ABSTRACT

This thesis describes the design and implement of a **prototype** compiler for the functional programming language PHI. The design is highly modularized and the authors think this should facilitate the understanding of both concept and implementation. The front-end of the compiler implements machine independent lexical and syntactic analyzers; top-down parsing techniques are employed. The back-end implements a machine dependent one-pass semantic analyzer and code generator.

Since this implementation is a **prototype**, it does not possess all of the qualities desirable in a full implementation. The basic constructs of PHI: functions and data definitions are implemented, as well as the integer, natural number, and boolean types. However, the necessary hooks are present and the design is mature enough to allow expanding the prototype to a full implementation.

I. INTRODUCTION

A. BACKGROUND — GENERAL

In its attempt to provide students with a well rounded background to the field of computer science, the computer science department at the Naval Postgraduate School offers courses covering recent developments in programming languages. One of the courses deals specifically with the methodology of functional, also known as applicative, programming. Both the theory and the practice of functional programming are covered, concentrating more on the practice than the theory. In order to fully appreciate the nuances of functional programming it would be desirable to provide the students with a functional programming environment. This would provide a first hand look at the fundamental difference in methodologies when programming in functional languages as opposed to programming in traditional imperative languages.

Of the languages currently supported in the department, LISP, on the UNIX¹ environment, comes the closest to meeting this requirement. Although LISP is considered a functional language by some, its many extensions and modifications actually brings it into the world of imperative programming. It is not a pure functional programming language.

There are several additional problems associated with using LISP to teach techniques of functional programming. Modern LISP dialects do not support all aspects of functional programming. Most notably they lack the ability to define higher-order functions. Dynamic scoping and the semantics of the language make it a pedagogical nightmare to teach.[Ref. 1:p. Ø-1] The goal of teaching functional programming would rapidly be overtaken by the necessity of explaining the idiosyncrasies of LISP. In an 11 week

¹UNIX is a trademark of Bell Laboratories.

quarter, time devoted to LISP would significantly detract from instruction of functional programming.

Recognizing the shortcomings of LISP, a pure functional language, PHI was developed by Dr. B. J. MacLennan for use in this course of instruction. The syntax of PHI closely follows that of standard mathematical notation. This means students should have little difficulty in learning how to write legitimate PHI statements. Instruction can now concentrate on joining these statements to create functional programs. Hopefully, this will lead to a greater understanding and appreciation of the methodology of functional programming.

B. BACKGROUND — THESIS

Creation of PHI solved the problem of finding a suitable language to use to demonstrate the methodology of functional programming. However, currently PHI programs are programs *on paper* only. There exists no programming environment for the PHI language. So it is impossible to machine execute PHI programs. This thesis attempts to remedy the above problem by providing the first component in a PHI programming environment — a prototype PHI compiler.

Conventional compiler construction techniques were chosen for this implementation for several reasons. By choosing conventional techniques, the authors were able to address the problems associated with utilizing conventional methods for implementing a compiler for a functional language². Additionally, realizing that both the language and system would change, the authors wanted a well documented and understood methodology. The cost of maintaining a system can be as much as three times the development cost [Ref. 2:p. 478]. Therefore, it was imperative to choose a methodology that supported a clean and structured design.

²Specific problems and solutions are covered later in Chapters Two and Three

Following conventional methodologies, the authors separated the PHI compiler design into a front-end³ and a back-end⁴. The overall general design of the PHI compiler is shown in Figure 1.1. The front-end, containing the scanner (lexical analyzer) and parser (syntactic analyzer) is essentially responsible for analysis of the external file containing the source program. The PHI compiler back-end couples semantic analysis with code generation to produce code suitable for execution on the target machine. [Ref. 3:pp. 5-6] The authors felt that a clear and distinct separation between parts would aid understanding of the system, simplify division of labor, and increase ease of development and maintenance. It should also result in greater flexibility for follow-on development in the PHI programming environment. As an example, the current front-end could be modified to support a PHI interpreter.

Figure 1.1 General Design of the PHI Compiler

C. BACKGROUND — FUNCTIONAL PROGRAMMING

Functional programming is a methodology in favor among academicians. Although applicative programming goes further back, it is generally agreed that, as a methodology, functional programming traces its roots to John Backus [Ref. 4:p. 404, Ref. 5:p. 65]. In

³Design and implementation of the front-end is discussed in Chapter Two.

⁴Design and implementation of the back-end is discussed in Chapter Three.

his acceptance speech for the 1977 ACM Turing Award, Backus criticized traditional programming languages and programming styles. He went on to propose a new methodology of programming that involved "the use of a fixed set of combining forms called functional forms." [Ref. 6:p. 619] This methodology is known today as functional programming.

1. Problems with Conventional Languages

Backus feels [Ref. 6:pp. 613-619] that the basic underlying problem with conventional languages is the existence of the assignment statement. The assignment statement plays a central role in conventional languages and breaks programming into two worlds. Backus calls the right-hand side of assignment statements, expressions, the first of these worlds. The second world is the world of statements, with the primary statement, of course, being the assignment statement.

Several problems are associated with assignment statements. First, they permit programs to be held hostage through access to their variables. Since variables are used to imitate the machine's storage cells; assignment statements allow, even encourage, state changes to take place. This access, either direct or indirect, permits such problems as side effects, unintentional state changes, and aliasing to arise. It then becomes difficult to reason about the correctness of these programs, so proving simple programs correct is an arduous task and proving complex programs correct is virtually impossible. Additionally, by permitting the value of variables to be changed, the assignment statement makes temporal order of execution of statements critical. For example, the following two pieces of code produce dramatically different results depending on which statement inside the for loop is executed first.

```
for (i = 0; i != some_value; ++i)
{
    if (i % 2 == 0)
        continue;
    DoSomething(i);
}
```

```
for (i = 0; i != some_value; ++i)
{
    DoSomething(i);
    if (i % 2 == 0)
        continue;
}
```

These problems interact so that it becomes extremely difficult to create new programs out of old ones. [Ref. 6:pp. 613 - 619, Ref. 1:pp. 1-2 - 1-2Ø]

Another problem associated with assignment statements is that each produces only a one-word result. In effect, they force programmers to think in a word-at-a-time manner. For example, to apply a function to an entire array of values, the programmer must access each value individually. Not only is this wasteful of computer assets, but it results in what Backus refers to as the "von Neumann bottleneck" of conventional programming languages. [Ref. 6:pp. 613 - 619]

2. Functional Languages

Backus proposes the methodology of functional programming as the solution to these problems. Functional languages have removed variables and the assignment statement from their syntax so that their basic building block becomes the function. It is through "the use of a fixed set of combining forms...plus simple definitions" [Ref. 6:p. 619] that the programmer is able to build new functions from existing functions. It thus becomes possible to form a new program by combining two or more existing programs or functions together.

The absence of assignment statements and variables removes the problems plaguing conventional languages caused by side effects, etc. because the program now operates exclusively in the world of expressions. This permits the programmer to maintain a clear conceptual view of the program. It is easier to understand and reason about the task the program is to perform [Ref. 5:pp. 65 - 69]. It now becomes not only possible, but practical to prove programs correct [Ref.6:pp. 624 - 625].

Another direct benefit stemming from the absence of side effects is order. The values of expressions are no longer dependent on the order in which they are evaluated. Therefore, functional languages provide a natural means of performing parallel computations [Ref. 7:p. 35]. Functional languages and the associated methodology of

functional programming may very well provide the key to programming the massively parallel computers entering service nowadays. All of the above benefits have applicability to ongoing research in the SDI program.

The authors feel that functional programming can best be summarized by the following thought — assignment statements are to functional programming what GOTO statements are to structured programming.

D. ASSUMPTIONS

An IBM⁵ personal computer/IBM compatible personal computer was chosen as the target machine for this implementation. The authors felt that the nature of the language and its intended use were better suited for the PC/personal work station environment as opposed to a mini- or main-frame time shared environment. The PC environment should provide greater flexibility and freedom when implementing follow-on tools for the PHI programming language. Also, future compiler improvements will not have to be concerned with extraneous interfaces to another system. Working with a PC environment eliminates the need to take into account the effects the PHI environment will have on another user of the system. The implementor is able to work with a system that remains constant — a known quantity.

The assumed target machine configuration is based on the equipment available in the Naval Postgraduate School's computer science microcomputer lab. Each machine is configured with 640K bytes of RAM, one (most have two) 20M byte hard disk drive, one 1.2M byte 5 inch floppy disk drive, and the 8087 math co-processor; each currently operates under the MS-DOS⁶ 3.x operating system. These machines are readily available to all computer science students at the Naval Postgraduate School, and many students own

⁵IBM is a registered trademark of Internal Business Machines Corporation.

