I. INTRODUCTION

Different computer systems have different programming environments in spite of their similar capabilities. Some system functions, utilized through programming language compilers, work in the environments supported by software production, or by system hardware. Although the environments of software development support similar algorithms and tools, they usually make software programmers write another program to obtain the same result from different computer systems. There is no standard interface for the various workstation (SUN, APOLLO, etc.) systems.

A. PURPOSE OF THESIS

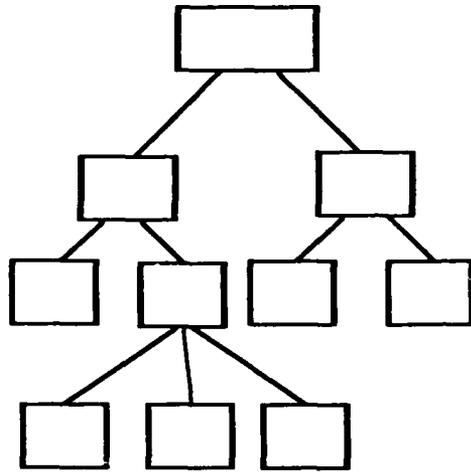

In this thesis, a common interface for a graphic software environment is established to create systematical functions which can be used for two different personal computing systems: Apple's Macintosh* and IBM PC series. The most important method used here to obtain this common interface is the Abstract Specification of data types, also named Abstract Data Type, consisting of a set of instances and a set of primitive operations which provide the only means for creating and interacting with the instances. The advantages of the Abstract Data Type, such as precise specification, modularity, and information hiding, can be very helpful for implementing the interfaces easily and with less errors. [Ref. 4, p. 18-19]

The development environment selected here is a graphics based software system that supports both window management and a menu driven style. The system is more user friendly and it becomes a definite trend toward the development of computer workstation systems because using the visual effects of graphics can generally communicate information more effectively than text. Menu displays save people the trouble of remembering many complex operation commands. The structure for user friendly system is different from the traditional structure of software (see Figure 1). The traditional software system is a kind of hierarchical structure that needs top-down approach to implement a program. The user friendly system needs a circular polling devices like mouse, keyboard, floppy disk drive, etc.

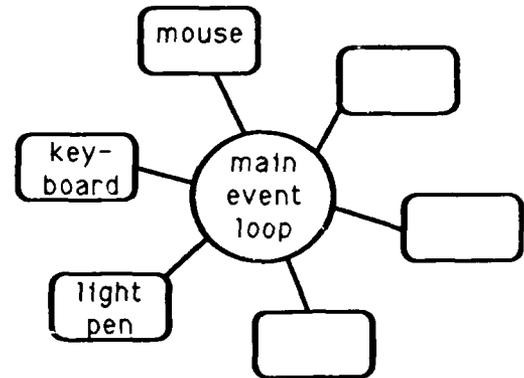

* Macintosh is a trademark of Apple Computer, Inc.

B. TOOLS

The primary development compiler and system language in this thesis is the C language. The C language is used primarily because it is easily ported to new systems and it allows the user to access his resources directly. For the Macintosh computer, LightspeedC™ (by THINK Technologies, Inc.) is used, and LATTICE C™ is used for the IBM PC computer with GEM (Graphics Environment Manager) which will be described later.

Traditional structure of software

Structure for user friendly system

Figure 1 Different Structure of Software Systems

II. PROGRAMMING ENVIRONMENT (User Interface Technology)

The operation and control procedures should be simple for the user to use the computer comfortably. A user-friendly system should provide all the information needed by the user in a graphics display. These graphic displays are referred to here as **desktop**. On the desktop, the user can slide documents around, organize work in folders, throw things away, or obtain new work—simply by moving the mouse and pressing the mouse button. The Macintosh Operating System supports such an operating and programming environment on Macintosh Computer [Ref. 2], and GEM provides a comparable environment for the IBM PC. GEM, developed by Digital Research, Inc.(DRI), is an operating environment which is similar to an operating system [Ref. 1]. Whereas an operating system allows the program to utilize console and disk devices in a standard manner, the GEM operating environment allows the GEM programmer to control a number of graphics devices and develop application interfaces in a consistent and standard fashion [Ref. 1]. So, these two environments allow a variety of high-level functions access to peripheral graphic devices and whose purpose is to make it easier for the application programmer to develop software that is both efficient and easy to use. In fact, the developed software is very similar to the window-type structure used in Macintosh software system, which is rather user-friendly in today's software development. Figure 2 shows the relationship between the application program, the user, and the computer [Ref. 1, p 4].

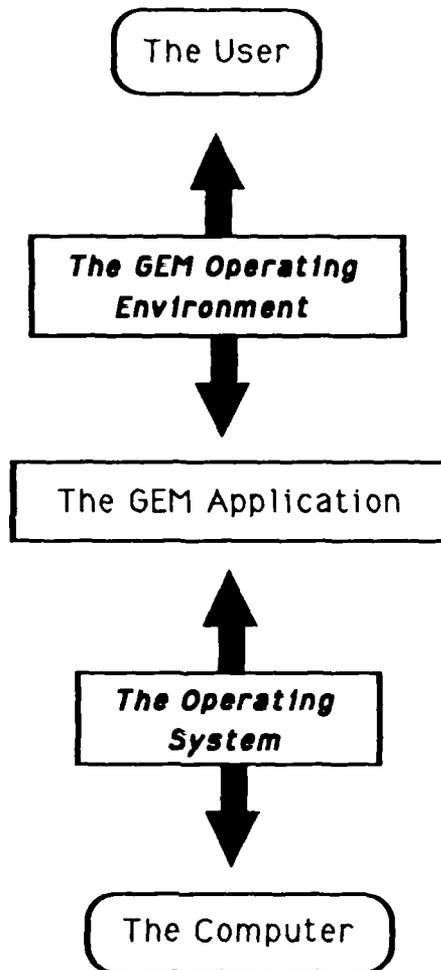

Figure 2 The Role of the GEM Operating Environment

With the GEM functions, the application program can control many devices manipulated by the user including the keyboard, the mouse, the screen, the printer, and the plotter [Ref. 1]. GEM is very similar to an operating system in that it allows the user to write programs without having to worry about what kind of mouse is attached to the computer, what resolution the screen has, or whether the computer's monitor is color or monochrome [Ref. 1].

Another example of a programming environment is the Operating System and the User Interface Toolbox in Macintosh [Ref. 2]. The application program will always call the routines which mostly are part of either the Operating System or the User Interface Toolbox and in the Macintosh ROM. The Operating System is at the lowest level; it does basic tasks such as input and output, memory management, and interrupt handling. The User Interface Toolbox is a level above the Operating System; it helps you implement the standard

Macintosh user interface in the application program [Ref. 3]. The user interface is the most important part of the user friendly computer system. In plain English, an interface is a junction or boundary where two things meet. In computerese, it refers to the set of rules and conventions by which one part of an organized system communicates with another. Whenever two components of the system come together, they exchange information by way of an interface [Ref. 3].

GEM and Macintosh software system both provide an operating environment in which the users can utilize all kinds of functions and routines to produce a user-friendly application program. Unfortunately, the programmers have to repeat the learning procedure and recode the source works if for some reason the application program is needed to run on both IBM PC and Macintosh microcomputers. In this thesis, a common interface is provided for programmers to reduce duplicated efforts and hopefully to get the same effect in both operating environments. The relationship between this common interface, the user, and the computers is shown in Figure 3.

