#### Tuning a major part of a clustering algorithm

Katherine M. Hansen and John W. Tukey

Princeton University Fine Hall Washington Road Princeton, NJ 08544

## ABSTRACT

Most proposals for clustering algorithms have been based on introspection. Few proposed algorithms have had their performance studied. Our approach involves (a) striving to avoid comparing distances on remote parts of the data (because metrics deserve only minimum trust), and (b) using a stochasticallydefined test bed to measure, and where possible understand, the performance of an evolving algorithm, with the intent of using our understanding to modify it in such a way as to improve its performance.

Our test bed involves 3 circular Gaussian samples, of size 50 each, centered at the vertices of an equilateral triangle of side  $i\sigma$ . In its use we assume that a 3-group answer is being sought. Thus we are only concerned with a part of the clustering process.

Our early algorithms begin to misbehave in the range  $5 \le t \le 7$ . Our successive steps of improvement work at smaller and smaller t. The last version we have tried still performs usefully (median misclassification about 16%) at t = 2.7, where knowledge of three populations would only let us hold misclassification to a median of 13.3%.

Comparison (by Kaye Basford) with a Gaussian maximum likelihood algorithm on the same set of triple samples shows only slightly better performance than for our algorithm.

The steps of improvement will be discussed.

Prepared in part in connection with research at Princeton University sponsored by the Army Research Office (Durham), DAAL03-86-K-0073.

### Tuning a major part of a clustering algorithm

Katherine M. Hansen and John W. Tukey

Technical Report No. 294 Princeton University Fine Hall Washington Road Princeton, NJ 08544

# 1. Introduction.

Since clustering ought to be an aspect of data analysis, we ought to plan to take an empirical evolutionary approach to its conduct. This is done here for a major part of the clustering problem: how to cluster *given* the number of clusters to be sought.

### PART A: Background and final performance

### 2. Clustering.

Some have argued that the purpose of clustering a set of points is to prove that points belong to different groups. We have taken the opposite extreme, expecting to have misclassification - - real problems are hard - - but striving to minimize it.

Most clustering procedures can be persuaded to give rise to a variety of answers; one putting all the points in one group, through putting them in two groups, in three groups, and so on up to each point its own group. When, as is most often the case, these subgroupings are nested - - e.g. every group of the set of 4 groups is contained in *one group* of the set of three - - or of two - - the

Prepared in part in connection with research at Princeton University sponsored by the Army Research Office (Durham), DAAL03-86-K-0073.

clustering is usually called *hierarchical*. Knowing where to stop the gatheringtogether process is obviously very important. However, we have not tried to work on this problem. Our work has focussed on doing a good job of making a prechosen number of clusters, specifically 3.

Many procedures operate by adding links - - connections of one vertex (one data point) to another - - step by step, often one at a time. Once two data points have been joined by a chain of links, there is no need to join them further. Thus most methods grow what are combinatorially *trees*, but what *look* - - in 2 and 3 dimensions where we can look - - like *vines*. We shall call sets of vertices linked in a way that includes no cycles *vines*.

Most clustering procedures begin with either an overall criterion or a • next-link-to-be-added rule. These criteria or rules typically come down from on high, like the famous tablets of stone. One can then only illustrate their performance. Our work has focused on *evolving* an algorithmic procedure, step by step, by looking for weaknesses of performance in the current algorithm, and then trying to find helpful modifications.

Most clustering procedures use single criteria or single rules. We have found it important to use successive steps that use quite different rules or criteria in different steps.

All clustering procedures use distance measures, or some sorts of surrogate. We have confined ourselves to starting with Euclidean  $(L^{(2)})$ distance, but have emphasized the rank of the nearness of other points to a selected point. Thus each link, say AB, has two such ranks, one for how near

- 2 -

(rankwise) a neighbor B is to A and one for how near (rankwise) a neighbor A is to B.

### 3. Test bed.

Our basic tool in evolving our procedures has been triple samples, of 50 each, from 3 circular Gaussian distributions, centered at the vertices of an equilateral triangle of side  $t\sigma$ . We have found 10 triple samples, for each t, enough to guide us in making the next step of improvement. More would, of course, be needed if one wanted more precise assessment of algorithm performance. We have drawn fresh sets of 10 triple samples for each t, so that performance consistency for nearby t offers independently supportive evidence. We have so far used, successively, t=7, 5, 4.5, 4, 3.7, 3.2, 2.9 and 2.7.

