I. Introduction.

N-isopropylcarbazole (NIPC) is a pyroelectric molecular crystal exhibiting strong tribo-¹ and pyroluminescent^{2,3} properties associated with the polar atructure of the crystal. A structural phase transition in NIPC at ca. 137 K, taking place between the C_{2v}^{21} (Iba2) high temperature structure and the C_{2v}^5 (Pbc2₁) low temperature structure, has been reported in the literature^{4,5}. Dilatometric,⁴ pyroelectric,^{2,4} and specific heat⁶ measurements reveal the first order character of this transition. The enthalpy of the transition is found to be $\Delta H^T = 125$ cal mol⁻¹, a value higher than most displacive⁷ or even order-disorder⁸ phase transitions in molecular crystals. Calorimetric measurements⁶ reveal an additional anomaly of the specific heat around 185 K, indicating the possible existence of another (non-first order) phase transition. Very little is known about the mechanism of the NIPC phase transition at 137 K. From the symmetry point of view, NIPC is a rare example of a molecular crystal exhibiting a phase transition without any point symmetry breaking; only the translational symmetry changes at the transition (the volume of the primitive unit cell doubles in the low temperature phase). Chloranil^{9,10} is another well known example of such a nonferroic¹¹ phase transition among organic solids.

A group theoretical analysis of the transition in NIPC suggests that the transition takes place at the Brillouin zone boundary⁵ and that the order parameter transforms according to a one dimensional representation of the group of the wavevector (only one vector of the star of the wavevector is involved in the transition). Bilinear coupling of the order parameter to macroscopic quantities at the zone center (e.g., strains) is thus forbidden by symmetry. The lowest order coupling permitted by symmetry is then a third order nonlinear interaction. Although this kind of transition does not

involve new macroscopic tensor components below the phase transition, anomalies of the elastic constants may arise due to the higher order couplings, as is the case for chloranil.¹⁰

The molecular mechanism of the phase transition in NIPC is not completely clear. Recent crystallographic data⁵ have shown large librational motion of the NIPC molecules at room temperature. In particular, libration around the molecular axis of largest moment of inertia exhibits surprisingly large amplitude (7.1°) , at least twice the amplitude of the two other principal axis librations. The amplitudes of the librations become almost equal and significantly smaller in the low temperature phase and only small rotation-translation shifts of the molecules occur at the transition. The carbazol group of the molecule itself is planar in both phases. The only significant change in molecular geometry at the phase transition is a rotation of the isopropyl group around the C-N bond by an angle of 14° and 10° for layers I and II, respectively. These results show that the phase transition in NIPC does not affect the molecular conformation in an essential way: the phase transition may be considered as an order-disorder or rotation-translation coupling type transition. Rotation-translation coupling, as well as "freezing" of the orientational motion of molecules in the low temperature phase, has been previously reported to characterize phase transitions in such molecular crystals as s-triazine,¹² benzil,¹³ and chloranil.¹⁰

NEW COLOR NEWSON SEAMOREM IN SEAMON NEWSON

As was already mentioned, the NIPC crystal is pyroelectric, and thus also piezoelectric, in both phases. The molecular dipole moments are directed along the C-N bonds of the molecules which are oriented about the direction of the two-fold c-axis; the spontaneous polarization of the crystal is, therefore, parallel to this axis. Due to the piezoelectric coupling, dielectric and elastic anomalies cannot be separated, in general. Therefore, some of the observed elastic constants must be corrected by¹⁴

 $\bar{c}_{\alpha\beta} = c_{\alpha\beta} - e_{k\alpha\beta}^2 / \epsilon_k$

in which $c_{\alpha\beta}$ is a bare elastic constant, $e_{k\alpha\beta}$ is a piezoelectric constant, and ε_k is a bare dielectric constant. Since the anomalous part of the dielectric constant of NIPC is much smaller than its normal part,⁴ the main effect of the piezoelectric coupling is to shift the absolute values of the elastic constants. Ignoring this effect, interactions between the order parameter and strains can be separated from interactions between the order parameter and polarizations.

In this report we present a complete study of Brillouin scattering in NIPC at one atmosphere pressure between 295 and ca. 100 K. The elastic constant tensor is determined and the temperature dependences of the elastic constants are given. The observed anomaly of the a-axis longitudinal acoustic phonon associated with the e_1 strain is discussed on the basis of Landau mean field theory and interpreted in terms of a Debye relaxation-dispersion of the elastic constant.

