PREFACE

The investigation reported herein is Phase I of a proposed two-phased project whose goal is the development of a prescriptive reservoir system operation model. The model, coined HEC-PRM, applies network-flow programming, a special case of linear programming, to reservoir system operation analysis. Phase I, begun 1 July 1990, developed and documented a trial model. Phase II, planned for 12 additional months, will expand the trial model, make technical improvements, apply the model to a system, document the application, and provide training.

The project is undertaken in accordance with a task order issued in July 1990 by MG Patrick J. Kelly, Director of Civil Works, HQUSACE. The model will be applied in the Missouri River Main Stem Master Water Control Manual Update Study. HQUSACE point of contact for the work is Earl Eiker, Chief Hydraulic and Hydraulics Branch, Engineering Division, Civil Works Directorate. The project is being jointly funded by the Missouri River Division, the National Drought Study, and the Civil Works Research and Development program.

The Project is a joint effort among the Hydrologic Engineering Center (HEC) responsible for model development and the Institute for Water Resources (IWR) responsible for economic aspects and development of the penalty functions for the Missouri River system. The IWR Phase I report is published separately. Mike Burnham, Chief Planning Analysis Division, served as project engineer. Bob Carl, Planning Analysis Division, developed the trial model and performed the test applications. David T. Ford, Engineering Consultant, provided expert advice and assistance in model formulation, development, and documentation. Darryl W. Davis, Director, provided general supervision and guidance for the project.

The Phase I report was reviewed by two individuals: Quentin W. Martin and Francis Chung. Quentin W. Martin is Manager of Water and Wastewater Utilities Program for the Lower Colorado River Authority. Francis Chung, Ph.D., P.E., who resides in Carmichael, California, is an engineer with applied experience with network-flow modeling

MISSOURI RIVER SYSTEM ANALYSIS MODEL

PHASE I

SUMMARY

A prescriptive reservoir model, designated as the Hydrologic Engineering Center Prescriptive Reservoir Model or HEC-PRM, was developed and tested for use in analyzing operation of the Missouri River main-stem reservoir system. The model represents the system as a network and uses network-flow programming to allocate optimally the system water. A network approach was selected because it satisfies institutional, economic, environmental, and engineering criteria.

The network representation of the Missouri River main stem system includes six reservoir and six non-reservoir nodes. The reservoir nodes represent Ft. Peck, Garrison, Oahe, Big Bend, Ft. Randall, and Gavins Point. The non-reservoir nodes represent Sioux City, Omaha, Nebraska City, Kansas City, Boonville, and Hermann. Goals of and constraints on system operation are represented with system penalty functions.

Prior to application of HEC-PRM as a decision-support tool for the master manual update study, HEC staff devised and executed a subjective validation test, using a five-year average period. As a consequence of this test, HEC-PRM was accepted for further analyses. However, the test pointed out HEC-PRM solutions are sensitive to definition of penalty functions.

Two applications of HEC-PRM were completed: (1) analysis of the critical period for the system with the best-currently-available estimates of system penalty functions; and (2) analysis of the same critical period with a hypothetical navigation penalty function for the reach between Sioux City and Omaha.

Phase II of the Missouri River system study will (1) expand the system analyzed; (2) refine the penalty functions used; (3) improve the model's user interface; (4) make technical improvements to the model; and (5) perform selected production runs with HEC-PRM.

PROBLEM DESCRIPTION

The Missouri River main-stem reservoir system consists of six reservoirs: Ft. Peck, Garrison, Oahe, Big Bend, Ft. Randall, and Gavins Point. These reservoirs and the area they service are shown in Figure 1.

According to the reservoir regulation master manual (USACE, 1979), the main-stem system is operated "...for flood control, navigation, irrigation, power, water supply, water quality control, recreation, and fish and wildlife." Current operation priorities in operating the reservoirs to meet these objectives are described as follows in the regulation manual (pg. IX-1, IX-2):