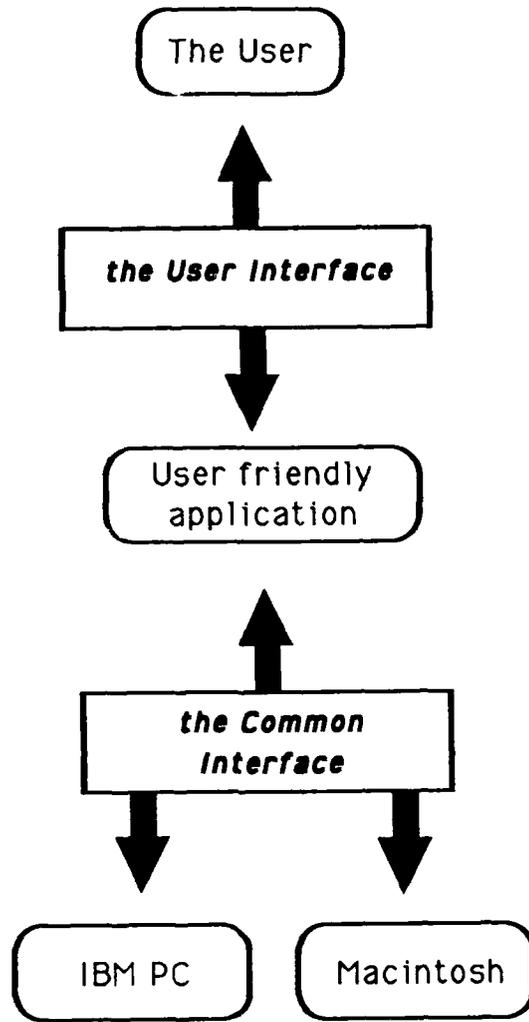

Figure 3 The Role of Common Interface

III. OVERVIEW OF GEM

The common interface mentioned last section actually consists of one interface with two drivers, one on IBM PC and the other on the Macintosh. It can be extended to any other mini- or microcomputers which provide a similar operating environment and a window and menu style structure. Before introducing the details of the common interface, the components of the GEM software environment will be described.

GEM consists of two major functional units: the Application Environment Services (AES) and the Virtual Device Interface (VDI); both provide a set of function libraries as a graphic interface [Ref. 1]. To build a typical GEM application, the user could implement the data fork and resource fork separately: the former basically consists of a set of procedures in the language that the program is written; the latter represents the menu bar and its associated submenus, form alerts, and dialogs created by another GEM application, known as the Resource Construction Set (RCS), which is provided by DRI. The RCS allows the programmer to construct the images, dialogs, and alerts that your application uses before any application code is written [Ref. 1]. GEM also provides some routines which build and deal with resources of application. It is less complicated when some important messages need to be modified without changing the application codes. This is a very important concept of establishing resources of a program because it saves the programmer a considerable amount of time and energy, when making complicated programming changes of some graphic structure. Thus, the application program is more flexible to change.

A. The Role of AES

The GEM AES provides routines which can be utilized to build the desktop and are organized in sets of related functions called *libraries* [Ref. 1]. For example, all the routines that manipulate windows are collected and form the Window Library of the AES, and all of the event routines form the Event Library, and so on [Ref. 1]. So, the AES represents a set of tools which can be useful when writing the first GEM application, the desktop, and in developing the common interface. AES includes a limited multitasking kernel, a screen Manager, and 11 libraries: Application, Event, Menu, Object, Form, Graphics, File Selector, Scrap, Window, Resource, and Shell. The GEM kernel is a limited multitasking system in that it can only handle five tasks: three desk accessory programs, one application, and the Screen Manager [Ref. 1]. Actually the Screen Manager is an internal task for event messages reporting to the AES event function. The GEM AES Event Library provides the

foundation that governs all user input in a GEM application. These input actions could be keyboard interrupts, mouse movement, mouse button changes, timer expiration, and messages in which some of them need the application to respond when receiving related events [Ref. 1].*

B. The Role of VDI

The purpose of the GEM VDI is to allow the user to control many different graphic devices with the same functions. The user can use the drawing routines to draw circles without considering what kind of output device will be used. This is very important because unlike IBM PC, Macintosh has more strict input and output constraints on hardware. IBM PC has a huge market share in the world and thousands of manufacturers who provide various competitive peripheral devices. Therefore, portability becomes indispensable for GEM. The VDI not only has a collection of drawing functions which can implement various shapes including points, markers, lines, polylines, graphics text, rectangle, and so on, but also control functions which open and close workstations (and virtual workstations) [Ref. 1].

* The details of all functions of other libraries can be found in the Programmer's Guide To GEM by Balma and Fidler (1986).

IV. OVERVIEW OF MACINTOSH

The Macintosh personal computer is designed in the way that the user can learn and use easily. Its revolutionary user interface distinguishes the Macintosh from other personal computers. Since the user interface acts as a good friend, it helps the user to communicate with the Macintosh comfortably. Everything on a Macintosh screen is displayed graphically; the Macintosh has no text mode. Generally speaking, the function sets are more detailed and includes more categories than GEM. All these functions are built into every Macintosh in ROM (read-only memory). The ROM can be divided into three parts: the Macintosh Operating System, which handles low-level tasks such as memory management, disk input/output, and serial communications; the QuickDraw graphics routines, which are responsible for everything displayed on the screen; and the User Interface Toolbox, which implements the higher-level constructs of the user interface, such as windows and menus [Ref. 3, p. 2]. The routines are divided according to function in Macintosh and are called "managers" [Ref. 2, p. I-9]. Figure 4 shows the whole function distribution in the Macintosh [Ref. 2, p. I-10].