⁶MS-DOS is a registered trademark of Microsoft Corporation.

personal computers with similar configurations. It is not necessary to utilize a hard disk when executing the PHI compiler.

E. CONSTRAINTS

As is the case with most implementation theses, time was probably the biggest constraint facing the authors. This involved making certain trade-offs; e.g. should the major effort be directed towards a full implementation of PHI while concentrating on a particular component of the compiler, or should the major effort be directed towards a full implementation of the compiler while concentrating on a subset of the PHI language? The authors felt that the greatest benefit could be gained by implementing a complete compiler. Having to actually face the issues and problems associated with designing, implementing, and interfacing a full compiler implementation would be much different than just reading about them in a text. As a result, this thesis implements only a subset⁷ of PHI.

Since PHI is an experimental language it is still undergoing changes and revisions. Trying to modify and update the compiler design with each version proved to be an impossibility. The authors were forced to freeze the design based on the language as it stood on 07 January 1987. Any follow-on work will need to update the front-end and back-end of the compiler to meet the requirements of these new versions of PHI. A description of the grammar as implemented and a description of the latest version of the grammar may be found in the Appendixes.

⁷This subset is discussed in the individual chapters on the front-end and back-end.

II. FRONT-END OF THE COMPILER

The authors separated the design of the PHI compiler into two modules, a front-end and a back-end. These modules were then further subdivided to produce the general layout of Figure 1.1. The authors believe this modularization simplifies the design and will aid in understanding the system, thus decreasing future maintenance problems.

The front-end of the PHI compiler is comprised of the scanner (lexical analyzer), the parser (syntactic analyzer), and their associated error recovery routines. Two possible interactions between the lexical and syntactic analyzers were considered. The first incorporates the scanner into the parser, and tokens are produced by the scanner only upon request of the syntactic analyzer. Thus, this system acts like a pipeline. An alternate method is to allow the scanner to tokenize the entire source program, store the tokens in some data structure, and pass this structure to the parser. [Ref. 3:p. 10]

For the prototype implementation of a PHI compiler, the authors based the design on the first interaction. Although the second method is conceptually very easy to understand, the authors think the current implementation is clean and will readily lend itself to future enhancements. Any input alphabet peculiarities are restricted to the lexical analyzer, and this independence should provide benefits for the next student(s) who work on the PHI programming environment.

A. LEXICAL ANALYSIS — THE SCANNER

The PHI compiler reads a source file of ASCII text which is fed to the scanner for lexical analysis. The principle task of lexical analysis is to separate or divide the source program into tokens for use during syntactic analysis [Ref.8:p. 84, Ref. 9:p. 155]. This is accomplished in the PHI compiler through a character-by-character examination of the

user's source file. These characters are assembled/grouped into the individual tokens which represent terminal symbols of the PHI grammar. Examples of some of the terminal symbols are operators, identifiers, keywords, and constants. A complete listing of the PHI tokens may be found in the header file for the scanner in Appendix E.

The primary advantage to tokenizing the source program is that the design of the syntactic analyzer needs to take into account only one type of data unit — the token [Ref. 3:p. 7]. This simplifies the design of the parser because provisions do not have to be made for handling white space and comments. The scanner has already removed them. Also, removing white space and comments and utilizing a fixed-length representation for the tokens saves space. Once tokenization is complete, the source program can be discarded and the compacted tokenized file can be utilized for further analysis.

In order to correctly tokenize the source file there must be some discrete means available to accurately represent each token. There are several ways of describing tokens. One means available is to use a regular grammar. In this method "generative rules are given for producing the desired tokens" [Ref. 3:p. 142]. An equivalent, but different, method is to use finite-state acceptors, FSAs, to recognize tokens. The authors found it easier to visualize this as a recognitive vice generative problem. For this reason the various tokens were modeled using FSAs. An example of an unsigned number recognizer is shown in Figure 2.1. The interested reader is directed to Tremblay and Sorenson [Ref. 3:Chapter 4] for an excellent introduction to the practice of using FSAs to model tokens. The authors found that utilizing FSAs greatly simplified the design, coding, and debugging of the lexical analyzer — one picture was worth a hundred lines of code.

The ideal grammar would allow each token to be uniquely and unambiguously identified. Once the lexical analyzer started on the path of building a token, it would be able to continue until the end with no backtracking. Due to limitations with the standard

Figure 2.1 Unsigned Number Recognizer

ASCII character set, the designer of PHI used multiple keystrokes, or characters, to represent various operators in the language⁸. This resulted in compound token types. Also, as in other programming languages, PHI overloads certain operators, allowing them to do double duty⁹ by taking on different context-dependent meanings.

The problem of dealing with compound token types was easily handled through the use of a single lookahead character. For example, upon finding the character "-", the scanner looks ahead to the next character to see if it is ">" (→) or another "-" (--). If the next character is neither of these two, it indicates that the token is just the simple token "-". Distinguishing overloaded operators was solved by essentially ignoring it in the scanner! The authors took the position this is basically a syntax analyzer problem and there was no reason to complicate the scanner by handling it. The scanner just identifies a generic token type, e.g. SUB_, and lets the parser make the proper determination of its true meaning, e.g. SUB_ or NEG_.

There are several design decisions relating to the lexical analyzer worth noting. The authors, following the example of Pascal, C, and other languages, took the position that

⁸Some examples of this are -> for →, == for = and <> for ≠.

⁹For example, + and - can serve as either an unary or binary arithmetic operator.

PHI's keywords¹⁰ are reserved words and may not be redefined and used as identifiers. Alternate decisions would have been to distinguish keywords from identifiers based on context, as PL/I does, or to precede them by some special character, as ALGOL 6Ø and ALGOL 68 do [Ref. 3:p. 91]. PHI has a very small set of keywords, smaller than C's, and the authors think that this decision makes life easier for the programmer by simplifying debugging of programs. It certainly made life easier for the authors.

PHI's grammar makes no provisions for programmer comments. The authors originally implemented comments by requiring the programmer to explicitly indicate the beginning and end of each comment with a special character. After scanning the special character at the beginning of the comment, the lexical analyzer would ignore all following characters until the special character was once again found. Following conversations with PHI's designer this implementation was changed. Comments are now implemented the same way they are in Ada¹¹: the comment terminator is the end-of-line character. Not only did this simplify the recognizer for comments, but it also completely removed the problem of runaway comments.

A name table is used to point to the names of all identifiers and constants. A symbol table was originally utilized but later discarded when the authors realized the syntax of PHI makes analyzing an abstract syntax tree easier than analyzing a flattened tree. The information normally associated with a symbol table is now held in the nodes of the tree. This permits just the first instance of each name to be placed into the name table. In other words, regardless of how many times and in how many scopes the identifier X is used, X appears only once in the name table. The token returned to the parser would indicate a

¹⁰A complete listing of PHI keywords may be found in the header file for the scanner in Appendix E.

¹¹Ada is a trademark of the Ada Joint Programming Office, Department of Defense, United States Government.

token type of identifier and the parser would then know to dereference the pointer to find the string containing the actual name, X.

Because keywords are reserved, each potential identifier must first be compared against the possible keywords prior to being placed in the name table. The authors implemented a keyword table to simplify this process. Knuth [Ref. 10:pp. 406-410] has shown that a binary search is the most efficient way of searching an ordered table, using only comparisons. For this reason the keyword table is kept in alphabetical order. The lookup, which is at worst $O(\log n)$, is performed using a binary search of the keyword table.

In an attempt to improve the efficiency of the name table, the authors implemented it as a hash table. McKeeman [Ref. 11:pp. 253-301] experimented with six different length dependent hash functions. He found that the function producing the best results involved summing the internal representation of the first and last characters of the variable's name with its length shifted four places to the left. This was the function utilized by the authors. The possibility of collisions is reduced by choosing a prime number as the table size. However, since this only reduces, not eliminates, the possibility of two or more names hashing to the same value; the authors had to make provisions for handling collisions.

A variant of the chaining method of collision-resolution was chosen. In PHI's implementation, each of the name table slots/buckets holds a data structure that can contain both the name of the variable and a pointer to another structure of the same type. So each hashed value points to a linked list of names. This method offers the advantage of providing better performance than linear probing [Ref. 12:p. 89], is conceptually easy to visualize/work with, and also solves the problem of possibly overflowing the hash table. It does require slightly more memory to implement, but the authors determined that the benefits of this method far outweighed the slight increase in storage requirements. [Ref. 12:pp. 83-93]

B. SYNTACTIC ANALYSIS — THE PARSER

The purpose of the parser is twofold: 1) to determine if the program, as represented by the output from the scanner, is syntactically correct; 2) to impose a hierarchical structure on the token stream, fitting it into the abstract syntax tree which is the output of the parser [Ref. 8:pp. 7-8, Ref. 9:p. 7]. Traditionally, these tasks are done by either a top-down or bottom-up methodology [Ref. 8:p. 41]. Both methodologies use the tokens generated through lexical analysis.