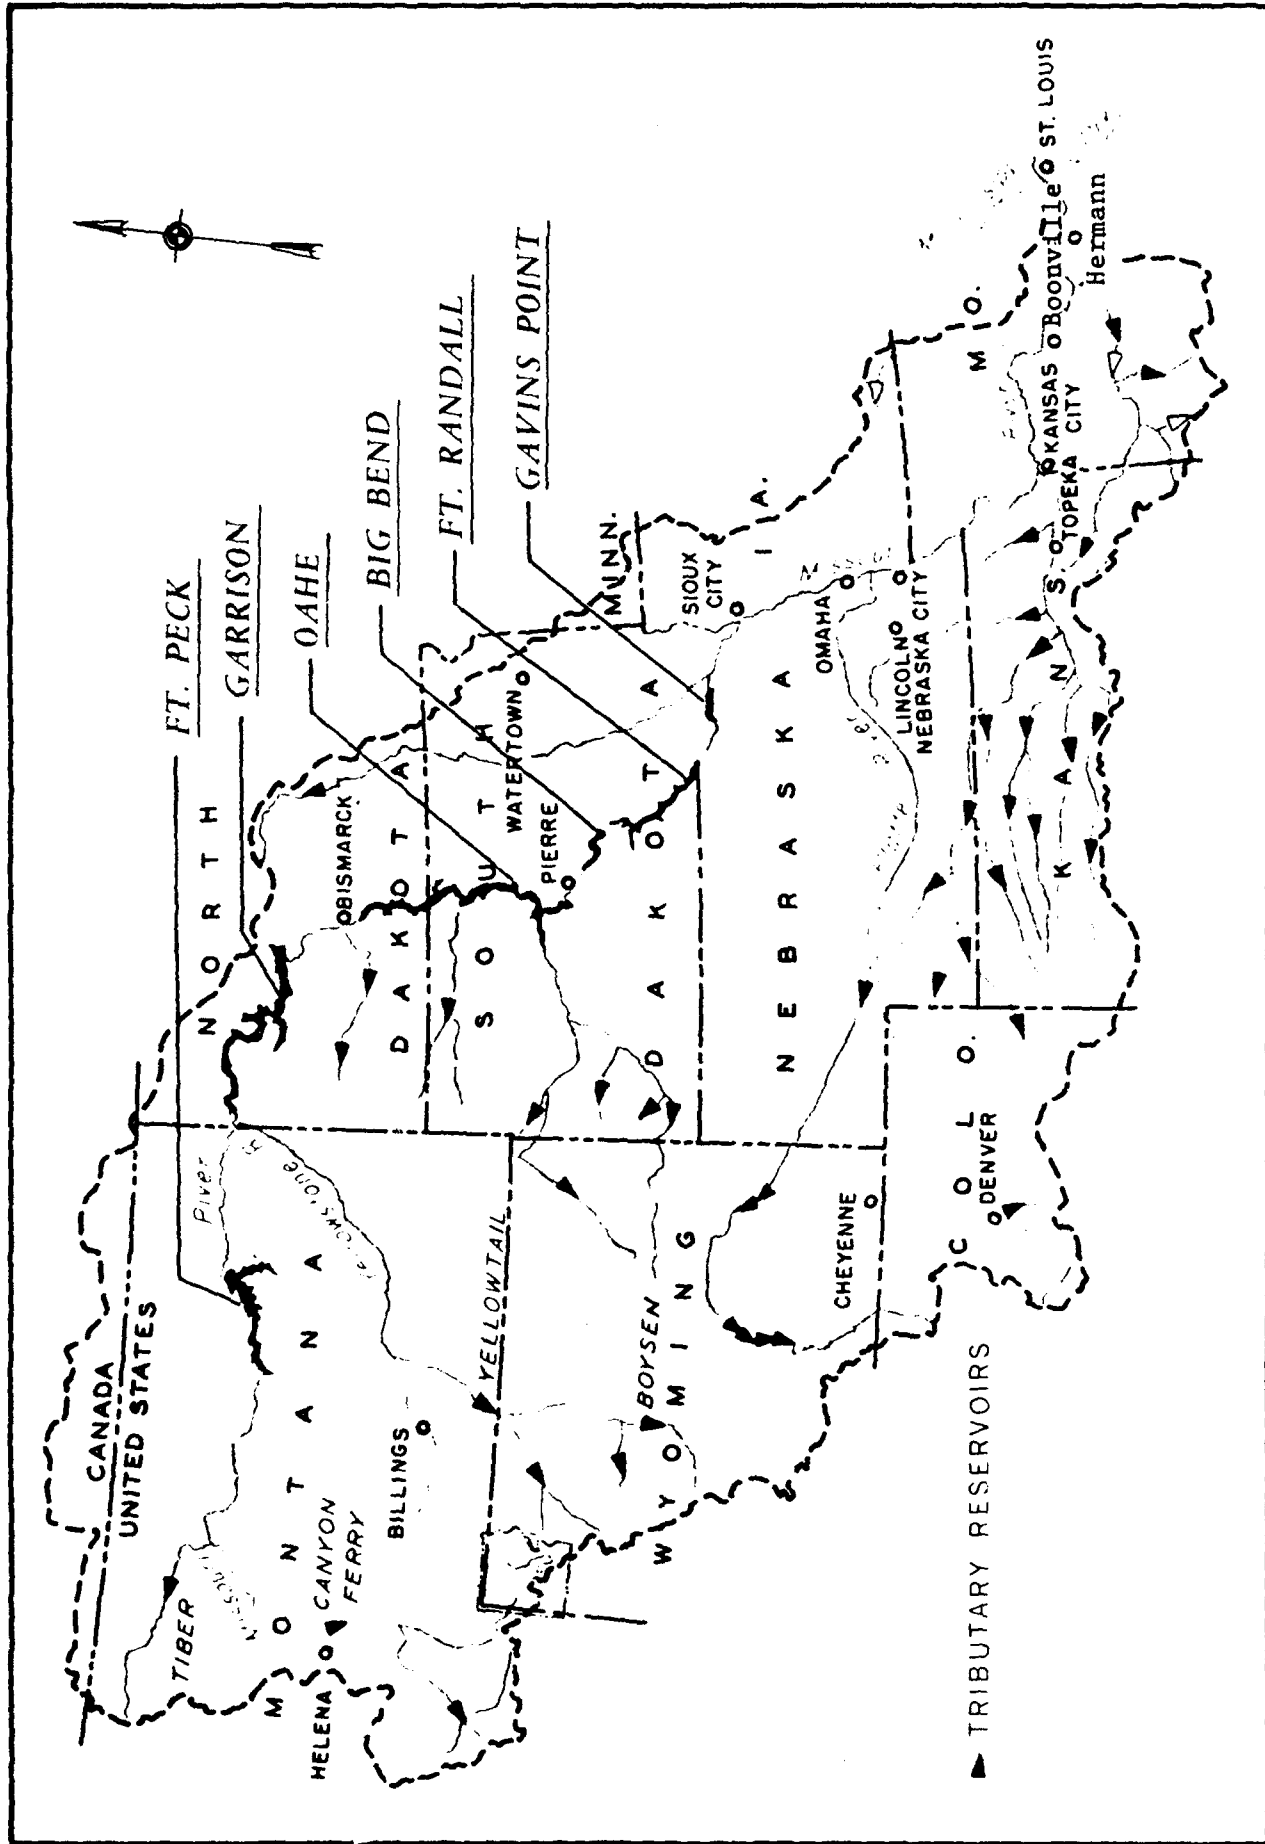

FIGURE 1 Missouri River Reservoir System

First, flood control will be provided for by observation of the requirement that an upper block of this intermediate storage space in each reservoir will be vacant at the beginning of each year's flood season...

Second, all irrigation, and other upstream water uses for beneficial consumptive purposes ... will be allowed for. This allowance also covers the effects of upstream tributary reservoir operations ...

Third, downstream M&I water supply and water quality requirements will be provided for.

Fourth, the remaining water supply available will be regulated in such a manner that the outflow from the reservoir system at Gavins Point provides for equitable service to navigation and power.

Fifth, ... the efficient generation of power to meet the area's needs ... will be provided for.

Sixth, insofar as possible without serious interference with the foregoing functions, the reservoirs will be operated for maximum benefit to recreation, fish and wildlife.

A review of these priorities was prompted by the following (USACE, 1990a):

- 1. It has been 10 years since the last update.*
- 2. The current (3 year) drought has pointed out that parts of the existing Master Water Control Manual may require change...*
- 3. Recreation on the reservoirs and the river downstream is becoming an increasingly important industry...*
- 4. The current drought has demonstrated the importance of Missouri River water to commercial navigation...*
- 5. The Master Water Control Manual needs to be updated to include regulation criteria for endangered and threatened species, new data collection methods, and flood history which has occurred since the last update.*

ANALYSIS PROPOSED

To review the priorities in a systematic fashion, an analysis tool is required. This tool must evaluate system operation for all purposes in terms of hydrologic, economic, and environmental efficiency.