We judge the performance of any procedure on a triple sample by the number of points misclassified - - specifically by the number of minorities, see below. The performance on a set of 10 triple samples is then measured by the median, or perhaps the mean, of the number of misclassifications.

4. Performance of the currently preferred procedure.

#### test bed \*

We now describe briefly the performance of the procedure summarized in Section 16, which is our currently preferred choice, both on the test bed and on some real data.

Two extremes of the 10 realizations of the test bed for t=2.7, one easy and one hard, are shown in exhibit 1. The numbers of misclassifications are 16

#### February 5, 1988

and 73, respectively. If we knew the 3 population distributions exactly, there would be an optimum partition of the plane into 3 120° sectors. Classification by these sectors would have made 16 and 26 misclassifications, respectively. (The median (mean) numbers of misclassifications, over the 10 realizations are 25.5(29.7) for the procedure, and 20(21.3) for infinite knowledge.)

### exhibit 1 about here

With only 3 samples of 50 each, we come, in median, within 5 of the number of misclassifications corresponding to knowing the populations (but not how many observations come from each). Any substantial further improvement seems unlikely.

In cooperation with Dr. Kaye Basford, the same sets of triple samples have been analyzed using a Gaussian maximum likelihood procedure (Basford and McLachlan, 1985), which does slightly better than ours (and, of course, still not as well as population knowledge). Since real data is not likely to be exactly Gaussian, and since no Gaussian assumption was explicit in our development (or visible in the final procedure) it is reasonable to hope that our procedure will at least equal the performance of Basford and McLachlan's on real data.

### \* real data \*

Our main test bed is conveniently 2-dimensional (3 population centers define a plane), but our algorithms make no explicit use of this fact. Thus we have no difficulty applying them to more dimensional data.

Our first real example is the well-known Iris data, due to Edgar Anderson

(1935) and used by R. A. Fisher (1936) in his basic paper on the discriminant function. In the present context, we neglect the information about species (there were 50 observations on each of 3) and use only the 4 coordinates (petal and sepal length and width) of each blossom. We find only 23 misclassifications (all of, course, involving the two most similar species). Standard methods give 31, 50 and 47, respectively.

Our second real example is geochemical, involving analyses of chemical results for samples from 3 carbonate microfacies (here labelled 1, 2, and 6). Several views of the data are given in exhibit 2. The first of 12 variables represents the weight percent of insoluble residue for each sample. The remaining variables represent concentrations of eleven elements. For this data, our procedure, given an exogenous choice of three as the number of clusters, makes only 3 misclassifications. (Earlier attempts with classical clustering procedures were quite unsatisfactory; 17 misclassifications for complete linkage and single linkage, 18 for average linkage. Ward's method gave 7 misclassifications.) (Data for the geochemical example provided by the courtesy of Ms. Ruth Strauss.)

## exhibit 2 about here

#### 5. What we have not yet done.

By limiting our more careful systematic studies to test beds involving

\_ exactly 3 populations

\_ each circular in shape

- 5 -

\_ in 2 dimensions

\_ Gaussian in shape

we have clearly only begun a careful investigation.

We have done a little to explore (a) a similar test bed in 5 dimensions, (b) a similar 2-dimensional test bed with 3 populations of different variances at d (c) a 2-dimensional test bed with 3 populations of different shapes. Our results have been sketchy but encouraging in all cases, (see Sections 18 to 20) as have very preliminary looks (not discussed further here) at ways to "squeeze down" unneeded dimensions.

- 6 -

2007/771\_R2020233

What can be done, once an overall clustering has been completed, to look at pairs - - or other small groups - - of clusters separately, with a view to polishing the clustering, is uncertain.

Clearly much further exploration would be helpful.

### **PART B:** Evolution of our procedures

## 6. Initial choices.

The shakiest part of any clustering procedure is the choice of the metric. No one has seen any way to avoid its use, directly or indirectly. Equally, no one has seen any way to use the final clustering as a basis for improving the choice. Alas, alack-a-day!

The sort of difficulty that can arise is well shown in exhibit 3, where a

ĸĸĸĸĸĸĸĸĸĸĸĸĸĸĸĸĸĸĸĸĸĸĸĸĸĸ

classical clustering procedure is run on data naturally falling into 3 groups of differing spread.

