## ABSTRACT

Providing a simplified representation of terrain characteristics has applications to optimal-path-planning programs using spatial reasoning. Utilizing computer vision techniques, our program creates polygonal homogeneous vegetation regions based on map vegetation data from a digitized Defense Mapping Agency database. Boundary points for regions are identified from the vegetation codes in the database, and then the boundary contours of the regions are traced using a modified look-left boundary tracing algorithm. Each region is then represented by a polyline comprised of line segments that meet a minimum threshold for fit using the linear least-squares criterion. The segments are determined by first recursively splitting the region boundary until all segments meet the fit threshold, and then merging adjacent segments that meet the threshold.

## I. INTRODUCTION

### A. BACKGROUND

Recent work at the Naval Postgraduate School has studied methods to determine the optimal path between two points in terrain. These methods assume that the terrain can be represented by homogeneous polygonal regions. Attributes of a region can include the degree of vegetation, type of vegetation, soil composition, elevation, slope, orientation of the slope, and man-made physical features within the area. Currently the optimal-path-planning research is using artificial terrain data. A program that will take Defense Mapping Agency digitized terrain data and create homogeneous regions would enable researchers to show the real-world feasibility of their path-planning approaches. In this thesis, we have developed tools to create these regions from vegetation data recorded at evenly-spaced sample points.

To create two-dimensional regions from vegetation data at evenly-spaced points we used two phases. The first phase identified the boundary points of a homogeneous region, points halfway between adjacent sampled points of differing vegetation. The second phase used a split-and-merge method with linear-least-squares constraints to reduce the complexity of the region boundaries (their number of vertices). The simplified regions enable us to represent the terrain characteristics in a clear and concise manner.

## **B. ORGANIZATION**

Chapter 2 introduces previous work in the areas of region representation by polylines, split-and-merge algorithms, and the linear-least-squares constraints method of approximating the fit of points to a line. Chapter 3 describes the Defense Mapping Agency Databases, and databases used for optimal path planning. In Chapter 4 we discuss in detail our program. Chapter 5 shows our experimental results in both qualitative and quantitative terms. Finally, Chapter 6 summarizes our contributions and discusses some of the possible areas for further research based on this work.

## II. REVIEW OF REGION REPRESENTATION BY POLYGONS

### A. POLYLINES

Polylines can be used to approximate the boundary of a region. A polyline representation consists of a list of points. See Figure 1. A region can be represented

Figure 1 Polyline Representation of a Region

to any degree of accuracy by the polyline depending upon where and how many points are used [Ref. 1:p. 232].

A common technique used to determine a polyline representing a region is splitting and merging. It can be proved that the number of line segments in a polyline constructed using a split and merge algorithm will never be greater than two times the minimum number of segments for a given line fit criteria [Ref. 2: p.283]. There are numerous methods to determine whether a given line segment should be split, merged or left untouched. Usually all methods split segments of a polyline until all subsegments meet criteria for linearity. Then usually adjacent segments of the polyline are merged together if they meet other criteria. The methodology used to determine linearity is problem-domain-dependent.

The linear least-squares method to determine the collinearity of points has been used in a merge-only scheme [Ref. 3]. Two adjacent points were arbitrarily selected and points added to their segment until the linear least-square fit of the segment failed the fit criteria. At that point a new segment was started and the process repeated until the region was completed. The start point for each segment determines the breakpoints of the region. The primary disadvantage of this method is that the merging without backtracking or splitting does not give the most aesthetically pleasing breakpoints.

## **B. APPROXIMATION OF FIT BY LINEAR LEAST-SQUARES METHOD**

The fit of a set of points with respect to a given line can be judged using several techniques. The linear least-squares method sums the squares of the distances from each data point to the line. In our work the line is determined by the two endpoints of the boundary-points subset tested. We use the general equation of a line:

$$Ax + By + C = 0 \quad (1)$$

Given two endpoints  $(X1, Y1)$  and  $(X2, Y2)$  of the line segment we can derive the value of the constants A, B, and C by:

$$\frac{Y - Y1}{X - X1} = \frac{Y2 - Y1}{X2 - X1} \quad (2)$$

Cross multiplying and solving for zero yields:

$$A = Y1 - Y2 \quad (3)$$

$$B = X2 - X1 \quad (4)$$

$$C = X1Y2 - X2Y1 \quad (5)$$

The slope and the intercept are:

$$M = -A / B \quad (6)$$

$$B = -C / B \quad (7)$$

The linear least-squares fit for n points with respect to the line calculated above is:

$$FIT = \sqrt{\frac{\sum_{i=1}^n (Ax_i + By_i + C)^2}{n(A^2 + B^2)}} \quad (8)$$

The fit is a calculation of how far on the average the  $n$  points are from the line. A fit of zero means that all of the points lie on the line. By squaring the distance from the line we give equal weight to points that are on each side of the line. The square root enables us to renormalize distance from the line.

### **III. SPATIAL TERRAIN DATABASES**

#### **A. DEFENSE MAPPING AGENCY DATABASES**

The Defense Mapping Agency maintains digitized terrain databases for most of the world. These databases contain information about elevation data, vegetation, bodies of water, and man-made objects. Typically these databases record data at evenly spaced sample points in latitude and longitude.

The Digital Terrain and Elevation Data (DTED) database used in our program contains two types of such information. The terrain elevation and the height of the vegetation coverage are encoded in two bytes for each sample point. The three most significant bits are the vegetation code and the remaining 13 bits are the elevation in feet. The three bits of vegetation code are explained in Figure 2. Vegetation codes 6 and 7 never occurred in the terrain samples we selected so we did not provide additional handling for these codes. The samples are conducted every 12.5 meters. Each square kilometer or grid square requires 6400 samples ( $80 * 80$ ) or 12,600 bytes.

#### **B. DATABASE USAGE FOR OPTIMAL-PATH PLANNING**

There are several approaches to determine the optimum path between two points. At the Naval Postgraduate School considerable research is being conducted using spatial reasoning. Spatial reasoning methods do not use traditional grid terrain modeling where the terrain is represented by evenly distributed sample points. Instead spatial reasoning uses descriptive terrain modeling where the terrain is partitioned into

VEGETATION CODE	VEGETATION HEIGHT

7	NOT USED

**Figure 2 Vegetation Codes**

homogeneous regions. The minimal-energy optimal-path-planning research conducted by Ron Ross uses partitioned regions based on the slope of the terrain, soil composition, and other factors [Ref 4].

The first step to implement this work was done by Seung Hee Yee who wrote a program for planar-patch terrain modeling based on the elevation data [Ref 5]. One of the three methods that he tested was joint top-down and bottom-up terrain modeling. His top-down phase used a quadtree subdivision method to divide the terrain area into regions represented by a plane and the fit of that plane to the data points. After all subregions meet the appropriate fit threshold, he used a bottom-up approach to merge similar adjacent regions. His bottom-up phase used two merging criteria. First, the adjacent planes must have a minimum difference of the squares of

the differences of the respective plane coefficients. Second, the data points from both regions must be representable by a plane which meets the same fit threshold as in the top-down phase. If both criteria are met, then the regions are merged and the new plane is stored along with its fit. During the year since Seung Hee Yee developed his program, Professor Rowe has improved it by including better techniques to insure continuity between the planes of adjacent regions. The planar patches or regions from these programs could be further partitioned into regions of homogeneous vegetation, but this has not yet been done.

The simplest minimal-energy optimal-path-planning programs run on the order of  $N$  squared with respect to the number of vertices per region and the number of regions. For this reason it is important to create regions which preserve the topology of the original sampled data and yet minimize the number of vertices.

## **IV. IMPLEMENTATION**

The program developed is a method to create polygonal homogeneous-vegetation regions from the Defense Mapping Agency database described in Chapter 3. To form these regions the program's first phase identifies which sample points in the database have different vegetation codes than their neighbors. These sample points are identified as boundary cells. A boundary-identification algorithm is then used on these boundary cells to determine sequences of boundary points between regions of different vegetation. A second phase then takes the sequence of boundary points for each region and performs a split-and-merge algorithm on the list of those points to redefine the regions in a more efficient form (one with fewer vertices).

