTUR(IOPT, ITEXT, X, Y, VAL)
C
C    SUBROUTINE TEXTUR IMPLEMENTS AN OBJECT-PLANE BACKGROUND/TEXTURE
C  MODEL BASED ON TRIGONOMETRIC-SERIES EXPANSIONS.  EACH TEXTURE IS
C  DESCRIBED BY VALUES FOR THE MEAN, STANDAGROUND/TEXTURE
C  MODEL BASED ON TRIGONOMETRIC-SERIES EXPANSIONS.  EACH TEXTURE IS
C  DESCRIBED BY VALUES FOR THE MEAN, STANDARD DEVIATION, AND CORRELATION
C  LENGTHS IN TWO DIMENSIONS.  THE NUMBER OF DIFFERENT TEXTURES THAT
C  CAN BE SIMULATED DEPENDS ON THE DIMENSIONS OF THE ARRAYS PROVIDED
C  THROUGH COMMON BLOCK / TXTUR /.  DEPENDING ON THE INPUT VALUE OF
C  VARIABLE IOPT, THIS SUBROUTINE CAN PROVIDE A VALUE FOR A TEXTURE
C  AT A GIVEN POINT OR CAN AVERAGE THE TEXTURE OVER AN AREA DEFINED
C  BY A 4-SIDED POLYGON.
C
C    THE ARGUMENT VARIABLES FOR THIS SUBROUTINE ARE AS DESCRIBED BELOW:
C
C
C  IOPT    OPTION FLAG TO CHOOSE BETWEEN EVALUATING THE TEXTURE AT
C          A POINT ( X(1),Y(1) ) OR TO AVERAGE THE TEXTURE OVER AN
C          AREA DEFINED BY 4 POINTS.
C
C          IF IOPT = 0    AREA AVERAGE
C          IF IOPT <>0    POINT EVALUATION
C
C
C  ITEXT   INDEX NUMBER OF TEXTURE THAT IS BEING REQUESTED.
C
C
C  X,Y     ARRAYS OF SIZE 4.  X AND Y COORDINATES OF THE VERTICES OF
C          THE 4-SIDED AREA FOR AVERAGING THE TEXTURE.  ONLY X(1) AND
C          Y(1) ARE USED FOR POINT EVALUATION.
C

C
C  VAL     OUTPUT TEXTURE VALUE.

18	0	255	32
19	0	255	73
20	0	255	115

172

Pixel Value	RED	GREEN	BLUE
21	0	255	157
22	0	255	198
23	0	255	240
24	0	241	248
25	0	214	235
26	0	187	221
27	0	161	208
28	0	134	195
29	0	107	181
30	0	80	168
31	0	53	154
32	0	26	141

From this point on all values of RGB are 0 for
all values of data through 255.

F. RGB Listing for 32Gray Look-Up-Table

32 GRAY SCALE LOOK UP TABLE- THIS LOOK UP TABLE COVERS
THE TOTAL DYNAMIC RANGE OF THE DISPLAY IN MONOCHROME

This appendix contains the RGB values corresponding
to the indicated pixel value.

Pixel Value	RED	GREEN	BLUE
1	255	255	255
2	247	247	247
3	239	239	239
4	231	231	231
5	223	223	223
6	215	215	215
7	207	207	207
8	199	199	199
9	191	191	191
10	183	183	183
11	175	175	175
12	167	167	167
13	159	159	159
14	151	151	151
15	143	143	143
16	135	135	135
17	127	127	127
18	119	119	119
19	111	111	111

Pixel Value	RED	GREEN	BLUE
20	103	103	103
21	95	95	95
22	87	87	87
23	79	79	79
24	71	71	71
25	63	63	63
26	55	55	55
27	47	47	47
28	39	39	39
29	31	31	31
30	23	23	23
31	15	15	15
32	7	7	7

From this point through the value of 255, the RGB values are all identically 0.

G. RGB Listing for 255Gray Look-Up-Table

255GRAY   LOOK UP TABLE

This appendix contains the RGB values corresponding
to the indicated pixel value.

Pixel Value	RED	GREEN	BLUE
1	255	255	255
2	254	254	254
3	253	253	253

The remainder of the RGB values for pixel
values through 255 are all identically 0.

I. Eglin AFB CO_2 Ladar System Specifications

Ladar System Specifications

TRANSMITTER:

RF pumped, EO modulated, 10.6 um laser

Pulsed or CW format

Average power of 10 W (minimum) in CW format

Average power of 5 W (minimum) in pulsed format with 22 ns pulsewidth @87 khz PRF (laser output)

PRF is adjustable from 30 khz to over 100khz

RECEIVER:

Heterodyne with local oscillator, 70 mhz offset

Log video output with 75 dB dynamic range

50 mhz IF bandwidth

First Pulse Logic

OPTICS/SCANNER:

Common aperture 7.5 cm diameter

IFOV 0.27 full angle "spatial resolution"

FOV 2 x 1.75 degree raster

128 lines per frame

PROCESSOR:

16 bit unambiguous range (> 5 km)

1 ns granularity

5 bit peak amplitude sample at 2 dB/LSB

MULTIBUS compatible digital acquisition and scan control

VITA

Norman Barsalou was born in Worcester, Massachusetts, on July 3, 1958. He graduated from Niceville High School in Niceville, Florida in 1975, and attended the University of Florida, from which he graduated in June 1978 with a Bachelor of Science in Mathematics. He was commissioned in the Air Force in June, 1979. Upon entering active duty he attended the Air force Institute of Technology to pursue a B.S. degree in Electrical Engineering. After receiving his BSEE from AFIT, he was assigned to the Air Force Armament Laboratory at Eglin AFB, Florida. He remained at the Armament Laboratory from March 1981 until his assignment to AFIT in May 1984.

He is married to the former Patricia Lynn Benson of New Orleans, Louisiana.

Abstract

A pseudo-color representation of CO_2 laser radar data is developed. The pseudo-color scheme is based on the dilution of a set of baseline hues by white. The synthetic generation of laser radar scenes is used for display creation, and the results of analysis on synthetic scenes is applied to data collected by a CO_2 pulsed ladar system.