## exhibit 3 about here

On careful examination, however, while it is apparent that while we *must* use the metric locally, it is far from obvious that we need use it globally. By focusing on the nearness-rank of each link from both ends, we focus on only relatively local uses of the metric.

While we do use the original metric for tie-breaking, it seems unlikely that such uses have substantial effects on the outcome of our procedure.

What we would like to have - - and have only begun to approach - - would be a near invariance of result when, for instance, one coordinate,

 $y, 1 \le y \le 10$ , were replaced by  $e^y$ . It seems likely that further steps on such a direction must come from procedures to reconfigure coordinates rather than from clustering procedures themselves.

#### 7. Nearest neighbors and total minorities.

Our methods are all based on ranks of neighborliness, equal to j if a point y is point x's  $j^{th}$  nearest neighbor, that is, when exactly j-1 points are closer to x than is y. Note that this is not necessarily a symmetric relationship, i.e. x need not be y's  $j^{th}$  nearest neighbor. We measure nearness using the Euclidean  $L^{(2)}$  norm.

The goodness of our cluster solutions on the triangular Gaussian test beds is measured by a *total minorities* criterion, which is computed as follows: • run the algorithm until exactly three clusters remain

• count the number of points in each output cluster coming from a

minority subswarm (from either subswarm other than the single subswarm

occurring most frequently)

• add up these counts, to find the total minority count.

For example, with the following output:

	subswarm A	subswarm B	subswarm C	Minorities
cluster # 1	45	7	2	9
cluster # 2	3	35	0	3

the total minority count is 22.

# 8. Minrank and maxrank - the first approach

Our initial algorithms are based on some simple properties of links between points. Consider a link joining two points, x and y. The link may be classified according to two ranks. If point y is point x's  $R_x^{th}$  nearest neighbor and point x is point  $R_y^{th}$  nearest neighbor, then define the following:

 $minrank = min\{R_{x}, R_{y}\}$  $maxrank = max\{R_{x}, R_{y}\}$ 

Sou exercit within which zame. Since

It is these quantities which we plan to substitute for distance. With either minrank or maxrank as our basic unit of link length, we will have a substantial problem with ties. Both here and later we shall break ties with Euclidean distance; however we will soon move to a criterion which has much less difficulty with ties.

Thus, if we are using maxranks, the first link to be added will be the shortest of all links having a maxrank of 1.

Both the minrank and maxrank methods were tested on the test beds with t=5 and t=7. Results are shown in exhibit 4. The performance of both algorithms is fair over most trials at t=7, and is poor at t=5. It seems that minrank does a better job than maxrank.

#### exhibit 4 about here

However, when we plot the actual vines, we have reason to suspect that using maxranks may be the more promising approach. This is due to the simple character of many of the maxrank failures.

# exhibit 5 about here

Exhibit 5 shows a poor maxrank solution for t=7. For this data set (total minorities = 49), we have been left with one very small cluster out of the three we have asked for. This is not surprising since a rather isolated point is likely to produce only links with large maxranks. Such a point will be added to a vine late in the selection process. This problem may be easier to diagnose and correct than the problems with the minrank algorithm.

### 9. The basic criterion.

We want to force links to isolated points to be added to vines earlier in the process. One way of identifying such links is by noting the sizes (counts) of the two vinelets (protoclusters) that would be joined by adding the link. For an isolated point the lesser of these counts will be one, so that we might consider a link-criterion of the following form:

basic criterion = (5 + maxrank)(1 + ln (lesser of counts)). At each step we add the link with the lowest criterion value, again breaking ties with the Euclidean distance between the two points joined by a link. Note that since cluster counts increase at each step, the basic criterion value for each edge must be recomputed regularly.

### exhibit 6 about here

Exhibit 6 shows the performance of this technique for t=4, 4.5, and 5. With t=5, performance is quite good; results for t=4 and 4.5 are not as satisfactory. Note, however, that at t=4 the performance of the basic criterion surpasses that of the minrank and maxrank algorithms at t=5.

At this part, we tried using minrank and (arithmetic and geometric) meanrank in place of maxrank in the definition of the basic criterion. Different values of the constants were tested. These adjustments did not give improved results.