### **A. DESCRIPTION OF THE BOUNDARY-IDENTIFICATION PHASE**

We chose C as the language for the boundary-identification phase. The program runs using a BSD 4.3 compiler on a VAX 11/785 or on an Integrated Solutions (ISI) workstation. Appendix B contains the source code for the boundary identification phase. This phase requires input from the Defense Mapping Agency DTED database. This database consists of elevation and vegetation data points every 12.5 meters. Our program builds regions containing sample points with the same vegetation code for a one kilometer by one kilometer grid square.

Several assumptions were required in the boundary-identification phase. First, each region formed is assumed to contain vegetation of only one kind. This is

fundamental to the concept of homogeneous regions. Second, regions will not consist of one sample point. These singular points which have no adjacent neighbors above, below, or beside them are changed to have the same code as the adjacent data point with the largest vegetation code (i.e. heaviest vegetation). Third, holes in regions will be detected only in the sense that another region will be formed inside of the outer region. No special classification is added to a region if it has a hole.

The boundary-identification phase is divided into two passes through the input data. The first pass identifies the boundary cells. A sample point is considered to be a boundary cell if any of its four neighbors above, below, or beside it have a different vegetation code. The sole exception to this rule exists when the point itself or its differing neighbor are singular points, which are not considered to be boundary cells in accordance with the second assumption. An example of vegetation codes and identified boundary cells is shown in Figure 3.

The second pass searches through the identified boundary cells and traces the contour for each region: as boundary cells are traced, they are marked and identified with a specific region number. Region numbers are generated as necessary beginning with 1. The search for a boundary cell to start the contour-tracing for each region is started in the upper left-hand corner of the input. The grid is searched in a left-to-right raster scan stopping at the first boundary cell that has not been assigned to a specific region. After this region has been traced by the contour-tracing algorithm from this start point, the raster scan continues.

The contour-tracing algorithm follows the traditional eight-connected look-left algorithm for traversing a maze [Ref. 6:p. 278]. At each boundary cell during the trace