The terminology top-down refers to the order in which the nodes of the parse tree are constructed. Top-down parsing starts from the root of the tree and proceeds downward towards the terminal symbols at the leaves. The parse tree is constructed from the top to the bottom by applying *productions* of the grammar to generate strings of terminals and nonterminals. On the other hand, bottom-up methodologies start from the terminal symbols at the leaves and proceed upwards to the root. The parse tree is constructed from the bottom to the top by applying *reductions* of the grammar to generate single nonterminals from strings of terminals and nonterminals. [Ref. 8:pp. 40-41, Ref. 9:pp. 134-136]

It is generally agreed that the popularity of top-down parsing techniques is "due to the fact that efficient parsers can be constructed more easily by hand". [Ref. 8:p. 41] The authors can attest to the fact that the concept of top-down parsing is very easy to grasp. When parsing PHI, it is natural to begin with the start symbol of the grammar, BLOCKBODY, and work forward from there to analyze the token stream. So, partially because of its efficiency, but primarily because of its ease of understanding and use, the authors chose the top-down methodology of recursive-descent parsing to design and implement the syntactic analyzer.

In recursive-descent parsers, separate procedures/functions are written to recognize each nonterminal of the grammar [Ref. 3:pp. 219-220]. This technique gets its distinctive name "because nonterminals can appear in the right-hand sides of each other's

productions, the procedures for recognizing nonterminals are recursive." [Ref.9:p. 150]

To state it more clearly, the function to recognize nonterminal 'A' could end up calling itself recursively if either 1) 'A' appears on the right-hand side of the production describing 'A' itself, or 2) 'A' appears on the right-hand side of the production describing another nonterminal 'B' and 'B' appears on the right-hand side of the production describing 'A'. Regardless of how one looks at the nature of the technique, one usually identifies a stack with recursion. What made this technique so easy to implement was that the authors were able to use C's underlying mechanism for handling recursive functions. The authors did not have to *explicitly* maintain a stack of symbols for each function call; instead, the information was *implicit* in the stack of activation records resulting from each function call.

Top-down parsing techniques, especially recursive descent, offer straightforward means of implementing a syntactic analyzer. However, these techniques are applicable only to a subset of the context-free grammars and it is **essential** that all left recursion be eliminated from the grammar [Ref. 3:p. 211]. In other words, there must not exist any productions describing nonterminal 'A' with 'A' appearing as the first element on the right-hand side of the production. Obviously, if this situation existed, it would be possible to present the parser with strings to parse that would cause it to enter "an infinite loop of production applications" [Ref. 3:p. 211], never to be heard from again. The PHI production `QUALEXP = QUALEX WHERE AUXDEFS` is an example of this type of string. The parser would hang up looking for `QUALEXP` and would never leave this loop until the machine ran out of memory stacking activation records. In order to employ top-down parsing techniques with PHI the authors rewrote the PHI grammar to be right-recursive¹². However, as shown below, even the new grammar does not lend itself to "pure" recursive descent parsing techniques.

¹²The right recursive syntax of PHI may be found in Appendix D

From the compiler writer's point of view the ideal grammar would allow the correct production rule to be applied in every step of the parsing process. Constructing the parse tree would then proceed in a completely deterministic manner. When this is not possible, there are two basic parser design methods for dealing with nondeterminism in the grammar [Ref. 9:pp. 151-152]. In the backtracking method, which is generally not applicable to recursive-descent techniques, the parser picks an arbitrary production and continues with the parse [Ref. 9:p. 151]. If the parse is successful it is assumed that the correct production was chosen. However, if an error is later discovered, the parser *backtracks* to the last choice, a new production is chosen, and the parser presses forward again. This process continues until either the parse is successful or the parser runs out of possible productions to choose from. The second method requires a modification to the grammar which results in a deterministic parser: the grammar is rewritten using a process called left factoring to avoid choices among nonterminals [Ref. 9:p. 151].

For the most part, the design of PHI is conducive to recursive descent parsing techniques. There are, however, several productions where this is not so. The result was that a degree of nondeterminism arose in the parser design. The authors attempted to solve this problem through a combination of left factoring and the employment of a simple single token look-ahead. This solution worked for all but the two productions described below. In one case a two token look-ahead was employed and backtracking was used in the other. This is not to say that the authors are absolutely certain that PHI is **not** an LL(1) grammar or that backtracking **had** to be used. These solutions were used because they solved the problem at hand.

A two token look-ahead was used for the production¹³ `ARGBINDING = [ QUALEXP OP ]`. When the token '[' is found, a flag is set to indicate that an `ARGBINDING` is being parsed. The first look-ahead token is utilized when parsing the `QUALEXP` part. `QUALEXP`,

¹³A complete description of the PHI grammar may be found in the Appendices

for example, may parse as TERM, which in turn may parse as either FACTOR or FACTOR*TERM. After succeeding on FACTOR, a look-ahead is employed to look for the MULOP, *, to see if a recursive search for another TERM should be initiated. This methodology works as long as QUALEXP was not called from ARGBINDING. If it was called from ARGBINDING, argbinding flag set, the operator * could be the trailing operator in the ARGBINDING production and not part of the TERM production. In order to make this determination, an additional look-ahead is utilized to look for the token 'J'. If 'J' is found the QUALEXP production is terminated, e.g., term does not recursively call itself again, and the ARGBINDING production is allowed to proceed to completion.

Backtracking was utilized when parsing productions of ACTUAL: ACTUAL = COMPOUND and ACTUAL = DENOTATION = FORMALS $\rightarrow$ ACTUAL. Legitimate PHI sentential forms produced by the production FORMALS = (FORMALS⁺) are proper subsets of the sentential forms produced by the production COMPOUND = (ELEMENTS), excluding the empty compound statement. Since any number of identifiers may appear between the parentheses, it is not practical during the parse to utilize look-ahead to determine the presence of the token " $\rightarrow$ ". In effect, the parser first realizes it was parsing a DENOTATION when it finds " $\rightarrow$ ". This problem was solved by designing the parser to apply first the compound production when presented with this choice. If " $\rightarrow$ " is later found, the parser then backtracks¹⁴ to the FORMALS production. The normal costs associated with backtracking were not evident in this isolated case. As described below, space trade-offs had previously been made and the parser was already working with an abstract syntax tree. The root to the subtree containing the previously parsed compound was simply passed to the FORMALS production to insure that the string could have been

¹⁴A purist would say that this instance of backtracking means that the PHI compiler does not in fact employ a recursive-descent parser.

produced by FORMALS. After ascertaining FORMALS, the parser now continues the parse using the DENOTATION production.

The production `QUALEXP = QUALEXP WHERE AUXDEFS` required a deviation from pure recursive descent parsing. The semantics of this production are such that a terminal (e.g., an identifier) may be used prior to its definition. In itself, this does not present a major problem for the compiler writer. However, this construct also changes the scope of the identifier since the *inner-most* scope, in the form of the QUALEXP, is parsed first and the parser then works its way to the *outer-most* scopes, the AUXDEFS. This problem is analogous to that of mutual recursion in Pascal, without the benefit of the forward declaration [Ref. 4:p. 213].

Originally, the parser was designed to output the parse tree in flattened form, essentially a post-order walk of the tree. This design implemented traditional symbol-table management routines. However, after obtaining a clearer understanding of the semantics involved with the problems mentioned earlier, notably the production `QUALEXP = QUALEXP WHERE AUXDEFS`, the authors realized a traditional symbol-table would be too inefficient. Management of the table would take an inordinate amount of assets and be too unwieldy to work with. The authors solved this problem by maintaining the status of the parse in an abstract syntax tree so the output from the parser is now in tree form. This permits information originally held in the symbol-table to be maintained in the tree itself. The parser is able to analyze the source program by *walking* the tree and *decorating* the nodes with required information. Maintaining a binary tree in memory does require more space, but this is insignificant when compared with the benefits.

Interestingly, maintaining the parse in tree form presented several additional benefits. The solution to the aforementioned problem of distinguishing between COMPOUND and DENOTATION became trivial because it was now simply a matter of returning to the appropriate subroot and rewalking the tree. Also, working with a binary tree permitted the

authors to perform a modicum of optimization in the parser. It becomes relatively straightforward to perform compaction on an actual tree.

The authors think that this design offers maximum potential for future enhancements of the PHI programming environment. One possibility would be to use this front-end to drive a PHI interpreter. Modularization of the front-end in this manner simplifies functional understanding of the front-end and should lead to increased ease of maintenance and portability. To demonstrate portability, the authors recompiled the front-end and executed it on a 68000 based processor. This was accomplished with no modifications to the source program, just replacement of C run-time header files for the new target machine.