Alternative Analysis Tools

Analysis tools appropriate for the Missouri River reservoir main-stem study may be classified broadly as descriptive tools or prescriptive tools. Descriptive tools typically simulate operation with a specified operation policy. The alternative policies considered are

proposed by a user, or an alternative-generating scheme. A prescriptive tool, on the other hand, relies on a formal definition of the goals of and constraints on system operation to define best system operation. It nominates automatically the alternative policies to be considered. It evaluates the feasibility of each with a built-in simulation model. With a formal definition of operation goals and objectives, it quantifies the efficiency of each feasible alternative. Finally, after considering all alternatives, it identifies the best policy. Examples of prescriptive tools are linear-programming models, nonlinear-programming models, and dynamic-programming models.

The study procedure proposed by Missouri River Division (MRD) staff uses a descriptive tool. Staff of the MRD proposed to conduct the study in two phases. In the first,

... the operation of the main stem reservoir system will be simulated over the period of record from 1898 to the present to provide a base line conditions. This base line condition will be analyzed in hydrologic, economic, and environmental terms to identify issues and conflicts. Alternative water control plans ... will be formulated and evaluated in hydrologic, economic, and environmental terms. The evaluation of these alternatives will identify which of these plans favor each of the main stem project uses (USACE, 1990a).

In the second phase, MRD staff propose to evaluate promising alternatives in further detail. The efficiency of a descriptive tool in application as proposed depends on the ability of the user, or alternative-generating scheme to nominate efficient alternatives for detailed evaluation.

HEC Proposal

After evaluating the alternative analysis tools, Hydrologic Engineering Center (HEC) staff proposed to develop and apply a prescriptive model for the Missouri River main-stem study (USACE, 1990b). The complete HEC proposal is included as Appendix A of this document.

The model proposed by HEC is a network model. Such a model represents the system operation problem with a set of nodes and arcs. A network solver finds the optimal allocation of available water to the arcs, subject to absolute limitations on that allocation. The network model demonstrates what will happen if a particular operation policy is adopted, and will indicate the policy preferred, given a set of priorities for operation. The network model is referred to herein as the Hydrologic Engineering Center Prescriptive Reservoir Model, or HEC-PRM.

HEC proposed (HEC, 1990b) to undertake the Missouri River study in two phases. In Phase I HEC promised to:

a. Prepare a document assessing the applicability of network-flow programming system analysis;

b. On a trial basis, formulate and apply a network-flow model to the Missouri River main stem;

c. Develop and document preliminary project output value functions (penalty functions) for use with the model; and

d. Present the results in a Phase I summary report.

Assessment

Appendix B of this document is HEC's assessment of applicability of network-flow programming system analysis (USACE, 1990c). HEC concluded and reported there that a network-flow programming model is appropriate for analysis of the Missouri River main-stem reservoir system because it satisfies institutional, economic, environmental, and engineering criteria.

Model Requirements

Prior to developing software to implement the proposed model, HEC staff considered the needs to be met by that model and published a software-requirements document (USACE, 1990d). The document is included as Appendix C of this report.

In summary, with HEC-PRM the reservoir-system operating problem is formulated as a minimum-cost network flow problem. All water conveyance and storage facilities are represented as arcs in the network. The volume of water allocated to the arcs depends on the cost; the objective is to minimize the total cost for the entire network.

As described in detail in Appendix D, goals of and constraints on system operation are represented with system penalty functions. The objective function of the network problem is the sum of convex, piecewise-linear approximations of these penalty functions. An off-the-shelf solver is used to define the optimal allocation of water within the system. The results of the solver are processed to report and display reservoir releases, storage volumes, channel flows, and other pertinent variables.

To the extent possible, the software is general purpose. It includes the following model-building components:

1. Inflow link;
2. Initial-storage link;
3. Diversion link;
4. Final-storage link
5. Channel-flow link;
6. Simple reservoir-release link;
7. Hydropower reservoir-release link
8. Reservoir-storage link; and
9. Node.

An analyst can specify the characteristics of and the configuration of these components to represent any system.