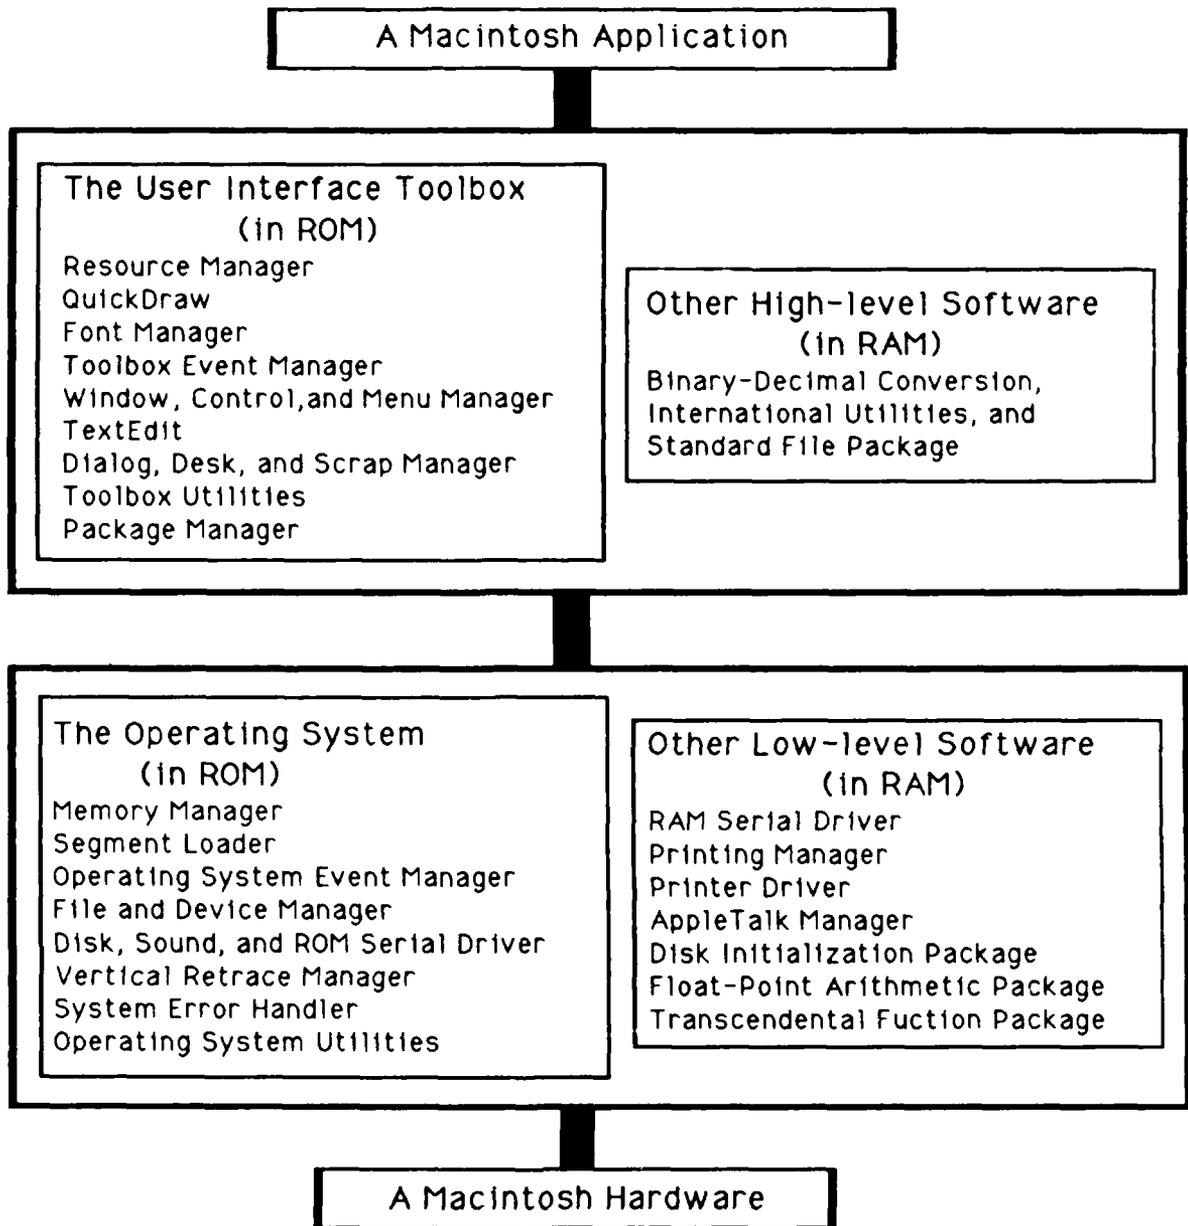

Figure 4 Overview of Macintosh

The Macintosh Toolbox also includes the Resource Manager which serves keep the data of an application separate from its code, making the data easier to modify and easier to share among applications. The Macintosh Resource Manager also supports more resource

types and more specified details than GEM. To manage and process the resource information, many utilities are available from the public domain [Ref. 2].

Before the Macintosh II come out, some routines in QuickDraw also enabled applications to do color drawing, including eight different colors, on color output devices. All nonwhite colors will appear as black on black-and-white output devices. In Macintosh II, more sophisticated color drawing routines are supported with 2^{32} colors.

Anyone who's used a Macintosh knows all about windows. The application displays all the information in the windows to the user, and the user tells the program what to do by clicking the mouse or hitting the keyboard. There can be any number of windows on the screen, and they can overlap in any order. Two different windows, the application window and the system window, both have their own characteristics to perform different tasks [Ref. 3].

Most of the time, the menu bar appears at the top of the screen, listing the titles of the available menus. One of the user's response to the program is to issue a command from an menu item under the title. Also, menus can be of various types in Macintosh to behave in certain standard ways. General speaking, the Macintosh Operating System and User Interface Toolbox provide a more complete function set of facilities for working with the User Interface than GEM does with its Operating Environment [Ref. 3]. For the same reason, it is also more complicated.

V. DESIGN OF THE COMMON INTERFACE

Before starting to implementing the common interface, we have to design what functions are required to provide the user access to the common interface, and we have to design common interface functions that both Macintosh and GEM can support. Basically the common interface is general purpose and should be extendable. Some special functions can be done by several algorithms and we need to think about possible procedures that can finish specified task, like window update and redraw, and also be compatible to different computers. Both GEM and Macintosh have detailed functions that may work in different ways, but their basic view of the user interface is similar. When we select the common portions of the functions, we may reduce function performance, but we also simplify the interface. Figure 5 shows the relationship of the Macintosh user interface, the common interface, and the GEM operating environment.

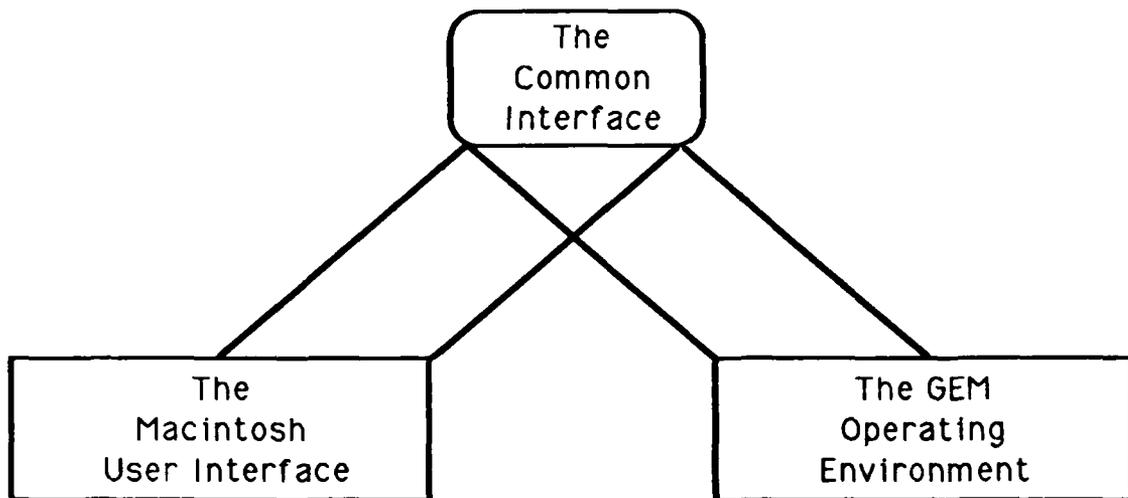

Figure 5 the relationship of all the interfaces.

To create the basic user-friendly interface, i.e., providing the complete graphical functions, at least four libraries must be built: the menu library, the primitive object library, the window library, and the event library.

A. Design Methodology and Abstract Data Type

When we decide to build a common interface which can perform graphic functions and window style, the most important consideration is the structure of this common interface and how to make the common interface easier to use. The structure of the

common interface can be divided into four libraries which can be implemented independently. Every library groups those functions which are relative to themselves. Also in every library, the functions can be further divided into several subgroups according to their tasks.