II. Experimental Procedures.

REPORT ASSAULT REPORT NOTION DURING DURING

Single, transparent crystal boules of NIPC (ca. 5 cm³ in volume), exhibiting a [100] perfect cleavage plane and [010] non-perfect one, are grown from the melt using a Bridgman technique.¹⁵ Oriented crystals are cleaved with a razor blade and/or cut with a wire saw into parallelepiped shaped samples (ca. 4 x 4 x 3 mm). The saw-cut faces are polished on a tissue soaked with ethyl acetate. In order to reduce surface scattering and prevent sample sublimation during experiments, crystal faces are coated with a thin layer of silicon oil prior to the experiment.

Right angle scattering experiments are performed using three different kinds of samples characterized by different orientations: 1) faces perpendicular to the three crystallographic axis - this orientation allows for measure-

ments of phonons in the directions [110], [101], and [011]; 2) faces oriented 45° with respect to the crystallographic axes in the ab plane - phonons in the directions [100] and [010] can be measured in this orientation; and 3) faces oriented 45° with respect to the crystallographic axes in the ac plane - either [100] or [001] phonons can be obtained.

The Brillouin scattering apparatus, including measuring techniques end temperature control, used in these experiments has been described previously.^{12,13} A Spectra Physics model 165 argon ion laser, operating at 5145 Å (200 mW) in a single cavity mode is used for the scattering source. Spectra are obtained with a Burleigh Fabry-Perot interferometer system in triple-pass operation with a standard finesse of 45 to 50. To analyze the spectra and to record the temperature dependences of the acoustic phonons, free spectral ranges between 15 GHz to 30 GHz are chosen. Typically, 50 or 100 accumulations of a 1s duration scan are accumulated and averaged in a multichannel analyzer and computer.

III. Results.

Employing the standard procedure for Brillouin scattering, the velocity of sound v in an optically anisotropic crystal can be calculated by 15

$$\omega_{\rm B} = \frac{2\pi}{\lambda_{\rm o}} v \left(n_{\rm i}^2 + n_{\rm s}^2 - 2n_{\rm i} n_{\rm s} \cos \theta_{\rm s} \right)^{\frac{1}{2}}$$
(1)

in which n_{i} , n_{s} are the refractive indices for incident and scattered light, respectively, λ_{o} is the incident light wavelength in vacuum and θ_{s} is the scattering angle (90° for right angle scattering). Thus, knowing the frequency shift (ω_{B}) and the polarizations of the incident and scattered light from the experiment, one can easily calculate the sound velocity, providing refractive indices of the crystal are known.

The refractive indices of NIPC are measured at 5145 Å by a prism minimum deviation method. The accuracy of this method in our case is only

slightly better than 5%; the error is mostly due to the poorly determined geometry of the prisms and the quality of their surfaces. The values of the refractive indices are subsequently verified and adjusted by comparing their ratios to the ratios of the Brillouin shifts measured along the principal axes in backscattering geometry for different polarizations. Refractive indices obtained in this way and used for calculations of sound velocities are $n_a =$ 1.846, $n_b =$ 1.648, $n_c =$ 1.664. Elastic constants of NIPC are calculated using the density $\rho =$ 1.15 x 10³ kgm⁻³ taken from x-ray data.⁵ A. Determination of the elastic constants at room temperature.

Elastic constant tensor and piezoelectric constant tensor for both orthorhombic phases of NIPC are given by

c ₁₁	°12	°13	0	0	0							
°12	°22	°23	0	0	0	and	o	0	0	0	e 15	٥
°13	°23	с ₃₃	0	0	0	and	0	0	0	e24	0	0

0	0	0	0	°55	0		-					-
0	0	0	0	0	^с 66_							

respectively. The equation of motion for the piezoelectric crystal is of the form

$$(\bar{c}_{ijkl} - \rho v^2 \delta_{ik}) u_k^0 = 0$$
(2)

in which

$$\overline{c}_{ijkl} = c_{ijkl}^{E} + \frac{(e_{pij}m_p)(e_{qkl}m_q)}{\varepsilon_{jk}^{s}m_jm_k}$$
(3)

are the elastic constant coefficients modified by the piezoelectric coupling, and the m's are the direction cosines. The solutions of the equations of motion corresponding to the phonons observed in our experiments are shown in Table I. Additional terms of the form of eq (3) in the Table describe the change of une velocity of those phonons which couple to the electric field via piezoelectric coupling. As already mentioned in the Introduction, the dielectric properties of NIPC do not show a large anomaly at the phase transition.⁴ As a result, interactions between the order parameter and strains can be, in principle, separated from interactions between the order parameter and polarizations. Thus, only the shifts of absolute values of the elastic constants will be considered in the determination of the elastic constant tensor and its temperature dependence. Values of these shifts cannot, however, be calculated from eq (3) due to lack of experimental data.