SYSTEM MODEL DESCRIPTION

The HEC-PRM developed for the Phase I study is a generalized computer program. Input data is entered into several files and the program is then run with no intermediate user interaction. It can be thought of as a batch execution. The heart of the program is software which solves linear equations. Built around this software is additional software which reads user input data, formats data to be consistent with the solver routines, and restructures results into comprehensible output. User input data is read from two sources: the normal ASCII (or "human readable" file) and HECDSS data files (binary files not directly readable). Penalty functions and regular interval time series data (flow and evaporation rates) are stored in HECDSS data files. The analyst enters a description of the network in the ASCII input data file in a fixed format. The description includes the time window for analysis, a list of all the nodes, a list of all the links, and information about each link. Link information includes pathname parts which form the pathname for penalty functions so the HEC-PRM may retrieve the penalty functions from HECDSS data files. It also includes connectivity and bounds information. Internally, HEC-PRM consists of several sections which perform the following:

- (1) Initializes variables,
- (2) Assigns pertinent disk files including ASCII input / output files and binary HECDSS data files,
- (3) Reads job parameters and network description (links and nodes),
- (4) Generates the solver matrix based upon the job parameters and network description,
- (5) Solves the matrix to compute a least cost solution for the system, and
- (6) Reformats the solver matrix and stores time series results in an output HECDSS data file.

HEC-PRM stores monthly computed flow and cost in the output HECDSS data file. The flow is stored in units of 1,000 acre-feet for each month. Separate flow and cost time series are stored for each link in the system. The analyst can modify, tabulate or graph the results using HECDSS utility programs. Manipulations include converting flow from 1,000 acre-feet per month to 1,000 cubic feet per second and computing costs for individual project purposes (e.g. recreations, flood control, etc.) using the original component penalty functions.

The network representation of the Missouri River main stem system includes six reservoir and six non-reservoir nodes, as shown by Figure 2. The reservoir nodes represent Ft. Peck, Garrison, Oahe, Big Bend, Ft. Randall, and Gavins Point. The non-reservoir nodes represent Sioux City, Omaha, Nebraska City, Kansas City, Boonville, and Hermann.

An inflow link terminates each period at the Ft. Peck, Garrison, Oahe, Ft. Randall, and Gavins Point reservoir nodes. There is no local inflow into Big Bend Reservoir and therefore there is no inflow link to that node. An inflow link terminates each period at all non-reservoir nodes. An initial-storage link terminates at each reservoir node in the first period of analysis. The network ends with a diversion link at Hermann each period. A final storage link originates at each reservoir node in the final period of analysis. Channel-flow links connect the six non-reservoir nodes each period. A reservoir-release link connects each reservoir node with the next downstream node each period. Storage in each reservoir each period is represented with a reservoir-storage link.