Before introducing the details of the libraries, we will discuss the design methodology and abstract data types of the common interface. In all of the primitive drawing objects, the rectangle acts a very important role in the common interface. When a circle, an ellipse, an arc, or a round rectangle are drawn, a rectangle is always needed for setting the drawing boundary and calculating the outline of the specified object. In GEM and Macintosh, they use different data structures to create a rectangle. GEM uses a top left point, a width and a height to specify a rectangle and Macintosh uses two points: a top left point and a bottom right point. It sounds tricky for us to decide which data structure is better. However, we are not going to worry about the data types of rectangle or point when using the concept of Abstract Data Type. We think about a rectangle in an abstract way. A rectangle consists of four points connected with four outer lines, and a point consists of two coordinate values, a horizontal and a vertical value, but not all the data are necessary to create a rectangle on the screen. In using the concept of Abstract Data Type, we simply design a set of functions that perform all the operations on a rectangle and achieve information hiding of the data structure. The programmer can do whatever he wants with a rectangle by utilizing these functions. Several representations, including the GEM and Macintosh ones, can be used to represent the rectangle and still support the rectangle functions defined in the abstract data type. The functions act like guards or interfaces that surround and protect the data structure in the center (see Figure 6). Obviously, the different data structures on the Macintosh and GEM are irrelevant. We follow the same design methodology of abstraction and information hiding on all the functions in the interface.

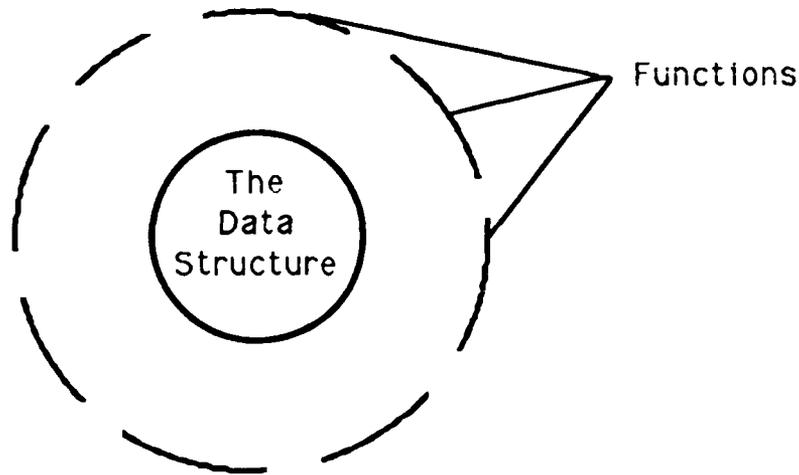

Figure 6 The Data Structure and Functions in Abstract Data Type

After implementing the design, the programmer won't need to manipulate the point and rectangle directly because he can utilize the functions which are provided by the common interface to deal with the rectangle or point. However, we still need to select a data type. In C, they are defined below:

```
typedef struct
{
  Int  v,h;
} Point ;
```

```
typedef struct
{
  Point  topLeft;
  Point  botRight;
} Rect ;
```

```
#define top      topLeft.v
#define left     topLeft.h
#define bottom   botRight.v
#define right    botRight.h
```

When the programmer wants to write an application program, the organization of the program becomes easy by using the concept of the common interface. In fact, the Event Library which provides the function that always generates fixed messages, or events, has

made the program only need to take care of the events. By notification of these events, the program can receive commands from the menu selection or handle the variation of the mouse button and movement issued by the user.

All the necessary definitions used by the common interface are put in the file "ASBIND1.H" for both Macintosh and GEM. To make sure that the program runs well, the programmer better selects the relative one when compiling the program. Similarly, the programmer might have a data type that is similar to the common interface to keep track of all the background information. The most obvious example in the DEMO program which will be introduced in next chapter, is the usage of the 'Winlist' structure which retains all the useful information about a window.

B. Design of the Primitive Object Library

The Primitive Object Library supports the manipulation of the primitive objects of the abstract specification — the Point and the Rectangle. As background, the graphic display device is subdivided into discrete areas known as pixels. As far as the graphic device is concerned, pixels are the smallest unit of manipulation. Reference to particular pixels on the abstract screen are via an imposed coordinate system. The origin or (0, 0) pixel is located at the upper left corner of the screen. In the Abstract Specification, there is a one to one mapping between points and pixels. A point is defined by specifying its horizontal and vertical displacement from the origin of a graphic environment. However, these displacements are relative to a particular window environment in which the point is used. Rectangles are defined by specifying the top left and bottom right corners of the rectangle (see Figure 7) [Ref. 2, p. I-140].

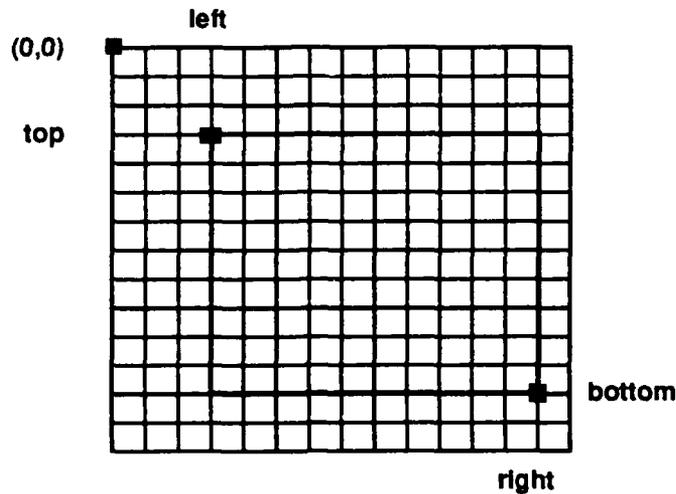

Figure 7 A Rectangle and the Origin

In the following description of the Primitive Object Library, as well as the other libraries, we will explain all functions in the C language style with their parameters. In the Primitive Object Library, the whole functions can be classified into three sets: the Point set, the Rectangle set, and the Point and Rectangle translation set.

1. The Point Set

As mentioned before, a point is specified by two integers which are coordinate values. We need enough functions to calculate or transfer the data type about point and integer. Some C compilers, because they do not allow passing **structs** as arguments, require the address of the Point to be passed instead. There are five functions in the Point set.

a. Set point by integers

Given two integers which represent the X and Y coordinate (the horizontal and vertical positions of the point respectively), the function returns a point.

State `set_point (x, y, pt)`
 Input: Int x, y the value of the X and Y coordinate respectively.
 Output: Point *pt the returned point.

b. Get X coordinate value from point

Function which returns the horizontal coordinate value of the input point.

Int `ret_val = get_x_coord (pt)`
 Input: Point *pt the given point.

Output: Int ret_val the X coordinate value.

c. Get Y coordinate value from point

Function which returns the vertical coordinate value of the input point.

Int ret_val = get_y_coord (pt)

Input: Point *pt the given point.

Output: Int ret_val the Y coordinate value.

d. Test two equal points

Function which determines if the two input points are the same point.

Bool ret_val = equalpt (p1, p2)

Input: Point *p1, *p2 the two given points.

Output: Bool ret_val TRUE, if p1 and p2 are the same point.
 FALSE, if not.

e. Copy point

Function which copies the source point into the destination point.

State copypt (source, dest)

Input: Point *source the given source point.

Output: Point *dest the returned destination point.

2. The Rectangle Set

Some functions, which pertain to the calculation of two rectangles, belong to this category.

a. Set intersection of rectangles

Function which determines the rectangle which is formed by the intersection of the two input rectangles. If the intersection is empty, the rectangle returned will be defined by a top left and bottom right point of (0, 0).

State set_insect_rect (r1, r2, rint)

Input: Rect *r1, *r2 the given two rectangle.

Output: Rect *rint the returned rectangle of intersection.

b. Test intersection of rectangles

Function which determines whether the two input rectangles intersect.

Bool ret_val = insect_rect (r1, r2)

Input: Rect *r1, *r2 the given two rectangle.