C. ERROR HANDLING

Tremblay and Sorenson [Ref. 3:p. 183] classify error responses into three categories:

- I. Unacceptable responses
 1. Incorrect responses (error not reported)
 - a. Compiler crashes
 - b. Compiler loops indefinitely
 - c. Compiler continues, producing incorrect object program
 2. Correct (but nearly useless)
 - a. Compiler reports first error and then halts
- II. Acceptable responses
 1. Possible responses
 - a. Compiler reports error and *recovers*, continuing to find later errors if they exist
 - b. Compiler reports the error and *repairs* it, continuing the translation and producing a valid object program
 2. Impossible with current techniques
 - a. Compiler *corrects* error and produces an object program which is the translation of what the programmer intended to write

In the prototype PHI compiler, the authors have implemented a limited form of error *recovery*. The primary benefit of error recovery is to "prolong the compilation life of the program as long as possible before the compiler gives up on the source program". [Ref. 3:p. 11] This allows the maximum number errors to be discovered per compilation, shortening the edit, compile, debug cycle inherent to writing computer programs.

The authors analyzed the intended environment and use of the PHI compiler and decided that lexical analysis and syntactic analysis were the most likely source of errors.

Lexical errors basically involve invalid characters or incorrect tokens. Common examples of these types of errors are unrecognized words, misspelled identifiers/keywords, or illegal characters. Syntactic errors relate to incorrect structure of the program. These errors arise when the programmer failed to follow the rules, productions, of the grammar. The form of the program is wrong. [Ref. 9:p. 226, Ref. 3:p. 185]

One thing the error handler should **not** do is exacerbate the situation by reporting bogus errors or executing an erroneous program. To insure erroneous programs are not executed, the authors inhibited object file production if any errors were discovered. The authors do not believe the compiler should allow code generation to continue, or even begin, if the source program has errors. Often times one error leads to an avalanche of errors being reported and this is extremely annoying to the programmer. The authors attempted to minimize this situation, but found it impossible to eliminate completely because some errors feed on others. To insure the programmer would not become overwhelmed with error messages, the authors terminate the compilation after 10 errors. Also, for programmer convenience, actual error messages are outputted instead of error codes. The authors saw no justification in using a cryptic code when a plain language message served much better. Since the authors anticipate students in functional programming classes to be primary users of the PHI compiler, error messages have their basis in the productions describing the PHI language. It is assumed that users of the PHI compiler have an understanding of PHI's syntax.

III. BACK-END OF THE COMPILER

A. OVERVIEW

The back-end of the compiler consists of the semantic checker and code generator. Semantic checking and code generation are completed in one pass, and the output is a sequence of bytes, held in memory, which correspond to ASCII characters. These characters are then written to a text file, which the assembler uses to output an object file. This output is linked to the appropriate run-time routines to make a usable program. For the current implementation, a RASM86 assembler and LINK86¹⁵ linker are used.

B. RUN-TIME ORGANIZATION

Since PHI is a structured language with scoping and function calls, it lends itself to a stack-oriented run-time architecture. The stack is set up to accomplish two tasks: 1) to hold pointers to the current operands, and 2) to hold activation records for functions currently in use. Both of these tasks are described below.

There is a 64 kilobytes limit on memory used while a program is running. This limitation is imposed because the memory is addressed as an offset from a base address, and the maximum offset is 64K. This space is competed for by the stack, current variables, and constants (see Figure 3.1). The stack grows from the top of this space down, and the variable space grows from the base of this space up, preventing wastage by either component. Because PHI is a functional language, a value is returned from each operation, and a pointer to this value is placed at the top of the stack. The returned value is placed in the lowest available space in the part of memory assigned to variables and constants. A heap allocation method is not currently used because 1) all data types currently implemented use only one word of memory, and 2) there is no fragmentation of

¹⁵RASM86 and LINK86 are trademarks of Digital Research, Inc.

memory because all types are currently static. If the next operation is a binary operation, a pointer to the second operand is placed on the stack, and the operation takes place using the two topmost pointers. The result is placed in memory, and the process begins afresh with new operands. If the next operation is unary (such as the negation operation), no change to the stack takes place and the variable in memory is altered as the program directs.

Figure 3.1
Memory Organization

If the second operand of an operation is to be the result of a function call (e.g., " $2 * f(x)$ "), an activation record is placed on top of the pointer to the first operand and the function's value is calculated. Then, the activation record is deleted and a pointer to the function result is saved and placed at the top of the stack.

Figure 3.2
Activation Record

The activation record itself, Figure 3.2, contains three parts: the static link, the static nesting level, and a pointer to the address in memory where the function's first variable is stored. The static link is a one-word pointer which points to the static nesting level space of the previous activation record, and is used to traverse the stack from activation record to activation record, i.e. a static chain. [Ref. 4:p. 77]. The static nesting level and the pointer to the base of the storage space for a scope's values are used to access variables and constants. In this design, a two-tuple (**B**, **L**) is associated with each variable. In this two-tuple, **B** represents the static nesting level and **L** is the offset within that level. By following the static chain for (current nesting level - target nesting level) links, the activation record of the scope of the target value can be accessed. Then, the address of the variable is calculated by adding **L** to the low address of the scope's variables. An alternate method would have been to store the values directly in the stack between or within activation records. However, this is a messy process when dealing with dynamic data structures such as sequences. Additionally, it is conceptually easier to divide the stack and the variables.

Functions are implemented as calls to assembly language subroutines, with pointers to the arguments placed on the stack before calling the routine. Using this scheme, and noting the fact that PHI cannot have side effects, the implementation of recursion is straightforward. Whenever a function is called, its activation record is placed on the stack and pointers to its arguments are placed on top of the activation record. If the function is

recursive, the assembly language subroutine simply calls itself until the base of its recursion is reached or until stack overflow is reached. Figure 3.3 shows an example of a series of activation records called by a program with a recursive function. Note that the data definition ("answer") has no arguments and simply calls the factorial function. The factorial function, on the other hand, has an argument and it uses that argument as an operand. So, a pointer to that value is put on the stack and the next operand, $\text{fac}(n - 1)$, is put on the stack as an activation record. When $\text{fac}(n - 1)$ is evaluated, a pointer to its return value is placed on the stack. This cycle of evaluation, pop activation record, evaluation will continue until the data definition "answer" is evaluated.

Figure 3.3
Factorial Program and Activation Records

As an example of the code generated for function calls and recursion, the following PHI program fragment is used : $C(n) == \text{if } n = 0 \text{ then } 1 \text{ else } C(n - 1) * n \text{ endif.}$

This, of course, simply calculates the factorial of the integer n. Figure 3.4 is the listing of the assembly language segment which is generated from this fragment.

Figure 3.4
Assembly Language Output from Factorial Program

The label "a10001" at address 0103 is the label of the subroutine which returns the factorial. When it is called, pointers to the values of the arguments are placed on the stack. If the subroutine is called before the base of the recursion is reached, a jump is made to label a10003. Then, the new actual value ($n - 1$) is calculated and placed in the low part of memory, a pointer to the value is put on the stack, and the values are prepared for calling

by the next subroutine (lines 0126 to 0143). The factorial subroutine is then called again. This process continues until the base of the recursion is reached; in this case a pointer to the integer value is put at the top of the stack (line 011D), and a jump is made to label a10002. Here, the subroutine "del_scope" tears down the activation record on the stack and puts a pointer to the result of the function at the top of the stack. Clearly, recursion in the PHI program can be implemented by a parallel recursion in the assembly language output of the compiler.

Another feature of the output code shown in Figure 3.4 is that there is an unconditional jump around the function (lines 0103 and 014F). This is a result of the decision to output inline code in spite of the fact that functions can be called at random. There are both space and time penalties to be paid for these jumps, especially since each function must have a jump and label instruction bracketing it. However, the ultimate effect of all these jumps is to get to the label at the bottom of the program. The result is that all but one jump/label pair could be eliminated by an optimizer, making the penalty trivial. Another solution considered was to generate code for functions and the "main" program separately, then combine the two when printing the output from the code generator. This was not done for reasons put forth in the section that describes the semantic analyzer.

Variable and constant storage is word oriented rather than byte oriented to take advantage of the 8086 processor's 16 bit capability. Integers and naturals are both represented as single words, and booleans are represented as integers, either 1 or 0. While this boolean representation is somewhat wasteful in terms of memory space, it allows for a great deal of overlapping in certain subroutines used in function calling and comparisons. It is planned to represent real numbers with two words of memory, and sequences using linked lists. Neither of these types have been fully implemented; however, there are provisions in the compiler for adding these features at a later date.