1.1.1

DESCRIPTION RECEIPTION AND DESCRIPTION AND ADDRESS OF

On the other hand, the change of the acoustic mode velocity due to the piezoelectric coupling can be estimated¹⁷ from the electromechanical coupling coefficients k_{ij} : specifically, $c^{eff} = c/(1-k^2)$. Preliminary measurements¹⁵ have shown that $k_{31} = 0.15$, $k_{32} = 0.18$, $k_{24} = 0.11$: k_{33} and k_{15} could not be measured due to weak piezoelectric signals. Employing these values of the electromechanical coupling coefficients, the largest change in the sound velocity caused by piezoelectric coupling is estimated to be 1.6%. Thus, the experimentally observed elastic constants c differ from bare elastic constants by less than -3%. The piezoelectric coupling will not be included in the ensuing discussion, as it is of little importance to the elastic anomalies.

The values of the elastic constants of NIPC are calculated using the appropriate relations from Table I. c_{11} , c_{22} , c_{33} , c_{55} and c_{66} are obtained directly from X₁, X₄, X₆, X₃ and X₇, X₂ and X₅, respectively, with an accuracy of ca. 2%. As we are not able to detect the transverse mode governed by the c_{AA}

elastic constant directly, its value is determined from the velocity of the TA phonon propagating in the [110] direction using relation X_{10} . The off-diagonal elements of the elastic tensor c_{12} , c_{13} and c_{23} are calculated from the relations $X_8 - X_9$, $X_{11} - X_{12}$ and $X_{15} - X_{14}$, respectively. Their values are determined with a relatively large error (~30%) due to the combination of the elastic constants in the employed equations, as well as to the relatively small values of the off-diagonal elements. The room temperature set of elastic constants found in the above manner is given in Table II.

Using the values of the elastic constants from Table II, angular sound velocity diagrams can be calculated. These diagrams, given in fig. 1, reflect the anisotropic nature of the crystal structure. The c_{11} elastic constant which governs the velocity of the [100] LA phonon is relatively large, whereas the molecular interactions in this direction, which is perpendicular to the cleavage plane, are expected to be weak.

B. Temperature Dependences of the Elastic Constants.

The temperature dependences of the six diagonal elastic constants are shown in figs. 2-4. The c_{22} , c_{44} , and c_{55} elastic constants exhibit the step-like changes expected for a first order phase transition. Only a small effect is seen for the temperature dependence of c_{33} . An interesting anomaly around the phase transition at 137 K is found for the c_{11} elastic constant, which involves the e_1 strain in the crystal and governs the propagation of the LA-phonon is the [100] direction. Fig. 5 shows the temperature development of the [100] LA-mode spectrum; the other mode seen in this figure is the [100] TA-mode governed by the c_{55} elastic constant. The Brillouin peak corresponding to the [100] LA-phonon in the spectrum exhibits considerable broadening at the phase transition. The latter phenomenon typically indicates a higher sound attenuation at the phase transition, possibly due to the critical fluctuations. The temperature dependences of the halfwidth of this Brillouin

peak and its intensity are shown in fig. 6.

The anomalous temperature dependence of the c_{11} elastic constant shown in fig. 2 may be fit using a phenomenological power law equation of the form

$$c_{11}(T) = c_{11}^{0} - aT - b\epsilon^{-\rho}$$
 (4)

in which the linear temperature term accounts for the behavior of the elastic constant in the absence of a phase transition and the last term represents the form of the critical anomaly. ε in eq. (4) is equal to $(T-T_0/T_0)$ or (T_0-T/T_0) for the high and low temperature phases, respectively. The values of the parameters which give the solid lines in fig. 2 are $c_{11}^0 = 15.11 \times 10^9 \text{ Nm}^{-2}$; $a = 1.5 \times 10^{-2} \text{K}^{-1}$, b = 0.35, $T_0 = 135.5$ K and $\rho = 0.67$ for the high temperature phase, and $c_{11}^0 = 17.19 \times 10^9 \text{ Nm}^{-2}$, $a = 1.5 \times 10^{-2} \text{ K}^{-1}$, b = 2.05, $T_0 = 140.8$ K and $\rho = 0.26$ for the low temperature phase.