Output: Bool ret_val TRUE, if r1 and r2 intersect. FALSE, if not.

c. Test equal rectangles

Function which determines if the two input rectangles are the same rectangle.

Bool ret_val = equalrect (r1, r2)
Input: Rect *r1, *r2 the given two rectangle.
Output: Bool ret_val TRUE, if r1 and r2 are the same. FALSE, if not.

d. Copy rectangles

Function which copies the source rectangle into the destination rectangle.

State copypt (source, dest)
Input: Rect *source the given source rectangle.
Output: Rect *dest the returned destination rectangle.

3. The Point and Rectangle Translation Set

A rectangle is specified by two points. We need the Point and the Rectangle have enough operations to cover the information exchange. For example, type transfer from points to the rectangle or from the rectangle to the points.

a. Set rectangle by points

Function which, given two points, determines the smallest rectangle that those points could define and sets the top left and bottom right points of the output rectangle to correspond to that rectangle.

State set_rect (p1, p2, r)
Input: Point *p1, *p2 the given two points.
Output: Rect *r the returned rectangle.

b. Get the top left point from rectangle

Function which returns the top left point of the input rectangle.

State set_topLeft (r, p)
Input: Rect *r the given rectangle.
Output: Point *p the returned top left point.

c. Get the bottom right point from rectangle

Function which returns the bottom right point of the input rectangle.

State set_botRight (r, p)
Input: Rect *r the given rectangle.
Output: Point *p the returned bottom right point.

d. Test point in rectangle

Function which determines if the input point is within or on the border of the input rectangle.

Bool	ret_val = pt_in_rect (p, r)		
Input:	Point	*p	the given point.
	Rect	*r	the given rectangle.
Output:	Bool	ret_val	TRUE, if point p in rectangle r. FALSE, if not.

C. Design of the Event Library

Whenever the user presses the mouse button, or types on the keyboard, the application program is notified by means of an event. In the Abstract Specification, all events represent the user's actions. Not only the user can generate an event, also the event can generate another event. For instance, when the user drags a window away, the uncovered original region may need to be updated, and a redraw event is issued by the program. In Macintosh, more complicated events are also provided like disk-inserted event, network event, and device driver event, but there are only fundamental events in GEM. There are eight events that are summarized for the event function to meet the basic interface requirement. Two other mouse functions which relate to events are also included in the Event Library.

1. Get event function

Function which senses user interaction with the program, determines the type of interaction, and reports the user interaction to the program via the message globe data item. At present there are eight different types of events which are reported to the program:

a. Activate event

A notification that the user pressed the mouse button while the cursor was over an inactive window (requesting) to make that window active, and the application has to reorder the windows.

b. Redraw event

A notification that the work area of one of the windows present on the screen has been disturbed or exposed and must be rewritten.

c. Close window event

A notification that the user has pressed the mouse in the close box of the active window (if present).

d. Mouse down event

A notification that the user has pressed the mouse button in the working area of the active window.

e. Keyboard event

A notification that the user has typed the keyboard.

f. Mouse up event

A notification that the user has released the mouse.

g. Menu selection event

A notification that the user has selected a menu item.

h. Scroll bar event

A notification that the user has pressed the mouse in some part of the scroll bar.

Two functions are taken care of automatically by this routine : changing the size of a window in response to the user dragging in the window's grow box and moving a window in response to a user dragging in the title bar of the window.

State get_event ()

Input: none.

Output: 11 messages, in the following, are declared in "ASBIND1.H" file.

• EVTTYPE: always has a value to represent an event. There are 8 kinds of events that their program codes are shown below. The coming event always appends some relative and useful information, also shown behind the event, which can tell the programmer more details about the event.

- REDRAW with EVTWINDOW, EVTRECT.
- TOPPED with EVTWINDOW, ENTPOINT, EVTMOD.
- CLOSEWIN with none.
- SCROLLBAR with EVTSCRPART, EVTSCRMOVE, EVTSCRPOSN.
- MOUSEDOWN with EVTWINDOW, EVTPOINT, EVTMOD.
- KEYBOARD with EVTKEY, EVTMOD.
- MOUSEUP with EVTWINDOW, EVTPOINT, EVTMOD.
- MENUHIT with EVTMTITLE, EVTMITEM.

- EVTWINDOW: the returned window ID.
- EVTRECT: the rectangular area that needs redrawn.
- EVTPOINT: the cursor position when the event happened.
- EVTSCRPART: the scroll bar position report which the possible value is
V_PAGEUP, V_PAGEDOWN, V_ROWUP, V_ROWDOWN,
H_PAGEUP, H_PAGEDOWN, H_ROWUP, H_ROWDOWN,
V_THUMB, H_THUMB.
- EVTSCRPOSN: the scroll bar current setting. The minimam value of any scroll bar is zero, and the maximam one is 1000.

- EVTSCRMOVE: the difference that current setting minus the old one.
- EVTKEY: the input ASCII code.
- EVTMOD: the states of the modifier keys.
- EVTMTITLE: the selected menu title.
- EVTMITEM: the selected menu item.

2. Get mouse location

This function gets the current mouse position and outputs it in the local coordinate system of the specified window.

State `get_mouse(Id, pt)`

Input: Int Id the given window ID.

Output Point *pt the returned point of the mouse position.

3. Test mouse button

This is the function we use to get the state of the mouse up or down. It's useful when the user presses and moves the mouse as an action.

Bool ret_val = mouse_up()

Input: none.

Output: Bool ret_val FALSE, if mouse button is pressed.
 TRUE, if not.

E. Design of the Window Library

1. The Structure of Window

In the Abstract Specification, all objects (points, rectangles, etc) are defined in relation to the window which happens to be active at the time. The window, as an object consists of two basic regions, a structure region and a content region. The structure region contains the following objects (see Figure 7 about window structure):

a. Title bar

Bar at the top of the window containing the window's title.

b. Move area

Lined area of the title bar which can be clicked in to move the window.

Normally the move area is the same as the title bar area.

c. Close box

White rectangle which when clicked in, signals that the user desires to close the window.

d. Scroll bar:

Bars on the right and bottom of the window, used to signal the user's desire to move the window's contents up, down or side to side.

e. Grow box:

Area at bottom right of window, which when clicked and dragged around, changes the size of the window.

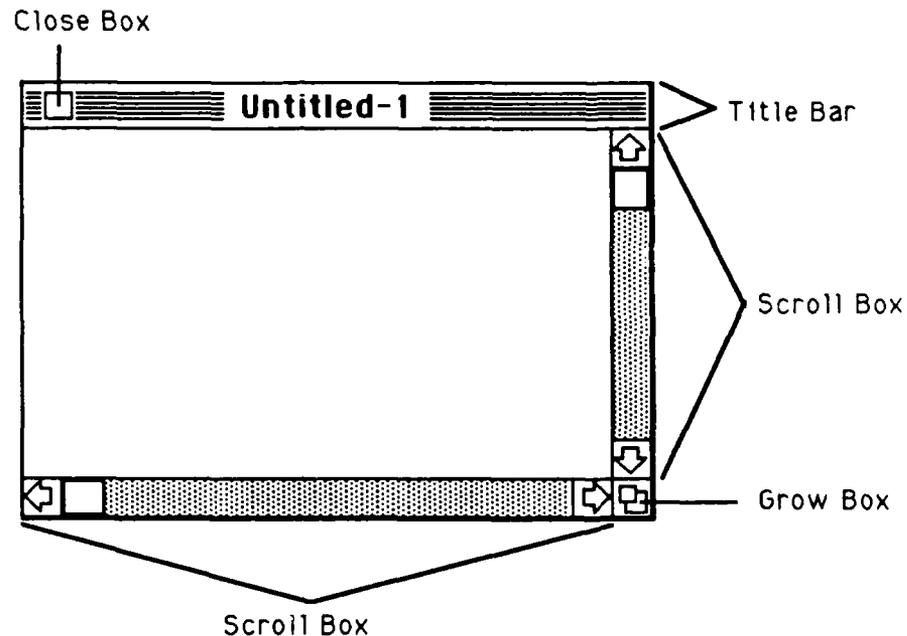

Figure 8 An active window

The remaining portion in the center of the window is the content region. This region can be thought of as an independent screen with its own local coordinate system whose origin (0,0) is at the top left corner of the content region. The basic system window, the desktop, is slightly different, having only a menu bar area at the top and then its content region. At any one time, there is a window which is "on top" of the screen. This window is the active window. All drawing activities take place in the active window except in the case of an update, in which case it takes place in the window specified.