As before, we turn to pictures of vine-clusters to reveal configurations giving poor results. Exhibit 7 shows the worst of the ten trials for t=4.5; this gave 44 total minorities. Clearly the difficulty lies with the filament running horizontally across the picture. We need to find ways to improve on such vines.

exhibit 7 about here

#### 10. Using core points - the basic method.

We would like to be able to emphasize certain "core points" which lie near the centers of each subswarm. If we can identify such points - - we shall suggest three ways of doing so - - we can build the framework of a cluster solution based on them.

Suppose that we have a list of about 50 core points, ignoring for the present how this list was obtained. Then we can use the following basic coregrowing technique:

• Start from the beginning with this reduced set of points, using the basic criterion algorithm to add links until exactly three clusters, involving only the 50 points, are left.

• Treat this structure as the beginning of a vinery for all 150 points.

• Links are now added - - between single points and pre-formed groups of size  $\geq 2$  (in practice, usually  $\geq 15$ ) until only 3 clusters remain - - in the order determined by the basic criterion, which in this case is equivalent to maxrank.

The three core-point vines serve as foundations to which the other points are added.

#### 11. Identifying core points I - high-order and vine neighbors.

One property of points in a vine is their *order*, or the number of links joining them to other points. The central part of the long filament running across the picture of Exhibit 7 is unbranched - - that is, all of the points are of order  $\leq 2$ . This suggests that we define core points based on properties related to order. Our first type of core points was identified as follows:

- run the basic criterion algorithm until a complete (n-1 links) vine has been generated,
- from this vine, choose as core points those points that
- (a) are of order  $\geq 3$  or

(b) are a vine-neighbor of such a point AND are on an arc of links joining one point of order ≥ 3 to another such.

The points satisfying these criteria for the data of exhibit 7 are in exhibit 8. These points do seem more clearly separated into three parts.

### exhibit 8 about here

Results for the basic core-cluster technique with core points satisfying the above criteria for the t=4 and 4.5 data sets are given in exhibit 9.

### exhibit 9 about here

We see a small improvement over the basic criterion method at t=4; this was not repeated at t=4.5. Examining pictures of core clusters indicates that inclusion of vine-neighbors of high order points may be responsible for some of the problems. It is this observation that leads us to the next method of describing core points.

## 12. Identifying core points II - high-order.

We now identify only points of order  $\geq 3$  as core points. The basic core-

cluster technique applied to these points for t=4 and 4.5 gives the results summarized in exhibit 10. A considerable gain over both the basic procedure and the first core-point procedure has been achieved.

exhibit 10 about here

### 13. Identifying core points III - local density.

A third way to select core points is to choose points lying in regions of high point-density, since these regions are likely to represent cluster centers. However, we do not wish to use a global measure of density directly - we want to use *local* properties to identify core points. To do this takes a several-step procedure. The approach we use is as follows:

• Build a complete spanning vine (combinatorially a minimum spanning tree) using the basic criterion.

• Find the density (global) at each point, defined to be (distance to 10<sup>th</sup> nearest neighbor)<sup>-2</sup> (other exponents might be appropriate for dimensions other than 2); other constants than 10 would be appropriate for other total numbers of data points.

• Compute for each point on the vine the following:

 $\log dens = \log (density).$ 

• Smooth logdens on the vine as follows:

- For a point of order 1, do not change logdens.

- For a point of order 2, replace logdens by the median of logdens values at the original point and at the two directly linked points.

- For a point of order  $\geq$  3, replace logdens by the second-highest of the logdens values at the original point and at each directly, linked point.

• Continue smoothing cycles until no further changes take place.

• Find all local maxima - - points which are not linked to higher density points - - either directly or through points of equal logdens.

• For every point, record the difference in logdens (log ratio of densities) from the highest local maximum that can be reached monotonically along the vine. (A local max can be reached monotonically along the vine from a point if an arc of links connects the two and if the logdens values at the points along the arc increase weakly monotonically towards the local maximum.) We use small logdens differences (zero for local maxima) as our measure of high local density.

• We want about 1/3 of the total points to be identified as core points. We will choose all of the local maxima and will select others in order of increasing logdens difference. Due to the smoothing of logdens values on the vine, it sometimes occurs that several points with equal logdens differences are tied for the 50th position on the list. In this case, none of the tying points are chosen as core points, and the total number of core points is less than 50.