There is currently no dynamic allocation of registers. Some registers are used for specific purposes; for instance, the SI register is used to mark the top of the program stack, and of course the BP and SP registers are used to manage the machine's stack. In general, arithmetic processes take place in the AX register, using other general registers as auxiliaries as needed. When variable space is needed, the highest unused address space is allocated and, when a function is finished, only the result is saved in storage; all other value spaces are returned for use by the program.

Error handling is probably the simplest part of the run-time routines. Any run time error such as overflow or division by zero errors will result in an appropriate error message to the user (see Appendix O for a full listing of error messages). Then, program execution will terminate and control is returned to the operating system.

C. SEMANTIC CHECKING and CODE GENERATION

The PHI compiler utilizes the recursive descent technique to perform semantic checking and code generation in one traversal of the parser tree. In most cases, tree nodes are filtered through the **semcheck** function, which calls various procedures based on the name of the node. These procedures, in turn, call **semcheck** for each of their children, and the process is repeated until the leaves of the tree are reached. The function **semcheck** then returns a type (e.g., integer, real, boolean), which the parent node uses to determine the semantic correctness of its subtree. With the information returned from the **semcheck** function, the parent procedure can do one of three things: return a type, convert one node to a different type, or declare an error condition.

Concurrent with semantic checking, code is generated. As noted above, this is assembly language code written to a buffer in memory. If an error condition is declared, however, a flag is set and code generation ends. Semantic checking will then continue until the tree is completely traversed or ten errors are accumulated; then, the semantic checking

process terminates. Unlike the parser, the semantic checker makes no attempt at error recovery; top-down checking simply continues normally from where the error was detected.

Top-down semantic checking results in a neat, trim package for the back end of the compiler. Unfortunately, there are some problems that pure top-down checking will not solve. For instance, determining if there is a one-to-one match between formals and actuals for a given function involves some detours from top-down checking, as explained below.

The scoping rules of PHI provided the largest challenge to writing the semantic checker. One solution is a multiplicity of stacks. The size of these stacks depends upon the number of its constituents visible at any one time. Usually, the proper match for an item is the one found closest to the top of the stack. However, because of the semantics of the "and" construct, checks against the variable-stack do not always follow this convention.

There are four stacks used by the semantic checker: the type-stack, the variable-stack, the definition-stack, and the and-stack. All but the type-stack are implemented as linked lists. This implementation sheds the disadvantage of static length arrays at the cost of a slight increase in memory and temporal resources. The type-stack uses a fixed-length array of 300 entries because 1) the basic types of real, boolean, integer, natural, and trivial will be accessed most frequently, because they are the building blocks of every type and sequence, and because they can be more easily accessed from an array than from a linked list, 2) a list of 300 type entries should not impose an extreme burden on the programmer, and 3) the planned implementation of sequences will be more straightforward if the type-stack is an array.

Figure 3.5
Type-Stack Entry

The type-stack, Figure 3.5, is meant to hold both the basic type definitions and user defined type definitions. This stack holds both the name of the type and the number of bytes needed in memory to implement the type. At compiler initialization, it contains the five basic types and user defined types are added as they are encountered. The **begin-end** construct of the language (not implemented yet) allows declared types to be visible over a specified range. It is planned to implement this construct by setting a pointer to the top of the stack upon encountering the **begin** node and then popping the stack to that point after both of the node's subtrees have been checked.

Figure 3.6
Variable-Stack Entry

The variable-stack, Figure 3.6, holds all of the variables, including function names, currently seen by the semantic checker. Each entry holds a pointer to the hash table containing labels, a type, a pointer to the tree node defining it, and a flag to designate whether or not it is a formal. Whenever a variable name is encountered and the name is not a call to a function and not a data definition, it is put into the variable stack. Then, when a scope is exited, the variables local to that scope are dropped from the stack. For example, after a function is defined, all of its formals are popped from the stack.

Figure 3.7
Definitions Stack Entry

The definitions-stack, Figure 3.7, contains all of the function and variable definitions visible in a given scope; e.g., the declaration $C : SR * SZ \rightarrow SB$ would put the definition C into the definition-stack. This entry would contain the type of C 's return value (Boolean), a pointer to the tree node that contains C , and a pointer to a linked list which contains its argument types (Real and Integer). This last field will be null if the declaration is a data definition. This stack grows and shrinks in the same way as the type stack.

The authors considered combining the definitions-stack and the variable-stack because of the similarity between their fields. In fact, one of the primitive implementations was designed in this way. However, this slowed down the search for both definitions and variables considerably, and the overhead needed to implement these two as separate stacks is small: three extra functions and one extra pointer.

The need for the and-stack is derived from the scoping rules imposed by the AND construct. This construct allows a variable to be referenced before it is declared without the benefit of Pascal's forward declaration or equivalent. This is true of other constructs in PHI such as the WHERE construct. However, the AND construct cannot be parsed in such a way that the semantic checker can see all variables before they are used, because either subtree of the AND statement can define variables used by the other subtree. So, a program such as the one depicted in Figure 3.8 needs a vehicle by which it can detect that the variable d is defined later in the program. The and-stack is such a vehicle.

Figure 3.8
Tree With Forward Variables

When the semantic checker reaches the AUXAND node, Figure 3.8, a flag is set to indicate that AUXAND has been traversed, and a pointer is set to the top entry of the and-stack. "Notfound" is returned from the `semcheck` function when the variable `d` is reached, but, since the AND condition has been set, a pointer to `d` is put in the and-stack. Note that `d` is later defined in a data definition (DATAUXDEF node), and when both the left and right subtrees of AUXAND have been checked, all variables in the and-stack are checked against variables in the variable-stack. If a match is found, `d` is defined and removed from the and-stack. In the event that a variable is not found when the AUXAND node's complete subtree has been checked, an error condition (UNDEFINED VARIABLE) would be set. The semantic checker would recognize this condition because the top of the and-stack would not be equal to the mark placed at the top of the stack when the AUXAND node was entered. Nested AUXANDS are possible, but they pose no problem because the top of the and-stack is marked when the auxand node is traversed.

Variables and functions are represented in the run-time by a call to an assembly language subroutine, and each subroutine must have a discrete name. Also, there are several labels found throughout the program, and each of these must have a name. These names are generated by the "name" function found in the `sem_u.c` module. Each name begins with the letter "a", followed by 6 digits. Examples can be seen in Figure 3.4.

Figure 3. 9
Tree for Function f

Function definitions presented a problem that was solved with a deviation from pure top-down semantic checking. When a function definition (FUNAUXDEF in Figure 3.9) is encountered by semantic checker, the following procedure would be followed (see Figure 3.10 for the function definition entry):

funid_node:

```

check for definition-stack entry for "f"
  if not found
    return (ERROR)
get a pointer to the first formal of f
get a pointer to the first formal of definitions-stack entry
while both pointers <> Nil do

```

```

        put variable in varstack; use type pointed to by the formal list
        advance both pointers
    end while loop

    if not (both pointers == nil)
        return (FORMALS MISMATCH)
    else
        put "f" in the variable-stack
        return (Type of f = INTEGER)
    end else
end.

funauxdef_node:

    left type = semcheck (Left Child)
    right type = semcheck (Right Child)

    if (left type <> right type)
        call a procedure which will either
        convert the right type to the left type or set an error flag.
    endif
end.

```

When a function is called with arguments, a similar process takes place (refer to Figure 3.11):

```

actualist :    Input is a pointer to the actualist node
                  Output is error condition

    Check definitions-stack for "f"
    if "f" not found
        set error (FUNCTION DEFINITION NOT FOUND)

    set elistptr to first element of element list

    elist (elistptr)

    check var stack for "f"
    if found,
        generate code to call "f"
    if not found
        if and_flag = TRUE
            put "f" in the and stack
        else
            set error (FUNCTION NOT DEFINED)
    end.

elist:    Input is a pointer to the element list node

    if pointer->rptr <> nil
        elist (pointer->rptr)

    check type of element against corresponding formal type
    if types don't match
        set error (IMPROPER ARGUMENT TYPE)
    end.

```

```

else
    generate code to put pointers to argument values on the run-time stack
end.

```

Figure 3.1Ø
Definitions-Table Entry For Function f

Type conversions are implemented in the semantic checker, albeit the code generator does not yet support this feature. The function **hnumconvert** (half number-convert, found in the module **sem0**) will check to see if a conversion of the right subtree of a node to the left subtree type should be accomplished. This is useful for function definitions, where the body of the function may be converted to the type the function returns, but the converse is not acceptable. In addition, the function **numconvert** (found in the **sem0** module) will convert either the left tree type or the right tree type of a node. This is useful for certain arithmetic operations. The semantic checker considers integer-to-real and natural-to-real conversions to be legal. Natural to integer conversions are not implicitly done, since both of these types are represented in exactly the same way. On the other hand, an attempt to return an integer value for a function which has a declared type of natural will result in an error.