NOT BOUNDARY  
CELLS

THE NUMBERS ARE THE VEGETATION CODES

Figure 3 Boundary Cells

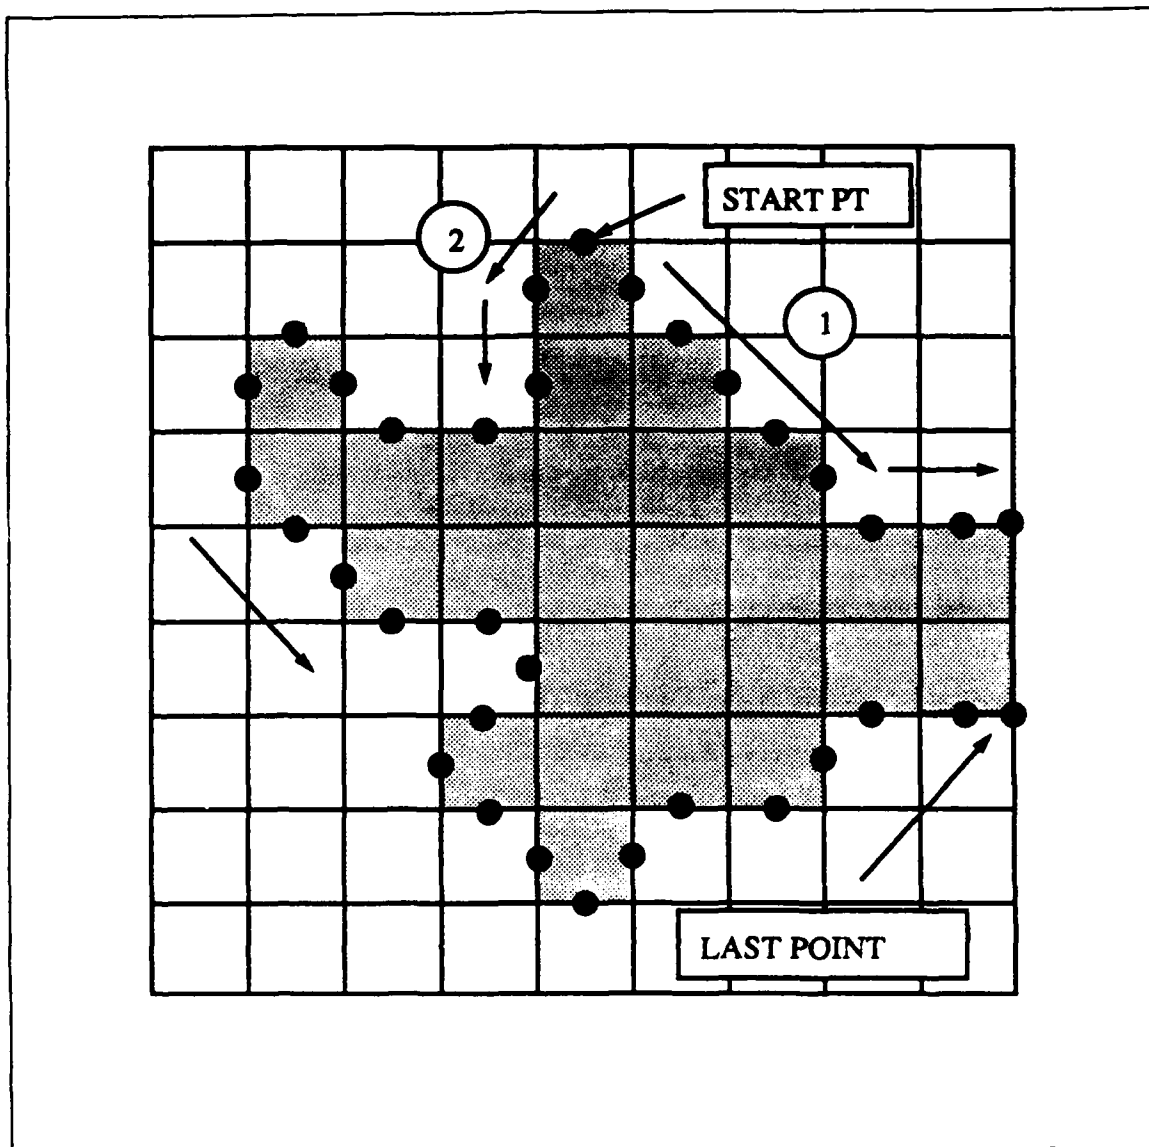

the direction of entry determines which way we look to find the next boundary cell; the direction of entry at the start point is defined to be the raster scan direction. Normally, we look to the boundary cell to the left of the direction of entry. If this cell is not a boundary cell of the same vegetation code we look one cell left and

forward. This process is continued clockwise until we find a boundary cell. The contour-tracing algorithm is continued until we reach the start point or a border of the picture (the first pass ensures that either event must eventually occur).

Several additions to the contour-tracing algorithm were included to enable us to handle conditions along the exterior borders of the overall 1km. by 1km. area. When the contour tracing reaches an exterior border, a check is made to determine if a border has previously been encountered for the current region. If a border has not previously been encountered, the tracing continues in the opposite direction starting at the initial point; otherwise, tracing stops. See Figure 4. Second, if the initial point of the region is next to the exterior border the tracing will start away from the border. See Figure 5.

A significant improvement in the representation of the data during this pass is gained by treating the actual boundary between two regions as the set of all points half-way between the centers of each pair of adjoining boundary cells with a different vegetation code. Tracing thus proceeds between these points. This is similar to the crack edges approach used to represent the boundary between regions in [Ref. 1:p. 78]. Additionally, this technique smooths the staircase effect created by the crack edges approach. See Figure 6.

The boundary-tracing phase trades memory space for clarity of code. The input is stored in an 80 x 80 array which represents the vegetation codes at each of the 6400 sampled points in row-major order. The first pass places boundary cells in a 6400 x 5 array in row-major order, classifying each by its x-coordinate, y-coordinate, vegetation code, whether it is a boundary point, and a flag for marking when the