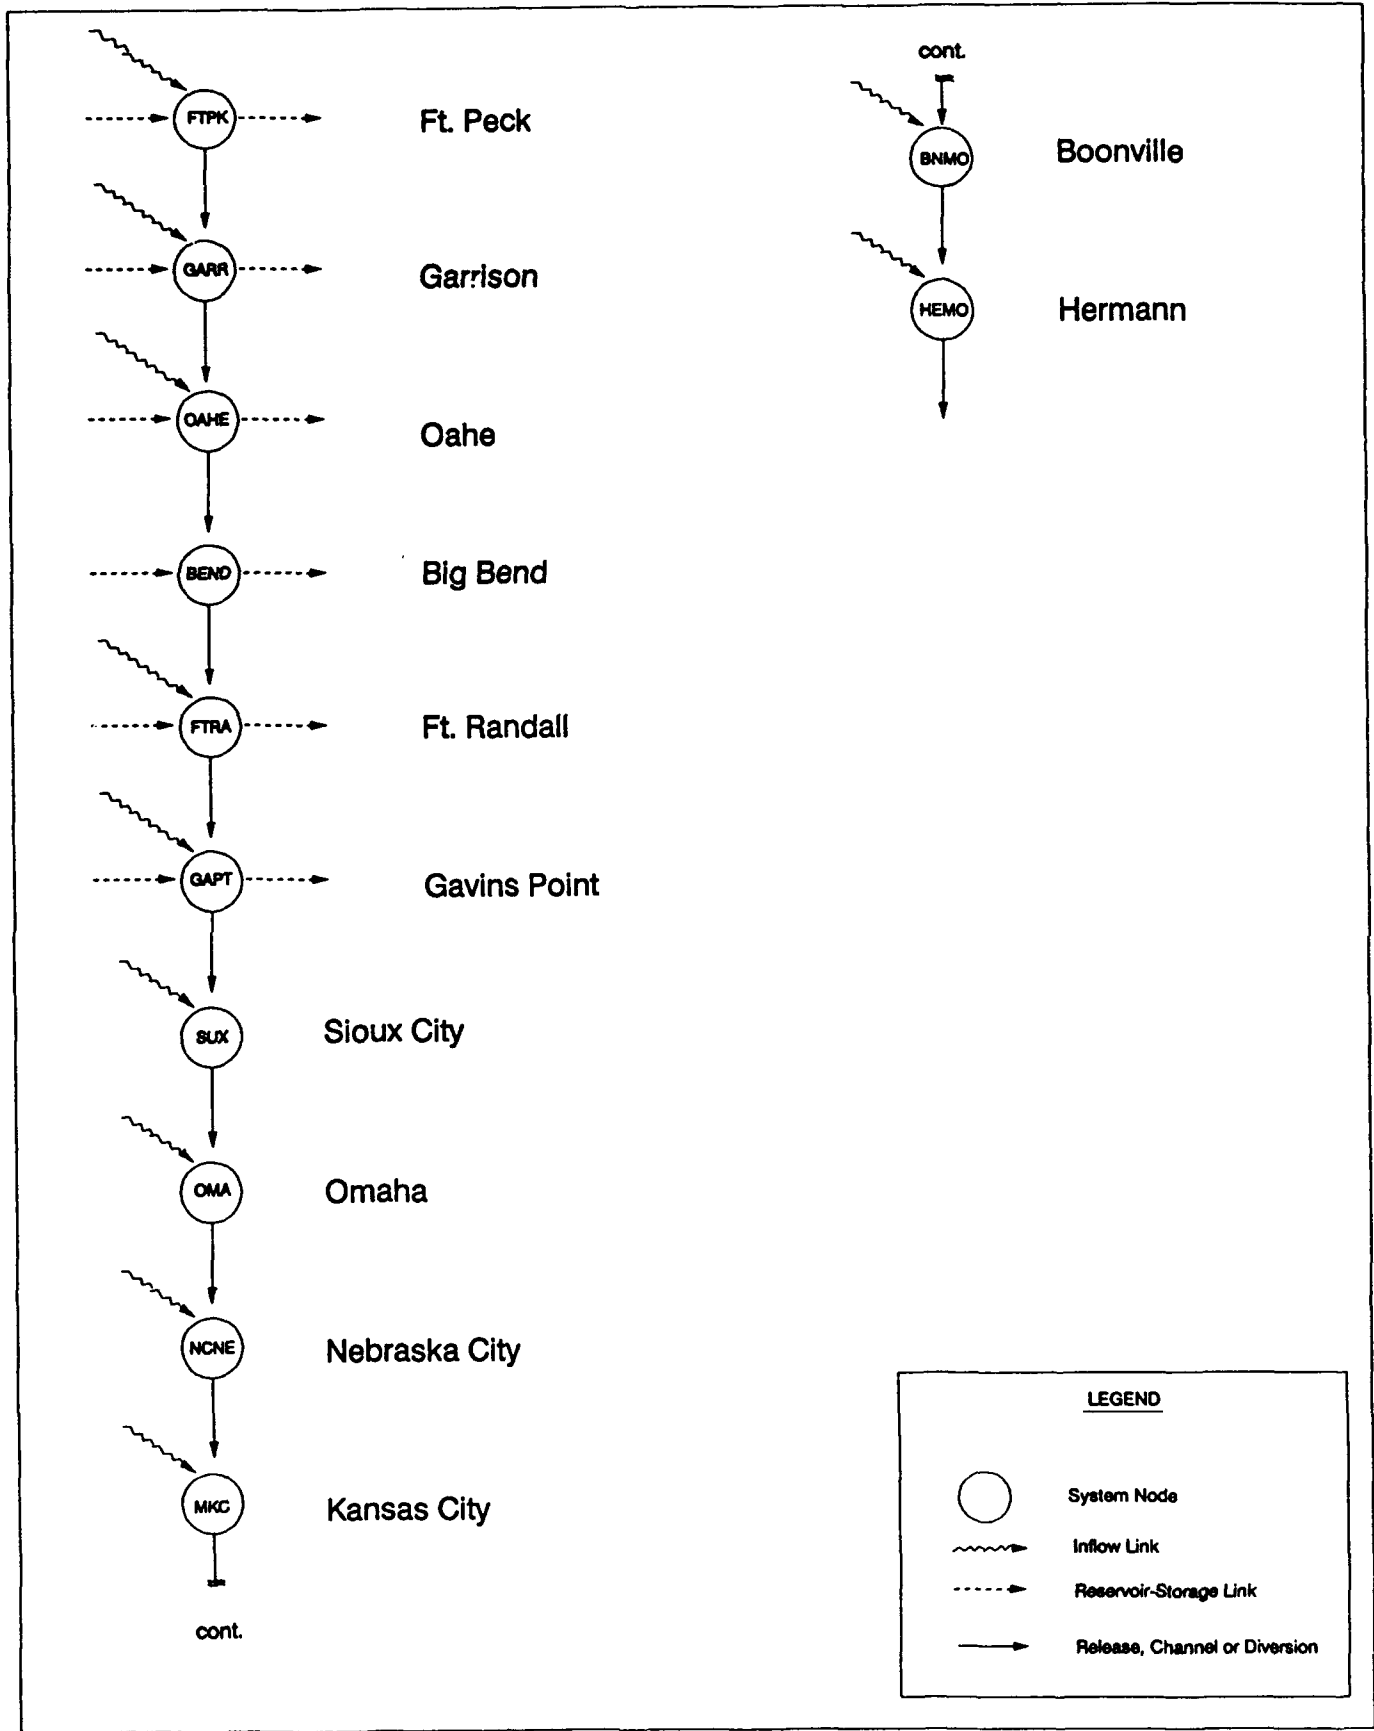

FIGURE 2 Single-period Link-node Representation of Missouri River System

Additional details of the network representation of the Missouri River reservoir system are presented in Appendix D. This appendix is a reproduction of HEC's description of the Missouri River system model (USACE, 1990e).

PENALTY FUNCTIONS

Goals of and constraints on Missouri River reservoir system operation are represented with system penalty functions. For the Phase I study, functions were developed by the Institute for Water Resources (IWR). Procedures for developing these functions are presented in a separate document (USACE, 1990f).

Penalty functions are of two types: cost-based or non-cost-based. The cost-based functions, "...show the loss in economic value as the flow in each model link deviates from the optimum flow (USACE, 1990f)." In this application, individual economic cost-based penalty functions were developed for the following outputs: urban and agricultural flooding; water supply; recreation; hydropower; and navigation. These functions vary by month if appropriate.

Non-cost-based penalty functions represent goals of system operation that cannot be quantified in economic terms. For example, a flow requirement for fish and wildlife protections may be represented with a penalty function in which the penalty arbitrarily is set to force the desired operation. In this case, "... the aggregate optimum system penalty cannot be interpreted in purely economic terms, and the cost-based and non-cost-based penalties need to be reported separately (USACE, 1990f)."

For analysis of system operation, the individual purpose penalty functions for each system location are summed. The resulting functions are represented in a piecewise-linear fashion for HEC-PRM. The piecewise-linear convex functions used in this study are included as Appendix E of this document.

MODEL VALIDATION