### exhibit 11 about here

Using the above approach to select 50 core points for each data set at t=4and 4.5, we obtain the results given in exhibit 11. The algorithm represents an improvement over the basic-criterion algorithm, and seems to be comparable in performance to the high-order algorithm. Exhibit 12 gives results for the local density and high-order algorithms with the t=3.2 and 3.7 data. For these data sets, the local density method generally gives lower minority counts.

# exhibit 12 about here

If all the data points adhere closely to a smooth curve - - which might be a straight line - - then the complete vine will have no points of order  $\geq 2$  and there are no high order core point so the first two approaches fail. However, the local density approach will still apply!

### 14. Basic bisector polish.

Examining pictures of vine-clusters formed from core points, we discover a pattern common to many of the failures of the local density and high-order algorithms. Exhibit 13 is a good example.

## exhibit 13 about here

The core points of each cluster are centered in an appropriate location, yet branches to outlying core points bring in data points from other subswarms. We would like to use information about the location of the core-point clusters without allowing distant points to join in the cluster. The easiest way to do this is to give up our reliance on handling links one at a time, in fact to limit the use of links to the core-point clusters. We suggest the following approach:

• Grow vines of core-points using the basic criterion, continuing until exactly three core-clusters remain (can a good stopping rule be found here?)

• Calculate the centers of gravity of the points constituting each corecluster.

• Calculate the Euclidean distance from each data point to each center of gravity. A data point is assigned to the cluster corresponding to the nearest center of gravity. (Note that some core points might be re-assigned to clusters other than their initial core-cluster.)

For the case of three clusters, the algorithm described above is equivalent to separating the clusters by the perpendicular bisectors of the triangle with vertices at the three centers of gravity. Exhibit 14 shows the bisectors for the data of exhibit 13, using the local density core points. The number of minorities has been reduced from 32 to 12.

exhibit 14 about here

#### 15. Bisector polish - notes, results, and comments.

We can use the basic bisector polish algorithm with either the high-order or the local density core points. We can also *iterate* the process by running the basic bisector polish algorithm and then computing the centers of gravity of each of the completed clusters. Points are then re-classified according to their distance from each of the iterated centers.

# PART C: Performance of current algorithm

# 16. Comparative performance.

Results from the basic bisector polish and the iterated bisector polish algorithms for t = 2.9 are given in exhibit 15.

# exhibit 15 about here

As we can see, bisector polishing represents an improvement over both the high-order and local density methods. Exhibit 16 gives the results of bisector polishing when *population means are used in place of core-point centers of gravity*. These are the best fixed partitions that can be chosen. Their performance gives a lower bound to the number of total minorities we might reasonably expect.

### exhibit 16 about here

A brief comparison with standard methods of clustering is given in exhibit 17.

exhibit 17 about here

### 17. Current preference.

Our current recommendation then is the following overall algorithm:

A) Use the basic-criterion algorithm (Section 9) - - with its step-by-step insertion of links - - to form a single spanning vine containing all data points.

B) Use the local-density algorithm (Section 13) - - with its near-neighbor density, vine smoothing, and differencing - - to identify core points.

C) (Here would be a logical place for a step to identify how many clusters we want.)

D) Use the basic-criterion algorithm (Section 9) again, this time on the core points only, to form 3 clusters.

E) Starting with the centers of gravity of these 3 clusters, use the iterated bisector algorithm (Sections 15, 16) to assign every point to one of the three clusters.

Notice the presence of 4 or 5 steps, using at least three wholly different algorithms. Our preferred procedure is not simple, but it seems to be effective.

Notice also that, while steps (A), (B), and (D) - - presumably together with (C), when such becomes available - - do fairly well in focusing on local comparisons of distances, step (E) compares much larger distances. A plausible place for a further step (after E) would involve looking even more carefully at pairs of adjacent clusters with the intent of improving their separation.

#### **PART D:** Sketches of further explorations

#### 18. 5-dimensional test bed.

We have looked briefly at 5-dimensional test beds constructed as follows:

• two of the dimensions represent the familiar circular Gaussians, with 3 subswarms centered on the vertices of an equilateral triangle of side  $t\sigma$ 

- 19 -

• the remaining 3 dimensions are independently sampled from the standard Gaussian distribution.

We tested the basic and iterated bisector polish algorithms on 10 realizations of the 5-dimensional structure at each of t = 3.2, 2.9, and 2.7. In terms of the median number of misclassifications, the basic bisector polish algorithms were inferior to the corresponding iterated bisector polish algorithms. Exhibit 18 shows the results for the iterated bisector polish algorithms.