Temperature dependences of the c_{12} , c_{13} and c_{23} elastic constants cannot be obtained directly; however, they may be estimated from the temperature dependences of the modes propagating along the diagonal directions [110], [101] and [011] (see Table II). The temperature behavior of these modes is given in fig. 7. Calculating the temperature dependences of c_{12} , c_{13} and c_{23} according to the previously described procedure employed in the determination of their room temperature values, one finds that the off-diagonal elastic constants do not shown any particular anomalous behavior at the phase transition. In other words, the temperature dependences of the diagonal elastic constants, c_{11} in particular, fully account for the anomalies shown in fig. 7. The temperature dependences of the c_{66} and consequently c_{12} elastic constants cannot be determined in the low temperature phase due to cracking of the sample at the

phase transition. In fact, several samples are used to obtain most of the temperature dependences shown in this paper.

Elastic constant anomalies which could confirm the existence of another phase transition at ca. 185 K, suggested on the basis of calorimetric measurements,⁶ are not observed. Nonetheless, a change in slope of the temperature dependence of c_{11} is found near 185 K.

IV. Discussion.

The present Brillouin scattering study reveals the softening of the [100] LA-mode governed by the c_{11} elastic constant, both above and below the phase transition at 137 K. Simulataneously a ~200% increase of the attenuation (halfwidth) of this phonon occurs at the transition. To explain these experimental findings, the Landau mean field theory and dispersion-relaxation processes will be considered.

A. Landau free energy.

Consider the group-theoretical analysis of the $C_{2v}^{21} \neq C_{2v}^5$ phase transition in NIPC. In the Brillouin zone of the high temperature structure (Γ_0^{v}) , five symmetry lines possess the C_{2v} point symmetry, appropriate to the considered transition;¹⁸ however, only three points of this symmetry $\underline{k}_{\Sigma} = (\frac{2\pi}{a}, 0, 0, 0), \underline{k}_{\Delta} = (0, \frac{2\pi}{b}, 0),$ and $\underline{k}_{\Lambda} = (0, 0, \frac{2\pi}{c})$, all located at the Brillouin zone boundary, give doubling of the primitive unit cell volume at the transition. Thus, the transition takes place at the Brillouin zone boundary. As the star of the wavevector has only one arm and is non-degenerate, the order parameter (e.g., optical phonon) driving the transition belongs to a one dimensional irreducible representation at the zone boundary.

Employing standard group theoretical methods¹⁹, the Landau free energy may be expressed in terms of the order parameter as

$$G_n = f_n^2 A(T)n^2 + 1/4B_n^4 + 1/6D_n^6 + \dots$$
 (5)

in which $A(T) = \alpha(T-T_0)$ stands for harmonic restoring forces of the optical mode. The elastic part of the energy is

$$G_{el} = \frac{1/2}{ij} \sum_{ij} c_{ij} e_{ij} e_{ij}$$
(6)

in which only the term $G_{el} = 1/2c_{11}e_1^2$ will be considered because only the c_{11} elastic constant exhibits anomalous behavior in NIPC.

As the bilinear coupling between the zone boundary order parameter and the zone center strains is symmetry forbidden, the lowest order couplings which may be considered are a third order nonlinear interaction and a biquadratic coupling. Thus, the free energy interaction term is represented by

$$G_{e_1\eta} = -1/2(Ke_1\eta^2 + Le_1^2\eta^2).$$
(7)

The total Landau free energy is then of the form

$$G = 1/2A(T)\eta^2 + 1/4B\eta^4 + 1/6D\eta^6 + 1/2c_{11}e_1^2 - 1/2Ke_1\eta^2 - 1/2Le_1^2\eta^2$$
. (8)

The solution of the Hamiltonian including only the third order nonlinear coupling is already known in the literature for the phase transitions in terbium molybdate²⁰ and chloranil¹⁰. The theory predicts a continuous downward displacement of the elastic constant below the transition, whereas above the transition the elastic constant is unaffected by the coupling.²⁰ In the case of NIPC the solution has the form

$$c_{11} = \begin{cases} c_{11}^{0}, & (T > T_{0}) \\ c_{11}^{0} - \frac{K^{2}}{2B + 4D\eta^{2}}, & (T < T_{0}) \end{cases}$$
(9)

in which \bar{n} represents the spontaneous value of the order parameter in the low-temperature phase.