Figure 3.11
Tree for Function Call

Variables of simple type (i.e, natural, integer, or real) need not be declared before use, although such a declaration may be made. If a variable is undeclared when defined by a data definition, the semantic checker will attempt to classify it. If the semantic checker expects to find a boolean value, the variable is easily classified as a boolean and an entry is put into the variable table. If a numeric variable is expected, the semantic checker will try to type it as an integer; failing this, it will be classified as a real number. However, the AND construct alters this somewhat. If a variable is used before it is defined by a data definition, it **must** have been defined using the LETDEF construct.

As noted in the section on run-time, some thought was given to generating all functions and data definitions to one buffer and the "main" program which calls these functions to another buffer. However, this would be an inefficient use of memory space.

since one buffer might run out of space while the other is under-utilized. Although there is a proliferation of jump calls in the output using one buffer, an optimizer could easily eliminate all but one call, as noted above.

D. OPTIMIZATION

There is no optimization module implemented in the PHI compiler. In this section an attempt will be made to identify three types of optimization which are suitable for implementation. Also, a small dissertation on what optimizations should not be considered is included.

The first suitable type of optimization is constant folding. The purpose of constant folding is to eliminate multiple consecutive constants in arithmetic expressions [Ref 3:p. 612], and the function **numconvert** in module **sem0** makes an excellent structure in which to implement this optimization. This is because most arithmetic operations call this function. It would be straightforward to put a function that tests the left and right children of an operand node to see if they are constants, then perform the operation in the compiler and generate code for a constant call. However, since the division operators do not call **numconvert**, the constant folding function would have to be inserted in **idiv** and **rdiv** also.

The other two optimizations are post-code generation optimizations. The first one considered is jump optimization. This should be the most worthwhile to implement: if the number of functions and data definitions is n , $n > 0$, there will be $n - 1$ unnecessary unconditional jump statements and labels.

These jump statements can be eliminated by replacing the first "jmp" statement with a jump to the last label in the code; then, because "jmp" is not used for anything except to circumnavigate functions and data definitions, all other unconditional jumps and their labels can be eliminated.

The last type of optimization is a form of peephole optimization. Occasionally, there will be a "call ppush" statement followed by a "call ppop" statement. This is unnecessary, and can be eliminated. The 8086 assembly code equivalent of "push" followed by "pop" should not occur in the present design.

Dead code optimization eliminates code inside a jump when that code contains no labels. It is not necessary to implement this type of optimization with the current design, since unconditional jumps are only used to bracket functions and definitions. However, if one accepts the premise that programmers occasionally make mistakes, it might be worthwhile to keep track of which functions are called and eliminate code for those which are not. A message to the programmer concerning this circumstance would be useful, too.

IV. RESULTS & CONCLUSIONS

A. RESULTS

The implementation described in this study demonstrates the design and implementation of a compiler for the functional programming language PHI. Since this implementation is a prototype, it does not possess all of the qualities desirable in a full implementation. However, the necessary hooks are present and the design is mature enough to allow expanding the prototype to a full implementation.

The PHI compiler front-end implements machine independent lexical and syntactic analyzers. This implementation is complete and faithfully follows the syntax of PHI — based on the design of the language as of 07 January 1987. In deciding which modules to include in the front-end and back-end, the authors were originally guided by the traditional methodology of placing the analysis functions in the front-end and generative functions in the back-end [Ref. 8:p. 20]. However, as the design of the PHI compiler progressed, the authors removed semantic analysis from the front-end and combined it with code generation. This produced a one-pass semantic analysis/code generation phase.

The PHI compiler back-end implements a machine dependent one-pass semantic analyzer and Intel 8086 code generator. The semantic analyzer implements the basic constructs of PHI: functions and data definitions may be defined, and the integer, natural number, real number, and boolean types are fully implemented. Implementation of code generation is congruent to that of the semantic analyzer, with the exception that the real number data type has not been implemented.

B. CONCLUSIONS

It is possible, using traditional technologies to design and implement a compiler for the functional programming language PHI. It is not possible to utilize either pure recursive descent or pure deterministic techniques for this implementation. The syntax/semantics of the language forced a degree of non-determinism, and one instance of back-tracking was required in the PHI compiler front-end.

The overall design is highly modularized facilitating the understanding of concept and implementation. The authors think that this approach will greatly reduce maintenance costs and provide greater flexibility in making changes and additions to the PHI programming environment. It should be possible, for example, to use the front-end described in this thesis to drive a PHI interpreter. Being able to abstract out this front-end and use it without change should make the implementation of a PHI interpreter relatively simple. Modularizing the design also increases portability of the compiler to other machines. To demonstrate portability, the authors recompiled the front-end and executed it on a 68000 based processor. This was accomplished with no modifications to the source program, just replacement of C run-time header files for the new target machine.

Removing the semantic analyzer from the front-end permitted coupling semantic analysis with code generation. The fixed-length buffer design of the code generator is suitable for this prototype implementation but should be redesigned utilizing dynamic buffer allocation methods in follow on implementations. The authors think that utilizing a single pass through the parse tree is practical for the basic constructs of PHI and believe this methodology is suitable for future designs of the PHI compiler.

V. FURTHER RESEARCH

Further research may be broken down into two major areas: short and long range projects. The former may be further broken down into two main areas: adding unimplemented features and improving the PHI programming environment. On the other hand, all long-range projects involve only the programming environment. All of these areas are discussed below.

In the prototype of the PHI compiler, both Real and Compound variable types remain unimplemented. Compound variable types consist of sequences, the Trivial type, user defined types, and tuples. Although all of these are recognized by the parser, the semantic checker will not recognize complex types and no code will be generated. The Real type is recognized by the semantic checker, which can discern if conversion from an integer or natural type should be accomplished; however, no code is generated to implement this type in the run-time structures. Note also that operators which operate solely on complex types and reals (e.g., the real divide and concatenate operators) are not implemented.

One other operator not implemented is the "|->" operator. In addition, argument bindings, functionals, and FILES are not recognized by either the semantic checker or the code generator.

Short-range improvements to the PHI environment may come either after a full implementation is accomplished or may be developed concurrently with the full implementation. Admittedly, the current environment is analogous to instrumentation on a helicopter: there is just enough to know that the system is running! The environment could be improved by implementing the interactive mode of PHI, as opposed to the current batch mode. A sample interactive session of PHI may be found in [Ref. 1:pp 1-17]. Also, an interpreter would be a good starting point toward developing a practical, working

environment for PHI. As noted above, the front end of the prototype compiler may be adapted for this purpose; alternatively, due to the structural similarities between PHI and LISP, an ambitious researcher may wish to write an interpreter in LISP.

One final short-range improvement which is not covered by either category would be to allow more than 64K of run-time memory. It would be worthwhile to take advantage of the large amount of memory most modern microcomputers have, especially since sequences and recursion, upon which PHI is based, gobbles up memory with abandon.

When the PHI compiler becomes a serious user's tool, some long-range research will become viable. Sophisticated input and output would be a vital consideration, and the minimal I/O methods now in use would need substantial improvement. The most ambitious researchers in this direction should consider a bit-mapped display with the possibility of a syntax-directed editor. Also, based on the authors' limited experience in PHI programming, a debugger would be a necessary tool for the serious programmer.

APPENDIX A

THE FUNCTIONAL LANGUAGE PHI — Φ

(CONCRETE SYNTAX OF Φ — 1Ø/16/86)

GRAMMATICAL NOTATION:

Both ' $\{C_1, C_2, \dots, C_n\}$ ' and $\left\{ \begin{array}{c} C_1 \\ C_2 \\ \vdots \\ C_n \end{array} \right\}$ mean exactly one of $C_1, C_2, \dots, C_n$.

Similarly, ' $[C_1 | \dots | C_n]$ ' and $\left[\begin{array}{c} C_1 \\ \vdots \\ C_n \end{array} \right]$ mean *at most one* of $C_1, \dots, C_n$. The notation ' C^* '

means *zero* or more Cs; ' C^+ ' means *one* or more Cs; ' $CD \dots$ ' means a list of one or more Cs separated by Ds. Terminal symbols are quoted when they could be confused with metasympols.