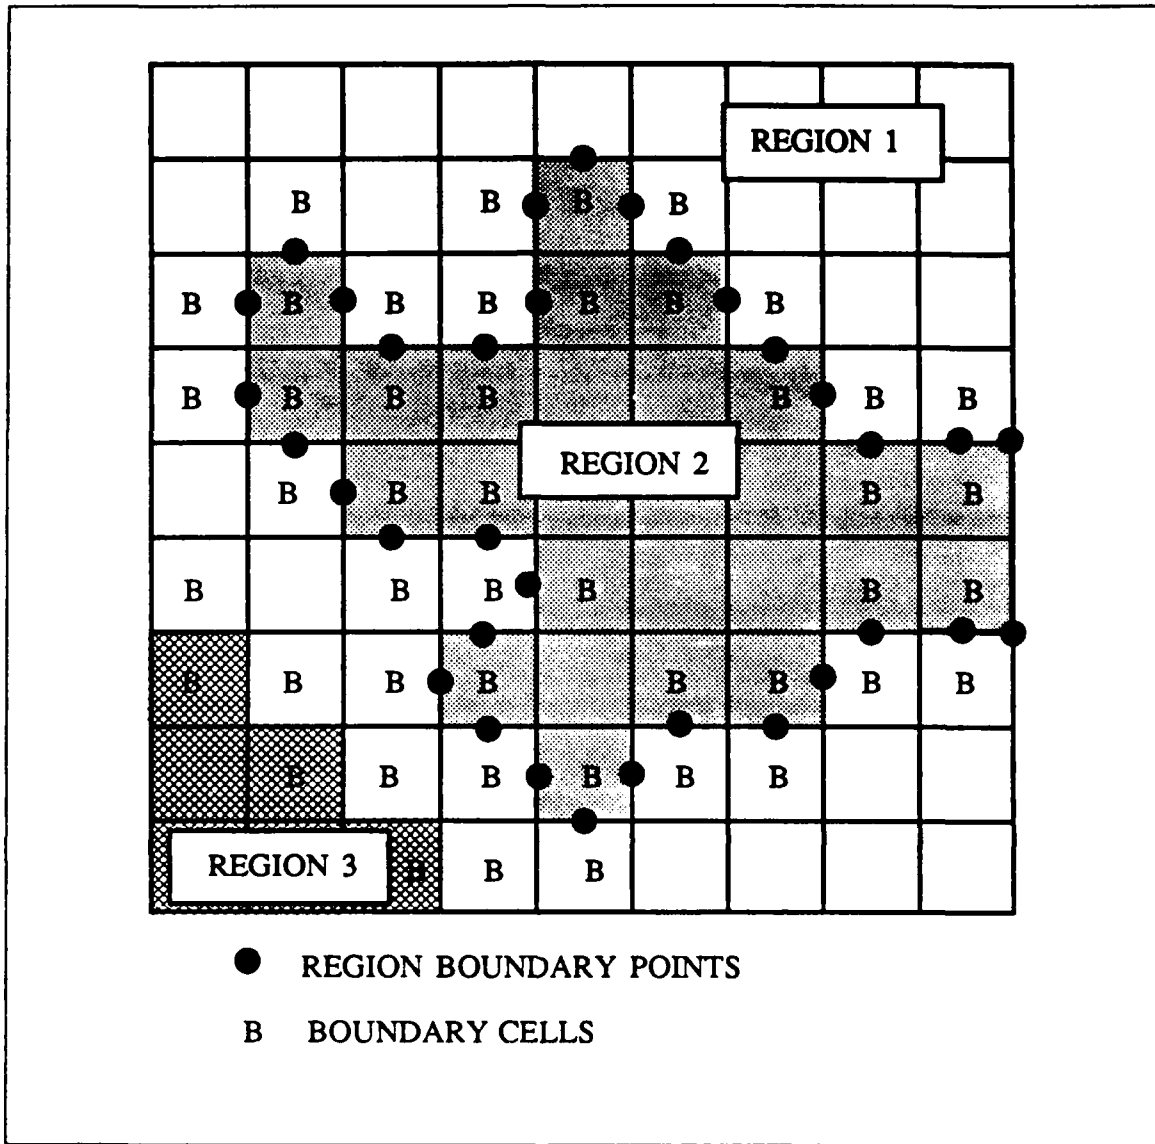

**Figure 4 Tracing after Hitting the Border**

second pass places the boundary point in a specific region. The second pass stores into a separate array for each region the sequenced boundary points x-coordinate, y-coordinate, and vegetation code. The array of regions is output to a formatted file which will be used as input to the split-and-merge phase described in section B.