All windows once allocated are managed by the window ID number which is assigned at the time of creation. To prevent out of memory errors, the maximum number of available windows is eight. In general, the programmer has to keep the ID information while manipulating multiple windows.

2. The Window Function Set

All functions used to manipulate windows and other relative objects, can be divided into six parts.

a. Window Manipulation

There are several basic functions here to manipulate windows as a whole entity.

i. Create a new window

Function which allocates space for a new window and displays it as the active window. The programmer can create new windows with different optional properties such as vertical and horizontal scroll bars, close box, grow box, etc.

Window_id ret_val = set_new_window (InitRect, Partspec, Title, is_Visible)

Input: Rect *InitRect a rectangle, given in global coordinates, determines the window's size and location.

 Bit16 Partspec specifies which optional parts of the window are to be included (see below).

 Parts (optional): defined in "ASBIND1.H" file.

 W_NAME include a title bar;

 W_CLOSE include a close box;

 W_SIZE include a size box;

 W_HSCROLL include a horizontal scroll bar;

 W_VSCROLL include a vertical scroll bar.

(To include more than one option, pass a bitwise OR of any combination of above)

 Char Title address of string to be used as a title for the window.

 Bool is_Visible TRUE, if the window is to be displayed;
 FALSE, if not.

Output: Window_id ret_val the identifier of the new window.

ii. Show window

Function which draws an invisible but previously defined window onto the screen. This window becomes the active window.

State show_window (Id)

Input: Window_id Id the given window identifier.

Output none.

iii. Hide window

Function which removes the specified window from the screen without deallocating it.

State hide_window (Id)
Input: Window_id Id the given window identifier.
Output none.

iv. Activate window

Function which causes the specified window to become the active window. It causes any window (but the desktop with a ID number of 0) to be moved to the top and a new background will be drawn in, however, the contents will not be automatically redrawn.

State activate_win (Id)
Input: Window_id Id the given window identifier.
Output none.

v. Close window

Function which closes and permanently deallocates the specified window.

State close_window (Id)
Input: Window_id Id the given window identifier.
Output none.

vi. Update window

Function which sets the system into the update window mode, drawing will be limited to the visible region of the window to be updated (as identified by the ID number input) to the function. When given a rectangular area to update, the function will return the intersection between that area and one of the rectangles which define the visible area of the window to be updated. In the Macintosh, the update event happens window by window (in front to back order). In GEM, when a REDRAW event is issued, a rectangle list, divided from the screen and window, is built for the program to update. Thus, the programmer always needs to pass the EVTRECT to this function.

Bool rec_val = update_win (ID, Up_rct, Dr_rct)
Input Window_id ID the ID of the window that will be updated.
 Rect *Up_rct the rectangle to be updated.
Output: Rect *Dr_rect the intersection of update rectangle and
 visible region.
 Bool ret_val TRUE, if need updat. FALSE, if not.

vii. Update next window

To solve the update problem of GEM and Macintosh, this function moderates the conceptual difference between two computers and completes the update mission without having much redundant work. In Macintosh, this function does nothing and always returns false. But, it is still useful for GEM.

Bool	rec_val = next_update (Up_rct, Dr_rct)	
Input	Rect	*Up_rct the rectangle to be updated.
Output:	Rect	*Dr_rect the intersection of update rectangle and visible region.
Bool	ret_val	TRUE, if next update is necessary; FALSE, if not.

viii. End updating window

Function to ends the update mode and restore the clip area to match the active (topmost) window. The programmer always has to call update_win() when receiving a REDRAW event, and call end_update() at the end of update.

State	end_update ()	
Input:	none.	
Output:	none.	

ix. Find active window

Function which shows the identifier of the active window.

Window_id	ret_val = get_active()	
Input:	none.	
Output	Window_id	ret_val the returned window ID.

b. Scroll Bar Manipulation

In fact, scroll bar is part of control facilities of a window to adjust the viewing position of the document of the window. The scroll bar is divided into five parts to perform different functions. The up and down arrows scroll the window's content a line at a time. The paging up and down regions scroll a page at a time. The thumb can be dragged to any position in the scroll bar, to scroll to a corresponding position within the document (see Figure 9) [Ref. 2]. Six functions are shown below.

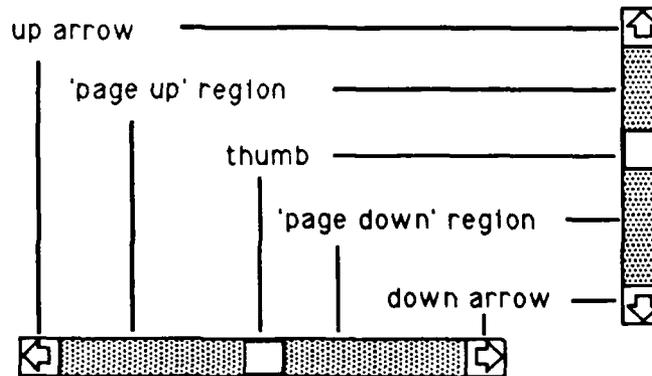

Figure 9 Parts of a scroll bar

i. Horizontal content scrolling

Function which scrolls the content area of the active window by the specified number of pixels. If the number is positive, the region will move to the left, and to the right if negative. The returned rectangle, which was previously covered, will show up now and should be passed for update.

State hscroll (num, Up_rect)
 Input: Int num the pixel number to scroll
 Output Rect *Up_rect return the rectangle which will be updated

ii. Vertical content scrolling

Function which scrolls the content area of the active window by the specified number of pixels. If the number is positive, the region will move up, and down if negative. The returned rectangle, which was previously covered, will show up now and should be passed for update.

State vscroll (num, Up_rect)
 Input: Int num the pixel number to scroll
 Output Rect *Up_rect return the rectangle which will be updated

iii. Set horizontal scroll bar value

Function which sets the value of the horizontal scroll bar of the active window.

State set_hscroll (val)
 Input: Int val new horizontal scroll bar setting.
 Output: none.

iv. Set vertical scroll bar value

Function which sets the value of the vertical scroll bar of the active window.

State set_vscroll (val)
Input: Int val new vertical scroll bar setting.
Output: none.

v. Get horizontal scroll bar value

Function which returns the horizontal scroll bar value.

Int ret_val = get_hscroll ()
Input: none.
Output: Int ret_val the returned horizontal scroll bar value.

vi. Get vertical scroll bar value

Function which returns the vertical scroll bar value.