Including both linear-quadratic and biquadratic interactions, as in eq. (7), the equilibrium values of the order parameter $(\tilde{\eta})$ and strain (\tilde{e}_{1}) are obtained by setting the generalized forces equal to zero

$$X_{1} = \left(\frac{\partial G}{\partial e_{1}}\right)_{\eta} = 0, \left(\frac{\partial G}{\partial \eta}\right)_{e_{1}} = 0$$
(10)

yielding,

$$A(T) + (B - \frac{K^2}{c_{11}^0 - L\tilde{n}^2}) \tilde{n}^2 + (D - \frac{LK^2}{(c_{11}^0 - L\tilde{n}^2)^2}) \tilde{n}^4 = 0$$
(11)

and

Ş

nd $(c_{11}^{0} - L\bar{n}^{2}) \tilde{e}_{1} - 1/2K\bar{n}^{2} = 0.$ (12)

Eq. (12) has been used to eliminate e_1 from eq. (11). In order to ensure that the transition is of the first order (which is appropriate for NIPC), $[B - K^2/(c_{11}^0 - L\tilde{\eta}^2)]$ must be negative.

B. The c₁₁ elastic anomaly.

Within the framework of the Landau theory, an effective elastic constant is calculated by a set of equations 2^{1}

 $\partial G/\partial \eta = 0; \ \partial G/\partial e_1 = X_1 = c_{11}e_1,$ (13)

Using the prescription of eq. (13) and eq. (8) gives

$$\partial G/\partial n = (A(T) - Ke_1 - Le_1^2)n + Bn^3 + Dn^5 = 0$$
 (14)

nd
$$\partial G/\partial e_1 = (c_{11} - Ln^2) e_1 - 1/2Kn^2 = X_1.$$
 (15)

In the high symmetry (high temperature) phase the strain and the order parameter possess only fluctuations, hence in eqs. (14) and (15) $\eta = \delta \eta$ and $e_1 = \delta e_1$. Employing the standard procedure, the c_{11} elastic constant becomes

$$c_{11} = c_{11}^{o}$$
, for $T > T_{o}$

8

in which c_{11}^0 is the background elastic constant which linearly increases with decreasing temperature.

In the low symmetry (low temperature) phase η and e_1 possess spontaneous values $\tilde{\eta}$ and \tilde{e}_1 given by eqs. (11) and (12). The order parameter and strain can then be described by small fluctuations $\delta \eta$ and δe_1 around the equilibrium values $\tilde{\eta}$ and \tilde{e}_1 , and thus

$$\eta = \tilde{\eta} + \delta \eta; e_1 = \tilde{e}_1 + \delta e_1.$$

Eqs. (14) and (15) can be written to linear order in fluctuations as

$$(A(T) + 3B\tilde{n}^2 + 5D\tilde{n}^4 - K\tilde{e}_1 - L\tilde{e}_1^2)\delta n - (K\tilde{n} + 2L\tilde{e}_1\tilde{n})\delta e_1 = 0$$
 (16)

$$(c_{11}^{0} - L\tilde{\eta}^{2}) \delta e_{1} - (K\tilde{\eta} + 2L\tilde{e}_{1}\tilde{\eta})\delta \eta = X_{1}.$$
 (17)

From this set of equations the elastic constant is found to be

$$c_{11} = c_{11}^{0} - L_{\tilde{\eta}}^{2} - \frac{(K_{\tilde{\eta}} + 2L\tilde{e}_{1}^{-})^{2}}{A(T) + 3B_{\tilde{\eta}}^{2} + 5D_{\tilde{\eta}}^{4} - K\tilde{e}_{1}^{-} - L\tilde{e}_{1}^{2}}$$
(18)

Using eq. (14)

kerred.

$$c_{11} = c_{11}^{0} - L\tilde{n}^{2} - \frac{(K + 2L\tilde{e}_{1})^{2}}{2B + 4D\tilde{n}^{2}}$$
 (19)

in which $\tilde{\eta}$ and \tilde{e}_1 are the equilibrium values given by eqs. (11) and (12). The above thermodynamic treatment which includes linear-quadratic and biquadratic coupling terms in the free energy (eq. 8) gives only discontinuous downward displacement of the elastic constant below the transition. Thus, higher order interactions do not explain the experimentally observed "softening" of c_{11} shown in fig. 2. These anharmonic terms further seem to be of little importance even close to the transition where critical fluctuations in η become large. These calculations indicate that the explanation of the critical behavior of the c_{11} elastic constant should be sought elsewhere; in particular, the dynamics of the system must be considered.