**FIGURE 5 Conditions for Starting Away from the Border**

The boundary-identification phase is limited to grids containing no more than 6400 input data points, and can handle up to 75 output regions of no more than 400 traced points. These constraints were selected to insure the program can handle grid squares with either many small regions, or grid squares with a few large regions. Although the normal cases for the boundary tracing algorithm have been tested, the

**Figure 6 Boundary Point Representation of Boundary Between Regions**

handling of all possible cases involving small regions, such as those containing 2 boundary cells near other regions, has not been verified to work, as in some unusual situations the tracing could skip points.

## B. DESCRIPTION OF THE SPLIT-AND-MERGE PHASE

The split-and-merge phase of the program is written in the M-Prolog programming language for the Integrated Solutions (ISI) workstations. The list-processing capabilities of Prolog enables us to treat each region as a list of points and conduct operations on the members of the list.

The input to the split-and-merge phase is a Prolog fact for each region detected in the boundary-identification phase. Each fact contains an identification number of the region, the list of points for the region, the vegetation code of the region, and the total number of points in the region. See Figure 7. The output of the split-and-merge phase is a set of facts which contain vegetation codes and lists of the coordinates of each vertex for the polygonal homogeneous vegetation regions.

The major data structures used in the split-and-merge phase are lists, expressed as facts asserted throughout the phase. A global variable is created for the processing of each region. This contains the list of boundary points for that region; indexing based on the placement of the boundary points in the list is used to access it in the **linear least-squares** module. This saves allocated memory in terms of the statement table, global stack, and the main stack. A **segment** fact is asserted each time the linear least-squares fit is calculated for a line segment during the splitting process of the split-and-merge phase. See Figure 9. These facts are asserted and retracted often as the program seeks the proper combination of segments.

The split-and-merge phase contains five modules; the source code is contained in Appendix C. The **split-and-merge** module controls the phase using the built-in automatic backtracking of Prolog. The **linear least-squares** module calculates the fit

of points in the vicinity of a line. The **list** module provides basic Prolog list-processing predicates. The **math** module provides math functions such as the square root which are not provided in M-Prolog.<sup>1</sup> Finally, the **regions** module provides the data input from the boundary-identification phase.

The split-and-merge phase processes one pair of adjacent regions at a time, starting with pairs with non-zero vegetation codes. For each adjacent region, the list of boundary points from the two adjacent regions is intersected to produce a list of adjacent boundary points. To achieve clean boundaries between the two regions, no

**Figure 8 Segment Facts**

merging of line segments is allowed to use points from boundary point lists of differing region pairs. See Figure 8. The adjacent point list between the two regions will be handled twice for the two regions of the pair; however, the list will be split and merged identically in each case.

The splitting process follows the traditional divide-and-conquer algorithm [Ref 2:p. 282]. The linear least-squares fit is calculated for a segment, and a **segment** fact is asserted. If the fit is less than the splitting threshold, the segment is split into two new line segments which share a common point, the new "breakpoint" between them, and the old **segment** fact is retracted. This process continues recursively until there are no more **segment** facts to be split.

The calculation of the linear least-squares fit is done in the **linear least-squares** module using equation (8) from Chapter 2. The end points of each line segment define the line that will be tested for the fit. The use of the end points to define the line segment, rather than searching for the "best" line, enables us to connect adjacent line segments at exactly the breakpoints.