Int ret_val = get_vscroll ()
Input: none.
Output: Int ret_val the returned vertical scroll bar value.

c. Drawing Background Manipulation

Abstraction Specification of graphic objects has three different kinds of characteristic: background pattern, mode, and color. Pattern includes black, dark gray, gray, light gray, and white. Mode includes *replace*, *transparent*, *xor*, and *reverse transparent*. Color includes light and dark which both include white, black, red, green, blue, cyan, yellow, and magenta.

i. Set pattern

Function which sets the pattern to be used to draw and fill in shape.

State set_pattern (newpattern)
Input: Pattern_id newpattern the given pattern ID.
Output: none.

ii. Set mode

Function which sets the global mode for drawing onto the screen.

State set_xfer_mode (newmode)
Input: Pattern_id newmode the given transfer mode ID.
Output: none.

iii. Set color

Function which sets the global color for drawing.

State set_color (newcolor)
Input: Color_id newcolor the given color ID.
Output: none.

iv. Get pattern

Function which returns the identifier of the drawing pattern.

Pattern_id ret_val = get_pattern ()
Input: none.
Output: Pattern_id ret_val the returned pattern ID.

v. Get mode

Function which returns the identifier of the drawing transfer mode.

Mode_id ret_val = get_xfer_mode ()
Input: none.
Output: Mode_id ret_val the returned transfer mode ID.

vi. Get color

Function which returns the identifier of the drawing color.

Color_id ret_val = get_color ()
Input: none.
Output: Color_id ret_val the returned color ID.

d. Drawing Object Manipulation

Drawing functions are the most important part of the Abstract Specification. The reason we put this function in the Window Library is all object drawing routines happen in a window. All of the drawing happens in the active window with the current setting of pen mode, pen pattern, and color. The coordinates of the input point or rectangle are assumed to be relative to the top left corner of the active window's work area. There are five kinds of object supported in the Abstract Specification : line, rectangle, ellipse, arc and round rectangle.

i. Draw a line

Function which draws a line in the currently active window.

State drawline (St_pt, End_pt)
Input: Point *St_pt the starting point.
 Point *End_pt the ending point.
Output: none.

ii. Draw a rectangle

Function which draws the outline of a rectangle in the active window.

State drawrect (In_rect)
Input: Rect *In_rect the given rectangle.
Output: none.

iii. Draw an ellipse

Function which draws the outline of an ellipse within the specified rectangular area of the active window.

State drawellipse (In_rect)
Input: Rect *In_rect the given rectangle.
Output: none.

iv. Draw an arc

Function which draws the outline of an elliptical arc between the two input angles within the specified rectangular area of the active window.

State drawarc (R, begang, endang)
Input: Rect *R the given rectangle.
Int begang the starting angle.
Int endang the ending angle.
Output: none.

v. Draw a round rectangle

Function which draws the outline of a round rectangle within the specified rectangular area of the active window.

State drawrndrct (In_rect)
Input: Rect *In_rect the given rectangle.
Output: none.

vi. Fill a rectangle

Function which fills the outline of a rectangle in the active window.

State fillrect (In_rect)
Input: Rect *In_rect the given rectangle.
Output: none.

vii. Fill an ellipse

Function which fills the outline of an ellipse within the specified rectangular area of the active window.

State fillellipse (In_rect)

Input: Rect *In_rect the given rectangle.
Output: none.

viii. Fill an arc

Function which fills the outline of an elliptical arc between the two input angles within the specified rectangular area of the active window.

State fillarc (R, begang, endang)
Input: Rect *R the given rectangle.
Int begang the starting angle.
Int endang the ending angle.
Output: none.

ix. Fill a round rectangle

Function which fills the outline of a round rectangle within the specified rectangular area of the active window.

State fillrndrct (In_rect)
Input: Rect *In_rect the given rectangle.
Output: none.

e. Text Manipulation

In the Abstract Specification, only a few functions are available for the basic manipulation of text.

i. Set text pen position

Function which sets the location of the next character to be drawn in the active window (location of text pen in window local coordinates).

State txtpen (inpt)
Input: Point *inpt the given text location.
Output: none.

ii. Get text pen position

Function which returns the location of the text pen for the currently active window (in window local coordinates).

State set_txtpen (pen)
Input: none.
Output: Point *pen the returned text location.

iii. Write string

Function which draws a string into the active window at the current location of its text pen.

State drawstring (strptr)
Input: Char *strptr the string which will be drawn.
Output: none.

iv. Write character

Function which draws a character at the current location of the active window's text pen.

State drawstring (inchr)
Input: Char inchr the character which will be drawn.
Output: none.

v. Get character width

Functions return the current character width.

Int ret_val = get_wchar ()
Input: none.
Output: Int ret_val the character width.

vi. Get character height

Functions return the current character height.

Int ret_val = get_hchar ()
Input: none.
Output: Int ret_val the character height.

f. System Manipulation

The programmer needs to call sys_init() and sys_end(), which will be described below, at the beginning and end of the program respectively.

i. System initialization

Function to initialize the system to run the Abstract Specification

Interface.

State sys_init ()
Input: none.
Output: none.

ii. Exit application program

Function which returns all allocated resources to the system at the end of the program.

State sys_end ()
Input: none.
Output: none.

E. Design of the Menu Library

Menu selection is a method used to issue a command to the application program. This is one of the most important and user-friendly characteristics of the common interface, the user just moves and clicks the mouse around the screen to control the application program without typing the keyboard. GEM menus are known as drop-down menus because when the user moves the mouse over the menu bar, the GEM Screen Manager drops the entire menu down onto the screen. In contrast, the Macintosh uses pull-down menus, which work by having the user click on the desired menu title, and, holding the button down, move through the menu highlighting each pointed-at item. By releasing the button the user selects the last highlighted item. Thus, on the Macintosh, the menu is displayed as long as the button remains depressed, whereas GEM menus are visible until the user moves the mouse out of the menu, either into another menu or to another part of a screen. GEM menus are also different in that the mouse button is used to select a menu item. As shown in Figure 10, the application highlights the title and displays the menu items [Ref. 2, p. I-52].

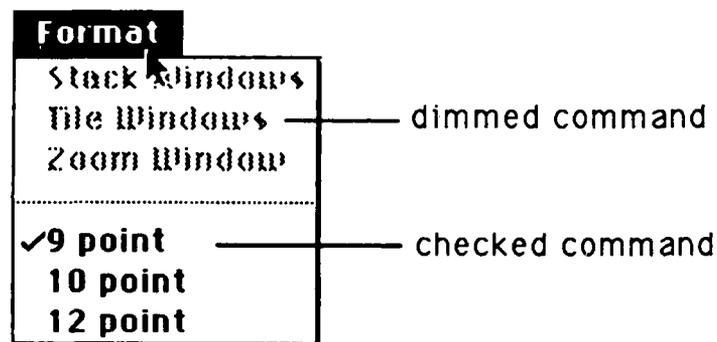

Figure 10 Menu

The GEM Menu Library only provides the fundamental functions required, but the Macintosh Menu Manager includes the complete works of the menu functions. To collect the necessary set, there are five basic menu routines that are chosen for performing menu functions.

1. Menu bar initialization

This function always has to be called by the programmer at the beginning of the application to show the menu bar. Here we need the resource file name prepared in advance. So before passing the resource file name to this function, the programmer must

utilizes the respective resource maker utility program supported from DRI and Apple Computer, Inc., to edit the menu resource for the application program* .

State init_menu (filename, barid)
Input: char *filename the resource file name
 Menu_id barid the menu ID specified by resource utility.
Output: none.