C. Other mechanisms.

As mentioned above, the linear-quadratic and biquadratic couplings between the order parameter and the zone center elastic modes do not affect the elastic properties within the Landau theory in the high temperature phase. The situation in the crystal is more complicated for the case of NIPC and other mechanisms which can at least in part contribute to the observed anomaly

of the [100] LA-phonon should be mentioned. Among these are (1) anharmonic <u>k</u>-dependent interactions between the [100] LA-mode and fluctuations of the order parameter, (2) a soft zone center optical mode which couples to the acoustic mode, (3) a mean field Landau-Khalatnikov contribution, and (4) dispersion of the elastic constant.

Anharmonic coupling to critical fluctuations of the order parameter $\langle n^2 \rangle$ may lead to a rounding of the discontinuity in c_{11} for T > T_o and generate an additional contribution in the low temperature phase.^{10,20} This mechanism accounts partially for the critical behavior in chloranil¹⁰, terbium molybdate²⁰ and ABO₃ perovskites.²² A soft optical mode at the Brillouin zone center seems to be one of the possible explanations assuming the coupling of such a mode to the Brillouin zone boundary mode during the transition exists. Coupling between strains and temperature dependent Raman-optical modes provides a satisfactory explanation for the elastic behavior in s-triazine¹² and the dependence of the qTA-mode in chloranil.¹⁰ A mean field Landau-Khalatnikov²³ contribution associated with the dispersion of the elastic constant can contribute to the elastic behavior in the low temperature phase as a rounding and restoring of the elastic constant. This mechanism is known to account partially for the behavior in layered perovskite compounds.²⁴

Although the above mentioned mechanisms can all contribute to the anomaly of the c_{11} elastic constant, especially in the vicinity of the phase transition, they cannot entirely account for the observed behavior. Thus we find them possible but not likely. As will be argued in the next section, the most reasonable explanation of the behavior of the [100] LA-phonon in NIPC is based on a dispersion-relaxation mechanism.

D. Dispersion of the elastic constant and dynamical mechanisms.

One possible explanation of the critical behavior of c_{11} is that the elastic constant exhibits a frequency dependent relaxation which undergoes

critical slowing down in the vacinity of the phase transition (ca. T = 137 + 40 K). We propose a semiquantitative interpretation of the phase transition in NIPC based on this assumption. Since no ultrasonic or neutron scattering data are available for NIPC, the detailed mechanistic dynamics cannot be treated in much detail. Measurements of the [100] LA-mode velocity by a piezoelastic "resonance-antiresonance" method^{6,15} give a value of 2150 ms⁻¹ at room temperature. The velocity is almost 30% lower than the velocity obtained by Brillouin scattering (2953 ms⁻¹). In the former method the velocity is measured at the frequency of a standing acoustic wave (~90 kHz) whereas in Brillouin scattering the velocity is measured at a frequency of ~10 GHz. The difference in the sound velocities measured by these methods is definitely outside the contribution from usual dispersion effects, typically less than 3%, and certainly much larger than the experimental errors. Moreover, the temperature dependence of the sound velocity obtained by both methods given in fig. 8 shows a slight suppression of the critical behavior in Brillouin scattering. In order to confirm the difference in the sound velocities at room temperature, we have additionally performed ultrasonic pulse-echo experiments at a frequency of 10 MHz. The velocity of the [100] LA-mode at 10 MHz is 2250 ms⁻¹.

The above experimental findings clearly suggest that dispersion/ relaxation and its critical behavior at the phase transition are important for the elastic properties of NIPC. Moreover, the change of the attenuation at the transition indicates that some dynamical relaxation process is involved in this behavior. One possible mechanism for such a relaxation effect would be a dipolar orientational-relaxation process. From the standpoint of a "ferroelectric" phase transition, the anomaly in NIPC could be represented as an order-disorder transition of the permanent dipole moments of the individual molecules. This mechanism remains in agreement with the gradual freezing of the librational motions of molecules observed in the x-ray measurements⁵ and with the temper-

ature dependence of the spontaneous polarization.⁴

The most straight-forward way to treat the frequency dependence in the high temperature phase is to assume a Debye relaxator form for the elastic constant:

$$c_{11}(\omega) = c_{11}(\omega) - \Delta c_{11}\left(\frac{T-T_{o}}{T_{o}}\right)^{-p} (1 + (\omega \tau)^{2}) - aT, \quad (20)$$

in which $\tau = \tau_{o}\left(\frac{T-T_{o}}{T_{o}}\right)^{-v}$

A good fit of the experimental results in fig. 2 to this equation may be obtained with parameters: $c_{11} (\infty) = 15.11 \times 10^9 \text{ Nm}^{-2}$, $\Delta c_{11} = 0.61 \times 10^9 \text{ Nm}^{-2}$, $T_0 = 135.5 \text{ K}$, $\rho = 1.01$; $\nu = 0.44$, $(\omega \tau_0)^2 = 1$ and $a = 1.5 \times 10^{-2} \text{ K}^{-1}$.