Grammar:

BLOCKBODY	=	$\left\{ \begin{array}{l} \text{QUALEXP} \\ \text{LET DEFS ; BLOCKBODY} \end{array} \right\}$
DEF	=	$\left\{ \begin{array}{l} [\text{ID}] \text{ FORMALS} \equiv \text{QUALEXP} \\ \text{ID : TYPEEXP} \\ \text{TYPE ID [FORMALS]} \equiv \text{TYPEEXP} \end{array} \right\}$

ROCK COMPILER — MAIN MODULE

```

/*****
* PUBLIC DOMAIN SOFTWARE
*
* Name       : Main Rock Module
* File       : Rock_main.c
* Authors    : Maj E.J. COLE / Capt J.E. CONNELL
* Started    : 01/06/87
* Archived   : 04/10/87
* Modified   : 04/13/87  Output files put to vdisk  EC
*****/
* This file contains the following modules for the PHI compiler:
*
*      R_Initial          Semcheck          Main
*
* Algorithm :
*   This contains the main procedure for the phi compiler, in add-
*   ition to the initialization procedure & the main semantic checking
*   procedure. The main module inits the program, sets up the screen
*   by calling "user ()", & decides whether an error routine needs
*   to be called. It also closes out the input file.
*   The "semcheck procedure is designed to be called by any function
*   with a ptr to a parse tree node as an argument. It will then
*   determine which sub-module is necessary to check the node.
*   "R_Initial" presently has the function of initializing the type
*   table.
*****/
* Modified : 04/13/87  Output files written to vdisk, "d:"  EC

ROCK COMPILER — SCANNER

```

PUBLISHED MAIN SOFTWARE
Name          Scanner
File          main
Authors       Mark E. LUTER, Capt. J.E. LUNNELL
Created       10-17-86
Approved      10-17-86
Modified      4-23-87 *kens n. longer input + intermediate files
.....
This file contains the executable modules for the scanner
.....
getTken()     IsKeyword()
.....
Argument      getTken() is called from FillBuffer() and returns an
integer value to uniquely identify the token
IsKeyword()   checks each identifier to insure it's not
an IBM Keyword
.....
Modified      10-17-86 *revisions to comply with latest definition
of the language "C"
11-17-86 *getTken() returns CONSTANT while READING
INTERDEFINITION
12-17-86 *getTken() very added and files modified
1-17-87 *revisions to partially comply with latest
definitions of the language "C"
4-23-87 *kens n. longer input + intermediate files
getTken()    called directly by the Parser now
.....

APPENDIX H

ROCK COMPILER — PARSER

```

/*****
PUBLIC DOMAIN SOFTWARE

* Name      :  parser pt 1
* File      :  parser1.c
* Authors   :  Maj E.J. COLE / Capt J.E. CONNELL
* Started   :  10/20/86
* Archived  :  12/11/86
* Modified  :  04/23/87 No longer set up to work with file of tokens.
*****
* This file contains the following modules for the PHI parser:
*
*   BlockBody()   LetDefs()   Defs()   DefAnd()   QualExp()
*   AuxExp()      AuxDefs()   AuxAnd()   Formals()   Expression()
*
* Algorithm :  The main module calls BlockBody() to start the parse
*              off.  BlockBody in turn calls LetDefs() first and then
*              QualExp() looking for a valid program.  The remaining
*              modules in Pt's 1-3 are called by these when trying to
*              validate a program.  The results from the parse are now
*              kept in an abstract syntax tree for type checking and
*              code generation.  Various utility functions are used
*              to build the tree and simplify parsing the grammar.
*
*****
* Modified   :  12/26/86 Flattened tree output changed to abstract
*              syntax tree form. JC
*             :  01/10/87 Corrections to comply with latest definitions
*              of the language. JC
*             :  01/27/87 Error Recovery added and files combined. JC
*             :  03/20/87 Token buffer implemented for parser. JC
*             :  03/29/87 Changed manner errors are handled - required
*              for integration with back-end.
*             :  04/23/87 No longer set up to work with file of tokens.
*              GetToken is called directly thru FillBuff().  JC

APPENDIX I

ROCK COMPILER — ERROR HANDLER

```

/*****
 *
 * PUBLIC DOMAIN SOFTWARE
 *
 * Name      : Error Handler
 * File      : errors.c
 * Authors   : Maj E.J. COLE / Capt J.E. CONNELL
 * Started   : 01/20/87
 * Archived  : 04/07/87
 * Modified  :
 *****/

* This file contains the execution modules for error recovery.
*
*      ErrorHandler(), EatEm()
*
* Algorithm : ErrorHandler() is called by other modules in the
* compiler. It insures the error count is updated and
* the* error is written to the error file. If required,
* ErrorHandler() calls EatEm() to gobble tokens to get to
* a known point in the parse. Used during error
* recovery. After MAXERRORS number of errors simply
* returns to calling routine.
*
* NOTE      : 'errorfile' must have been initially created before
* ErrorHandler() is first called - don't want to append
* to last times errors!

* This file contains the following modules for the PHI parser:
*
*      Matchfor      Tfunauxdef      Tfunid
*      Tactualist    Tid              Act_Walk
*      Telist
*
* Algorithm :
*   This module contains the procedures needed to define and call
*   functions. Tfunauxdef will set up the run-time structure of the fun-
*   ction, tfunid will check the semantics of the function, & matchfor,
*   called by tfunid, checks for the proper type & number of formal pa-
*   rameters.
*   Tactualist coordinates the checking of a function call. It uses
*   both telist and act_walk. Actwalk determines whether the number &
*   type of actuals is correct, and telist checks each element list and
*   returns its type.
*   Tid performs semantic checking for program variables.
*

* This file contains the following modules for the PHI parser:
*
*      Trdivide      Tidivide      Tarithop
*      Tprimary      Tconvert      Tconstant
*      Tand          Tor           Tnegation
*
* Algorithm :
*   This module contains the procedures necessary for implementing
*   arithmetic & boolean operators. Tarithop coordinates the semantic
*   checking of arithmetic ops by calling the proper function based
*   on the operator type. Trdivide & Tidivide handle semantic checking
*   for real & int division, respectively. For all other arithmetic
*   ops, the numconvert procedure (sem0) is called to perform seman-
*   tic checking, then code is generated.
*   For each boolean operator, the appropriate child(ren) is checked
*   and code is generated for the operation.
*   In addition, tconstant checks the type of a simple constant by
*   calling convert, & then returns either the constant type or an error
*

ROCK COMPILER — CODE GENERATION MODULE

```

/*****
* PUBLIC DOMAIN SOFTWARE
*
* Name       : Code Generation Module
* File       : Code_Gen.c
* Authors    : Maj E.J. COLE / Capt J.E. CONNELL
* Started    : 02/06/87
* Archived   : 04/10/87
* Modified   : 04/13/87  Code output to vdisk  EC
*****/

* This file contains the following modules for the PHI compiler
*
*      C_Store_Code      C_Startup      C_Off_Insert
*      C_Ending          C_Printcode    C_Ztor
*      Acode             C_Jmp          C_Start_Proc
*      C_I_Const         C_I_Form       C_End_Proc
*      C_I_Op            C_Call_Proc
*
* Algorithm :
* This module contains the procedures necessary for code generation.
* C_startup initializes the run_time file, & the semantic checker will
* call the procedures as necessary. Note that "c_store_code" is a
* generic generator which will spew any string given as an arg to the
* output file.
*

ROCK COMPILER — USER INTERFACE

```

/*****
* Name      : User Interface
* File      : User.C
* Authors   : Maj E.J. COLE / Capt J.E. CONNELL
* Started   : 04/01/87
* Archived  : 04/10/87
* Modified  :
*****/
* This file contains the following modules for the PHI compiler
*
*      User_err      Getname      Prog_name
*      Print_header  P_Close      User
*
* Algorithm :
*   This module contains the procedures necessary for the user in-
*   terface.
*   Prog_Name gets the user's choice of program by calling Get_Name
*   Print header is called to print the initial screen display on con-
*   sole, & the User procedure is the overall coordinator of the inter-
*   face.
*   User_Err and P_Close are both independent procedures. User_Err
*   handles output in the event that an error or errors have been found.
*   P_close is called by "Rock_Main" to ensure the input file has been
*   closed.
*