2. Menu item enable

To make sure the user can issue the proper commands, the application program may only allow certain commands to be selectable. This function corresponds to the menu item disable which will be mentioned next.

State item_enble (menunum, itemnum)
Input: Int menunum the menu title number
 Int itemnum the menu item number
Output: none.

3. Menu item disable

In some specified situation, some unacceptable or unnecessary commands must be disabled. A disabled item cannot be chosen; it appears dimmed in the menu and is not highlighted when the cursor moves over it. You can change the enabled or disabled state of a menu item with this and the last function.

State item_disable (menunum, itemnum)
Input: Int menunum the menu title number
 Int itemnum the menu item number
Output: none.

4. Set menu item check mark

The programmer can place a check mark to the left of the text of the menu item. This action can clearly tell the user which command is working or what state is presenting. With this function, the programmer can set or clear the check mark.

State item_mark (menunum, itemnum, mark)
Input: Int menunum the menu title number
 Int itemnum the menu item number

* There are several utilities available, include RMaker, ResTool, and ResEdit, for the Macintosh computer. Also, GEM has the Resource Construction Set supported by DRI for the same purpose.

Bool mark if TRUE, then a check mark will appear each subsequent time the menu is pulled down. If FALSE, then remove the check mark from the menu item.

Output: none.

5. Menu title highlighting

When an item is selected, the menu title in the menu bar remains highlighted until the command has completed execution. So after the menu is selected, the application should perform the chosen task and then call this function to unhighlight the chosen menu title. The programmer can also use this function to highlight the menu title. Since only one menu title can be highlighted at a time, it unhighlights any previously highlighted menu title.

State menu_hilight (menunum, hilight)

Input: Int menunum the menu title number

Bool hilight if TRUE, then hilight the title of given menu. If FALSE, unhilight the chosen menu title.

Output: none.

VI. IMPLEMENTATION

In this section we will discuss some details of implementing the common interface and the testing of a demonstration program. This mini interface actually provided only basic functions for building an application program. To fully utilize the available functions, we have to introduce all the other necessary features and properties of the programming environment. First, we will examine the designing of the data structures, then all the functional abilities of these libraries. In the view of a design task, the design of the data structures should be put last. But the whole design is actually digested in the GEM and Macintosh programming environments to get a feasible intersection. So, here we just use the data structure to establish the direction of the implementation work.

There are several special data structures and defined constant data which were designed for the Event and Window Library to be utilized by the programmer. The following descriptions show some detail notes about the Abstract Specification of implementation:

- **The window type and limitation**

- The maximum number that an application can open at a time is limited under seven to prevent out of memory. Because we have to control our own window by the data structure which summarized from the GEM and Macintosh, and specify the number of windows during the compile time.
- Every window has its own identifier instead of a window pointer to its location.
- The scroll bar is regarded as part of the window structure. The thumb value is between zero and 1000.
- The Desktop on the screen has the window identifier value zero. When an invalid window happens in any function its identifier value is -1.
- A newly created window has options to include title, close box, grow box, the horizontal and/or vertical scroll bar.

- **The event structure**

- the notification of of a event is always accompanied by different information which depends on the event. A keyboard event comes with the key stroke and the state of the modifier keys. Menu selection events come with the selected menu title and item. Redraw event comes with the window and rectangle which needs redrawn. Mouse down event comes with the mouse down window,

cursor point, and the state of modifier keys. Update, close window event comes with the window where the event happened. Scroll bar event comes with the specified part of scroll bar, and the new thumb position.

- all events are enqueued into an internal first in first out data structure.
- all windows can always be dragged or sized, but the actions might generate redraw events depending on whether the hidden parts of inactive window appear.

- **The graphic object structure**

- the graphic objects can be line, rectangle, ellipse, arc and round rectangle. Except line object, the other objects can be drawn either outline only or with pattern in.
- the background of all objects include color, pattern, and mode that they all can be represented by the specified identifier value.

- **The basic structure of a standard program**

- the DEMO program shown in appendix has a basic structure and it can be a good reference for the programmer. Normally, the programmer takes responsibility of the content of the include file and resource file for the application.
- the programmer should always include the "ASBIND.H" and "ASFBIND.H" files. The ASBIND.H comprises the binding data type of Abstract Specification, the ASFBIND.H includes all the binding functions call of Abstract Specification.
- the following flow chart shows the basic style of an application.

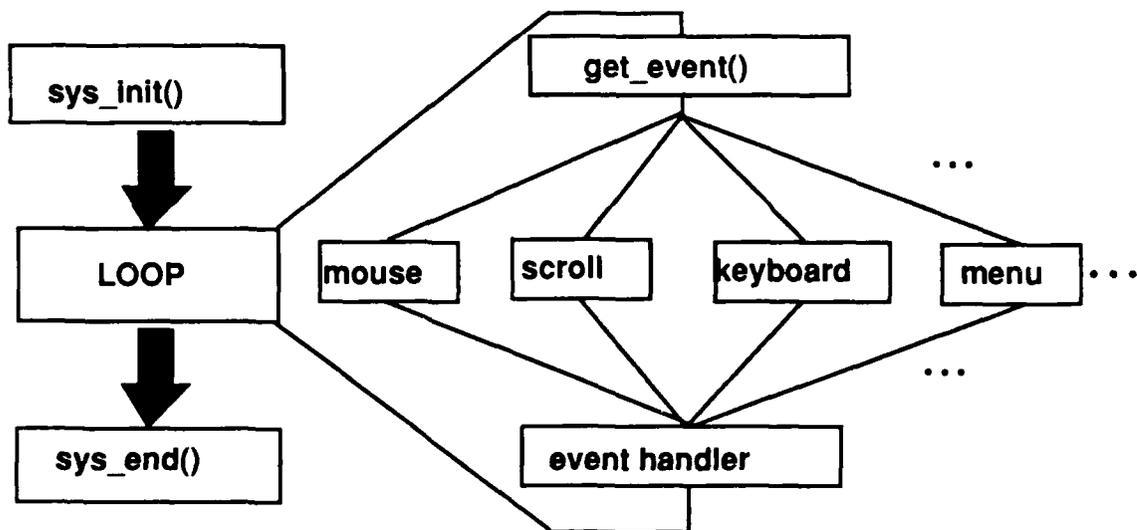

Figure 11 The Basic Structure of an Application Program

For the purpose of understanding how this Abstract Specification of the common interface will work, there is a demo program in appendix illustrating the basic graphic application and how those functions can be applied by the user.

VII. CONCLUSION AND RECOMMENDATION

In the beginning of this paper we mentioned that the purpose of this common interface is to make the same source code run on an IBM PC under the GEM environment and the Apple Macintosh with the same effect. This idea could be used to improve the portability of many applications since the application could be separated into system dependent and system independent (common interface) routines. We have achieved this purpose since the source code that uses the common interface of either system is independent. When the programmer want to run the same result on other different machines, he can just rewrite the system dependent part. In this thesis, we just prove that it is possible to support the common interface (system dependent part) to the programmer and save duplicated works. Clearly only one drawing demo program cannot prove that the common interface will work correctly when further used in other more sophisticated application program, but it does prove the feasibility of the idea. Of course, in the intersection of the GEM and Macintosh we lose some of their original powerful abilities, but if the system dependent part of an application can expand and provide other functions, then the concept of the common interface could be an important idea.

For further study, we recommend that this idea be examined on other systems. For example, can the same abstract design be implemented on top of X-Windows on Unix, or MS Windows on MS-DOS? Such an effort would lead to a better understanding of this type of interface.