### 19. Unequal-variance test bed.

All of the core-point algorithms were tested on a series of synthetic data sets containing 3 circular Gaussian subswarms of unequal variance. As before, the subswarms are centered at the vertices of an equilateral triangle. the triangle has sides of length  $(\frac{1}{2}\sqrt{2} + \frac{1}{2}\sqrt{3})\lambda\sigma$ , where the first subswarm has variance  $\sigma^2$ , the third has variance  $3\sigma^2$ . We generated 10 such data sets at each of  $\lambda = 3$  and  $\lambda = 2.7$ .

The iterated bisector polish algorithms out-performed both the basic corepoint and bisector polish methods. Results for the iterated bisector polish algorithms are summarized in Exhibit 19. Exhibit 20 shows the results from classification by maximum likelihood and the population bisectors. Each of the densities was completely specified for the maximum liklihood calculations; only the means were used to calculate population bisectors.

## 20. Unequal-shape test bed.

We generated series of test beds containing 3 2-dimensional Gaussian subswarms of unequal shape. The subswarms lie along an horizontal line segment of length 2t, we centered at each endpoint of the segment; the third subswarm is centered at the midpoint. The central subswarm has standard deviation  $\sigma$  in the direction parallel to the segment and  $3\sigma$  in the direction perpendicular to the segment. The subswarms at the endpoints of the segment are circular Gaussians with standard deviation  $\sigma$ .

We generated 10 test beds for each of t=3.7 and 3.2. Exhibit 21 shows two realizations of the unequally-shaped test beds. Results for the iterated bisector algorithms are given in Exhibit 22.

EXHIBIT 22: Total minorities for the iterated bisector algorithms with the unequal-shape test beds.

\* Actual total minorities: 2,7,7,11,11,15,17,24,30,34

\*\* Actual total minorities: 10,14,22,30,30,32,34,34,37,50

\*\*\* Actual total minorities: 6,8,9,9,9,12,16,17,19,27

\*\*\*\* Actual total minorities: 13,16,25,28,30,30,32,33,37,50

Note: For "h" see note to Exhibit 4.

B

## APPENDIX - Code for Algorithms (by Katherine M. Hansen)

All the clustering programs are written in the "C" language. We provide code for all the high-order and local density core-point algorithms below. The printout is divided into 6 files, formatted as follows:

1) "defs.c" (2 pages)

This file contains all of the type definitions and variable declarations required by the programs.

2) "hiormain.c" (1 page) - basic high-order algorithm

"densmain.c" (1 page) - basic local density algorithm "hoibmain.c" (1 page) - high-order and (basic & iterated) bisector algorithms

"ldibmain.c" (1 page) - local density and (basic & iterated) bisector algorithms

These are the main modules for each of the 4 core-point programs.

3) "modules.c" (10 pages)

This file contains the modules (functions) called by the main modules.

To run one of the algorithms on a particular data set, the user should:

- Copy the data into the file "datfile". Each line of the file should contain exactly one entry. The first entry should be the first variable for the first data point. The second entry is the second variable, first data point, etc. The last line of "datfile" should be the last variable of the last data point.
- 2) Edit the first 8 lines of "defs.c", so that NROW, NCOL, NCLUST, NCORE, and NN are set appropriately. (For the high-order algorithms, NCORE and NN may be set arbitrarily.)
- 3) In order, join the files "defs.c", the desired main module, and "modules.c". On a UNIX operating system, the command would be, for example:

cat defs.c hiormain.c modules.c > hiorder.c

The required source code is now held in the file "hiorder.c".

4) Compile the source code, to generate an executable file. On a UNIX system, the appropriate command would be:

cc hiorder.c -lm

The executable code would be contained in a file a.out.

5) Run the executable program. The classifications will be placed in a file called "countfile". Additional information may be placed in other files, as follows:

"corefile" (all 4 programs). Information on the NCORE-NCLUST edges of the core point vines. For each edge the 6 values just described above are placed in the file.

"noncorefile" (hior and dens). Information on the NROW-numcore edges linking non-core points to core point vines. For each edge, the 6 values described above are placed in the file.

"gravfile" (hoib and ldib). Coordinates of the (iterated) centers of gravity of the core point clusters. Each row of the file contains the coordinates of the core center.