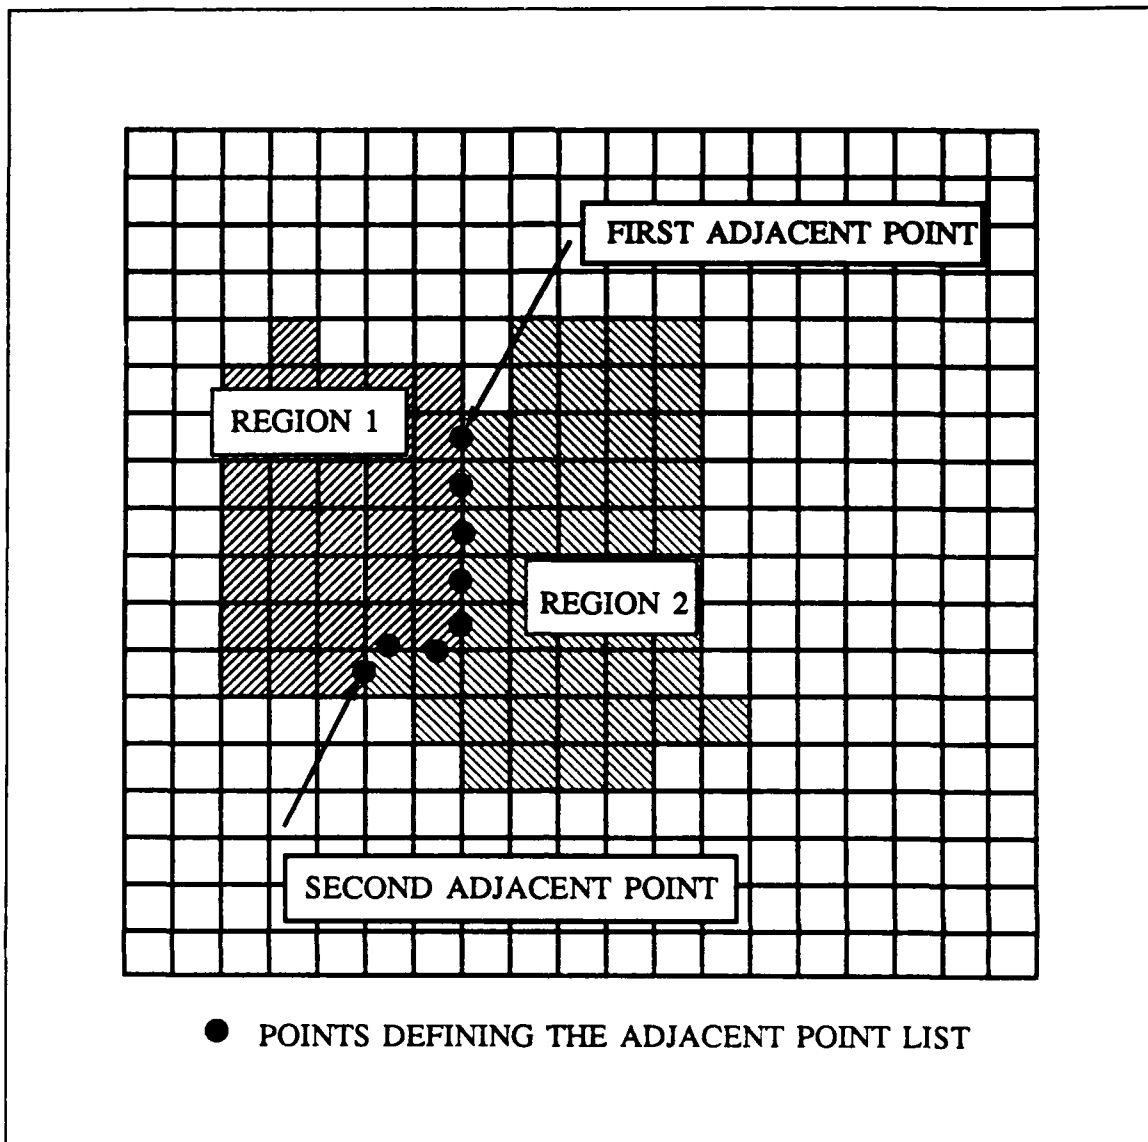

Figure 9 Adjacent Regions

The merge process examines each pair of line segments with a common index number (breakpoint) in the **segment** facts list. The segments are provisionally merged and the fit is calculated. If the fit is less than or equal to the merge threshold, the provisional merge is made permanent. A new **segment** fact is then asserted, and the

two original **segment** facts are then retracted. This process is continued until no more adjacent line segments can be merged.

The final process in the **linear least-squares** module of the split-and-merge phase takes the list of index numbers (representing the placement of the boundary points within the input list) and finds their actual x and y-coordinates. This shortened list is then bound to a **newregion** fact along with the value of the region.