In the low temperature phase a restoring of the c_{11} elastic constant is expected as temperature decreases from T_o . The increase in c_{11} can be expressed in a manner similar to the critical softening of eq. (20)

$$c_{11}(\omega) = c_{11}'(\infty) - \Delta c_{11}' \left(\frac{T_o - T}{T_o}\right)^{-\rho} + (\omega \tau')^2 - aT$$
 (21)

in which $\tau = \tau_0^{-\tau} \left(\frac{T_0 - T}{T_0}\right)^{-\nu}$. The parameters which give a good fit of eq. (21) to the observed behavior in the low temperature phase are $c_{11}(\infty) =$ $17.19 \times 10^9 \text{ Nm}^{-2}$, $\Delta c_{11} = 3.96 \times 10^{-3} \text{ Nm}^{-1}$, $T_0 = 140.8 \text{ K}$, $\rho' = 0.43$, $(\omega \tau_0)^2 =$ 1 and $\nu' = 0.27$. If one expands eq. (20) and (21) in a power series in $(T - T_0)/T_0$, respectively, eq. (4), previously used for fitting the data, obtains. The fits of eqs. (20) and (21) to the data are not completely unique because of the number of available parameters. Consequently, a, T_0 , c_{11} (∞) and c_{11}' (∞) are chosen to correspond to the appropriate values obtained by fitting the phenomenological eq. (4) to the data. Moreover, since for Brillouin scattering typically $\tau_0 \omega \sim 1$ near the transition, $\tau_0 \omega \equiv 1$ in the above procedure. Nonetheless, the values of Δc_{11} , p and ν are not completely determined and siminlar quality fits can be obtained for small ($\pm 20\%$) variations of all three parameter values.

Assuming a Debye form for the dispersion, the relaxation time may be obtained, as shown in the case of barium sodium niobate, 25,26 by combining the temperature dependence of c_{11} from fig. 2 with the increase of attenuation displayed in fig 6. Employing the theory of a complex elasticity with a single relaxation time, 13 the elastic constant may be written as

$$c_{11}(\omega) = c_{11}(\infty) - \frac{\Delta c_{11}}{1 - \omega \tau (T)}$$
 (22)

Separating eq. (22) into real and imaginary parts yields

$$pv \left[100\right] = \text{Re } c_{11} = c_{11}(\infty) - \frac{\Delta c_{11}}{1 + (\omega \tau (T))^2}$$
(23)

and

$$\Gamma_{11}(T) = \Gamma_{\infty} + \frac{\Delta c_{11} \tau(T)}{1 + (\omega \tau(T))^2} - \frac{q^2}{2\pi\rho}$$
(24)

By combining these two equations one obtains a very simple expression for the relaxation time

$$\tau(T) = \frac{\Gamma_{11}(T) - \Gamma_{\infty}}{c_{11}(\infty) - c_{11}(T)} - \frac{2\pi\rho}{q^2} .$$
 (25)

Equation (25) is valid even if the relaxation time and coupling are wavevector dependent, since it involves data from a single frequency ω and wavevector q. Fig. 9 shows the inverse of the relaxation time as a function of temperature.

The line in the high temperature phase is of the form

$$\tau^{-1}(T,q) = \left| \frac{T-T_o}{T_o} \right| \quad \tau_1^{-1} + \tau_2^{-1} \quad (q) \quad .$$
 (26)

The fit to this equation gives $\tau_1 = 1.16 \times 10^{-12}$ s and $\tau_2 = 1.08 \times 10^{-10}$ s. In the low temperature phase

$$\tau'^{-1} (T,q) = \left| \frac{T_0^{-T}}{T} - \tau_1'^{-1} + \tau_2'^{-1} (q) \right|$$
(27)

with values of the coefficients $\tau_1 = 2.4 \text{ x} 10^{-12} \text{s}$ and $\tau_2 = 1.07 \text{ x} 10^{-10}$. The above temperature dependences of the relaxation times satisfy the prediction of a mean field critical slowing of the order parameter fluctuations in the vacinity of T_0 .