;* Authors   :   Maj E.J. COLE / Capt J.E. CONNELL          *
;* Started   :   01/26/87                                    *
;* Archived  :   16 Feb 87                                    *
;* Modified  :   16 Apr 87 Stack/Varspace Crash error check EC *
;*****
;
;*****
;ALGORITHMS
;
; 1.   Input/Output: The first section of the program contains input and output
;
; 2.   Virtual Space: A virtual space is set up in the extra segment to hold both the
;   stack. The middle of this space is denoted by the symbol "vars", and variables
;   offset ( $\pm$  32700) from vars. In this implementation, the program stack grows from
;   vars grow from the bottom. The virtual space is assumed to be made up of words
;   (two bytes), so only
;   even numbers may be used to access it.
;
; 3.   Stack: The stack pointer is the si register, which is initialized to 32700.
;   grows, the si register is reduced by two. Ppush and ppop will push and pop two
;   registers. "Push_one" and "Pop_one" will push and pop single words to and from
;
; 4.   Addressing Program Variables: Each program variable is assigned a two-tuple A
;   scope and O is the offset from the base address of variables in that scope.
;   turn the address of a variable given A.
;
; 5.   Scoping: Initially the scope is set to 0: the global scope. The variable
;   space containing the outer scope, and the variable "S_Nest" contains the current
;   new scope is created, "S_Nest" is increased by one, and the three-tuple S =
;   (L = Static Link, pointing nesting level of the outer scope, N is the nesting
;   is the base address of display of variables for this scope.
;   When a scope is deleted, the top of the stack is saved, the top instantiation of S
;   and S_Link and S_Nest are recalculated.
;
; 6. Inserting/Extracting Program Variables: "I_Assign" will insert an integer or
;   scope contained in S_Nest when it is requested. "Iputvalue" will insert the
;   responding tuple A on the stack. "Igetvalue" will pop the tuple A off the top of
;   the value of the integer pointed to by A.
;
;*****
;*****
;* Modified   : 22 Feb 87 Add/del_scope changed to save TOS. EC *
;*           : 16 Apr 87 Added check for stack/varspace crash, includes*
;*           : message to observer *

APPENDIX N – TEST SUITE

SIMPLE TESTS OF FUNCTIONS AND VARIABLES

```
let c : $Z -> $Z;  
c (20) where c (n) == if 1 = 2 then 3 * n  
      else 3 + n endif
```

--Simple "Hello I'm Alive Test"

```
let c : $Z -> $Z;  
c (1 * 2) where c (n) == n * 3
```

-- Test for expression in functions's formals

```
let c : $Z -> $Z;  
c (k + 2) where k == 2 and  
      c (n) == if n = 1 then n * 3 else n + 4 endif
```

-- Test for expression in function's formals

TESTS FOR RECURSION

```
let c : $Z -> $Z;  
c (k * 2) where k == 2 and c (n) == n * 3
```

-- Test for expression in function's formals

```
let c : $Z -> $Z;  
c (0) where c (n) == if n = 0 then 1 else c (n - 1) * n endif
```

-- Test for recursion in functions

```
let c : $Z -> $Z;  
c (5) where c (n) == if n = 0 then 1 else c (n - 1) * n endif
```

-- Test for recursion in functions

```
let c : $Z -> $Z;

APPENDIX O - ROCK COMPILER USER'S MANUAL

I. Installation

The rock compiler program comes on a 5.25" disk with all public domain programs necessary to run it. To install this program on another floppy disk or a hard disk, use the following procedures:

- 1) Change the system drive to the disk drive containing the floppy disk.
- 2) Type "INSTALL", followed by a space and the drive and directory on which you want the program installed.

Note that the Rock compiler uses three unsupplied files to operate: RASM86, LINK86, and your choice of word processor. The RASM86 and LINK86 programs must be installed on the same directory as the compiler.

II. Running the Compiler

- a. Type in "ROCK" and wait for the screen display shown in figure 1 to appear.

Figure 1

- b. When the prompt appears, type in the file name of the source file you want to compile, then press return. The compiler will accept directory specifications in the file designation. If the source file is found, the compilation will begin immediately, and the screen will appear as shown in figure 2. If the file is not found, the screen will appear as shown in figure 3.

c. If a successful compilation takes place, the prompt for a source file reappears. If the compilation is not successful, error messages will appear on the screen, and a copy of these messages can be found in a file

```

                                ROCK COMPILER
                                Press Escape Key to Exit Compiler

Program to Compile ->  SQRT.PHI

                                Compiling: Please Wait

```

                                ROCK COMPILER
                                Press Escape Key to Exit Compiler

Program to Compile ->  NOTFOUND

                                file not Found
                                Press ESCAPE to exit, any other key to continue

```

Figure 3

named Errors.Phi. A typical error display is shown in figure 4. After perusing the errors, you may press any key to return to the prompt for a source file.

ROCKY ERRORS

```
line 1 : formals list missing or error in formals list
line 1 : misplaced or missing ==
number of errors = 2
```

PRESS ANY KEY TO CONTINUE

Figure 4

d. If compilation is successful, both an .exe and an .obj file will be created. In the event that an error occurs, neither file will be created.

WARNING : If you choose to compile two programs with the same prefix, ensure you save the first one before compiling the second one; otherwise, the second compilation will overwrite the output file of the first compilation.

e. To cleanly stop the compiler, press the ESCAPE key any time the system asks for an input. If you have started to compile a program and you need a "panic" exit, press "Control-Break". If you do this, the cursor will not reappear on the screen. However, you can get it back by running the ROCK program again and making a normal exit

III. Error Handling

Errors are divided into two categories - those found during compilation and those found during run time. The following two sections list the errors messages from both categories which you might encounter. Each message includes a brief synopsis of what causes the error.

COMPILER ERRORS

Message	Explanation
incomplete "l->"	Either an "l" or "l-" was found where "l->" was expected
^ without following /, logical OR is V	A single backslash was found where a logical or construct (^) was expected

'\$' without following 'R', 'N', 'Z', 'B', or 'I'	An incomplete type declaration was found.
invalid numeric constant ==> 3.	An illegal constant was found; in this example, "3."
literal without ending	An unterminated literal was found, or a literal spanned more than one line.
unidentified char in input program ==> #	A character with no meaning was found in the source file; '#', in this example.
MEMORY OVERFLOW DURING COMPILATION	The source program is too big for the host machine to compile.
error in statement following ==> *	An illegal statement follows the specified character; '*', in the example.
error in type definition following ==> *	An illegal type definition follows the specified character; '*', in the example.
unable to complete definition of blockbody after keyword LET	An unspecified error was found after LET, and the compiler is so completely sandbagged that it cannot recover.
missing or misplaced ':' after definition	A declaration, preceded by "LET", was not followed by a semicolon
valid qualexp/exp not found in the def/auxdef	An invalid expression was found
valid typeexp not found in the def	An expression defining a type was either missing or incorrect.
formals list missing or error in formals list	Formals were expected but not found, or formals were incompletely specified.
misplaced or missing ')'	A PHI keyword or delimiter was expected or not found; ')' in the example
at least one identifier must follow keyword TYPE	TYPE found without an identifier
unable to complete def/auxdef following keyword AND	Improper or no expression found following AND.

missing or invalid auxdef after keyword WHERE	Improper or no definition following WHERE
missing or misplaced closing paren in formals list	Formals found without closing parenthesis.
error in processing multiple Actuals	One actual was found, but an error was spotted in a subsequent actual.
missing literal after keyword FILE	FILE was found without a file- name being designated.
missing or invalid exp following KEYWORD	A keyword was spotted, but the following expression was illegal.
IF statement w/o ENDIF	No ENDIF to close off an IF statement.
error in formals preceding l->	"l->" found, but the formals list preceding it contained an error.
missing or invalid QualExp following COMMA operator	A list of elements was found with an illegal expression in it.
error in ArgBinding - check QualExp or closing bracket	An improper expression in an argument binding was found, or the closing bracket on an argument binding was not found.
OZONE LEVEL 1 -	Unimplemented feature found. for 19.99 the feature can be implemented in 1999
NUMERIC VALUE EXPECTED	Non-numeric type found where a numeric type was expected.
NATURAL EXPECTED	Natural type was not found where it was expected.
INTEGER OR NATURAL EXPECTED	Either an integer or natural type is proper, but neither was found
ERROR IN TUPLE DEFINITION	A tuple is improperly defined the source file used improper types or number of types in defining the tuple. This can also mean a single variable was improperly defined
UNDEFINED VARIABLE IN AND SCOPE	An undefined variable was found in one of the two branches of an

	in its scope.
FUNCTION WITHOUT FUNCTION DEFINITION	A function was defined without a declaration of its type and formals.
FORMALS MISMATCHED	Formals in a function definition are not the same in either type or number as those in the function's declaration.
FUNCTION CALLED WITHOUT FUNCTION DEFINITION	No function definition found for the function called.
REAL NUMBER EXPECTED	An incorrect type was found where a real number was expected.
INVALID CONSTANT EXPRESSION	An invalid constant was found.
BOOLEAN VALUE EXPECTED	A boolean value was expected, but none was found.
BOOLEAN OPERATOR EXPECTED	A boolean operator was expected, but none was found.
OUT OF RUN-TIME MEMORY SPACE	Not enough space to accommodate the program during run-time.

RUN-TIME ERRORS

DIVISION BY ZERO	Division by zero attempted.
MULTIPLICATION OVERFLOW	A multiplication operation resulted in a numeric value outside the language limits.
ADDITION OVERFLOW	An addition operation resulted in a numeric value outside the language limits.
SUBTRACTION OVERFLOW	A subtraction operation resulted in a numeric value outside the language limits.
STACK/VARIABLE SPACE CRASH	The stack overwrote the variable space.