## V. RESULTS

### A. PERFORMANCE MEASURES OF THE BOUNDARY-IDENTIFICATION PHASE

In test runs, the boundary-identification phase appears to properly define the boundaries of both convex and concave regions, including regions with holes. The maximum error for any point on the region boundary is equal to one half of the distance between the sample points, ignoring singular points. Since the input data points were evenly spaced every 12.5 meters, the maximum error at any point is equal to 6.25 meters.

The phase is memory-intensive. The program allocates 196800 bytes for the three arrays that are used to temporarily store information. This is more than three times the number of bytes required to process any of the test grid squares. Since we are not trying to optimize the code, we allocated more room than would probably be needed. Extensive use of file I/O, and the  $N^2$  nature of the boundary-identification algorithm, where  $N$  is the length of the square grid, slow the program to an average run time of 1 minute.

### B. PERFORMANCE MEASURES OF THE SPLIT-AND-MERGE PHASE

The regions obtained from the split-and-merge phase appear to represent the input database without significant error. Examples of input terrain and the regions formed are contained in Appendix A. As expected, the fit threshold determines the

number of vertices for the output regions. Table 1 shows several thresholds and the resulting number of vertices for each region.

**TABLE 1 EFFECT OF VARYING THE THRESHOLD ON THE NUMBER OF VERTICES PER REGION**

REGION #	<u>NUMBER OF POLYGON VERTICES</u>			
	THRESHOLD	THRESHOLD	THRESHOLD	THRESHOLD
	0.10	1.0	2.50	10.0
0	21	11	7	3
1	3	3	2	2
2	5	4	3	2
3	23	15	9	5
4	21	11	6	4
5	21	12	4	4
6	18	12	7	4

A threshold of 0.01 allows almost no merging. Conversely, a threshold of 10.0 reduces the regions to only a few vertices.

The split-and-merge phase is expensive in both time and space. Table 2 shows the maximum observed quantities for the Main Stack, Global Stack, Statement Table, Evaluations, cpu run time, and the real run time. The stacks and statement table are managed dynamically in our program, so the numbers vary through the running of the program. The higher numbers were obtained while processing large lists in the linear

**TABLE 2 MAXIMUM OBSERVED SIZE FOR M-PROLOG SYSTEM  
PARAMETERS IN THE SPLIT-AND-MERGE PHASE**

<u>PARAMETERS</u>	<u>QUANTITY</u>
MAIN STACK	1057 ITEMS
GLOBAL STACK	4544 ITEMS

REAL RUN TIME	30 MINUTES

**least-squares** module. Prior to entering the **linear least-squares** module the Main Stack, Global Stack, and the Statement Table were 860 items, 660 items, and 60,836 statements respectively. These numbers only reflect the points in the program that we observed the system parameters. It is possible that these parameters could exceed the figures stated in Table 2 in other portions of the program.

## VI. CONCLUSION

The primary objective of this work was twofold. First, we needed to show the feasibility of creating a polygonal region representation of terrain vegetation from digitized map data. Our program shows that this can be done. The program provides a suboptimal solution that visually appears to properly represent the terrain. But the split-and-merge phase of the program is time-consuming as the program searches for proper line segments. The many calculations involved implementing the fit calculations in M-Prolog is the main reason; other less mathematical methods for determining the fit of lines do exist and could easily replace the linear least-squares calculations without changing the rest of the split-and-merge phase.

The second objective of this work was to provide a working tool for path-planning research at the Naval Postgraduate School. This program will enable researchers to create polygonal regions of terrain vegetation.

The program only considers a 1km. by 1km. grid square. A more useful program for optimal path planning could consider much larger areas of terrain. This would probably require more efficient data storage in the boundary-identification phase and possibly optimizing and compiling the split-and-merge phase. An alternative and less costly technique would take the results from several adjacent grids and attempt to splice regions together that hit their respective borders.

Another topic for future research would be overlaying the results of this work with the three-dimensional planar-patch terrain models that Seung Hee Yee and

Professor Rowe developed. This would create partitioned homogeneous regions of constant slope as well as vegetation.