V. Conclusions.

The elastic properties of NIPC in the temperature range 90 K - 295 K have been investigated by Brillouin scattering. In particular, the nonferroic, first order phase transition at ca. 137 K has been examined. Our findings can be summarized as follows:

1. The c_{11} elastic constant associated with the [100] LA-phonon exhibits an anomaly extending ca. 40 K above and below the phase transition at 137 K. The anomaly has the form of a softening of the c_{11} elastic constant; c_{11} falls to a minimum value in the transition region. The halfwidth at half maximum of the [100] LA-phonon also possesses anomalous broadening around the transition temperature.

2. The c_{22} , c_{44} , c_{55} and most likely also c_{66} elastic constants exhibit a step-like anomaly at ca. 137 K characteristic of a first order transition. Practically no anomalous behavior is observed for the c_{33} elastic constant. Only weak anomalies for the c_{12} , c_{13} and c_{23} elastic constants are found.

3. Sound velocity diagrams in the three crystallographic planes are calculated at room temperature using the values of the elastic constants determined in our experiments.

In order to explain the anomalous behavior of the c_{11} elastic constant two possibilities are considered: 1) an elaboration of the Landau theory with the inclusion of the linear-quadratic and biquadratic couplings between the zone boundary order parameter and zone center elastic strain; and 2) dispersion of the elastic constant combined with a temperature dependent relaxation process.

EXECUTION REPORTED FOR THE PROPERTY IN THE PROPERTY INTERTY IN THE PROPERTY IN THE PROPERTY INTERTY IN

The c_{11} snomaly cannot be understood within the framework of the Lendau theory which can only account for the downward discontinuous change of c_{11} at the transition. The anomaly can be understood by assuming dispersion of the elastic constant, possibly due to some relaxation process. This dynamical approach is justified by experimental findings: a large difference in the velocity of the [100] LA-phonon measured by experimental techniques employing different frequency domains; and suppression of the critical behavior at high frequencies (~10 GHz). In the framework of this latter approach the experimental data are reproduced using a power law equation including a term due to the assumed Debye relaxation behavior. The temperature dependence of the relaxation time is calculated by combining the temperature dependences of the elastic constant and attenuation. This behavior is found to satisfy the mean field dependence characteristic of critical slowing down.

FIGURE CAPTIONS

Figure 1 Polar plots of the sound velocity of different acoustic modes in the ab (a), ac (b), and bc (c) planes of NIPC, obtained using the nine independent elastic constants listed in Table II. The lines are calculated using the general solutions of the equation of motion, eq. (2). Particular solutions in the directions of the crystallographic axes and diagonals are given by relations from Table I. The units are 10³ ms⁻¹.

- Figure 2 Temperature dependence of the c₁₁ elastic constant. (o), (x) correspond to two different experimental runs performed using the samples of different orientations. The two runs are normalized at 190 K. The lines represent fits to the phenomenological eq. (4) with the values of the parameters given in the text.
- Figure 3 Temperature dependences of the c₂₂ and c₃₃ elastic constants: (o) and (x) represent different experimental runs.
- Figure 4 Temperature dependences of the c₄₄, c₅₅ and c₆₆ elastic constants: (o) and (x) correspond to two independent experimental runs.
- Figure 5 The temperature development of the NIPC Brillouin spectrum due to [100] phonons. The free spectral range is 21.8 GHz. The longitudial and transverse modes, labeled L and T, respectively, correspond to the Rayleigh peak marked R. The spectra are taken in right angle scattering ($\theta = 90^{\circ}$) in triple-pass.

Figure 6 Temperature dependence of the Brillouin helfwidth at halfmaximum for the Brillouin feature corresponding to the [100] LA-mode in fig. 5. The halfwidth was not deconvoluted with respect to the width of the Rayleigh peak. (o) and (x) correspond to the two independent experimental runs. The lower points represent the temperature dependence of the Brillouin intensity of the same Brillouin feature taken as the area underneath the peak.

- Figure 7 Temperature dependence of the effective elastic constants corresponding to [110] (a), [101] (b) and [011] (c) acoustic phonons specified in Table I. (o) and (x) correspond to different experimental runs.
- Figure 8 Temperature dependences of the sound velocity of the [100] LAmode obtained by Brillouin scattering (crosses) at a frequency 12 GHz and "resonance-antiresonance" method (circles) at a frequency 90 KHz. The scales are slightly shifted with respect to one another for easy comparison.
- Figure 9 Temperature dependence of the inverse relaxation time associated with the c₁₁ elastic constant. Solid lines are the least squares fits to eqs. (24) and (26) in the high and low temperature phase, respectively.
