<u>Problem studied</u>: The objective of this research was to characterize and understand the shock wave consolidation of metal powders. A primary concern was the assessment of this process as a means of consolidating rapidly solidified powders without destroying the unique microstructures obtained during the rapid solidification processing.

<u>Principal accomplishments</u>: The conclusions of this work have been given in detail in the publications listed subsequently, and only a summary outline is presented here. More information can be obtained from the publications cited by number at the end of each listing.

1. Measured the shock Hugoniots of unsintered copper, 4330 steel and rapidly solidified aluminum + 6% silicon powders and showed that ductile materials can be described by the "p-a" model of pore collapse. Generally, irregular, low packing density powders achieve full density at the lowest stresses for any given material; likewise spherical powders required higher stresses [1].

2. Developed an elementary model for surface heating based on the flux of energy at the surfaces of powder particles during the rise of the compaction shock. This model was shown to agree with experimental observations of the fraction of localized material modification. It was concluded that: (1) The specific area of the powder and the rise time of the shock are important quantities which, with the net specific energy, determine the surface temperatures achieved; (2) Most of the energy of the shock is deposited at powder particle surfaces; (3) For given compaction conditions, the highest surface temperatures are obtained in powders of moderate packing density and small specific area; (4) Heating and cooling rates at particle surfaces can be extremely high ($10^8 - 10^{11}$ C/s), and metastable structures may form from locally melted or modified material; (5) For monosized spherical powders, the energy flux is independent of particle size, and the surface temperature increases with particle size [2-4].

3. Characterized the microstructures of compacts of copper, 4330 steel and aluminum + 6% silicon, and concluded that: (1) Localized thermal modifications can take the form of solid-state phase transformations (martensite in the steel) or surface melting (Al + 6% Si); (2) Knowledge of the shock history is essential to the interpretation and control of the consolidated microstructure; (3) Residual temperatures following compaction at stresses sufficiently high to induce desired surface modifications may produce undesirable changes in the final compact microstructure. The minimum powder size is fixed by the maximum residual temperature; (4) Confirmed the melting and rapid resolidification of material as a result of severe local deformation [5,6].

4. Produced consolidated aluminum + 6% silicon with tensile properties comparable to those of wrought material [6,8].

5. Showed that carbon piezoresistive sensors could be used to determine the '&I stresses during the consolidation of unsintered metal powders [7].

6. Wrote a review (by invitation) of the dynamic consolidation of metal powders [8].

7. Studied particle size effects in samples of explosively compacted stainless steel [9].

8. Performed cursory, low and high pressure compaction experiments on copper-zirconium rapidly solidified powder. Complete melting was observed at 60 GPa [10].