Unlike a descriptive model, a prescriptive model cannot be validated directly by comparison with an observed data set. No such data set can exist because historical operation is never truly optimal for the objective function used in the model, and the objective function used in the model never reflects exactly all goals of and constraints on operation.

Model logic, input data, and solution algorithms can be scrutinized. HEC staff did so. In addition, HEC staff explored model validity by applying HEC-PRM to analysis of a meaningful period, comparing the results to operation with current rules, and assessing critically the differences. If the HEC-PRM results were judged reasonable for this test application, the model would be accepted as a tool for subsequent analyses.

Validation Procedure

MRD system operation was analyzed with HEC-PRM for a five-year average flow period, March 1965 to March 1970. This period was recommended by MRD staff as one which includes no extreme high-flow or low-flow events. Hydrologic data for the period were provided by MRD; these data include monthly reservoir inflows and local flows, depletions, and lake evaporation rates. Initial and final storage values for the main-stem reservoirs are identical to those used with the MRD reservoir simulation model applied to the same period.

Composite, piecewise-linear penalty functions were developed for all purposes at all locations and were provided by IWR. Only economic (cost based) penalty functions are used. For this validation, the nonlinear hydropower penalty functions were approximated as a linear function of reservoir release only by assuming a fixed head. Maximum reservoir storage was limited to the top of annual flood-control and multiple-use zone. Minimum storage was limited to the top of permanent pool.

To test the reasonableness of the results, HEC staff compared HEC-PRM results with those of the MRD reservoir simulation model. This comparison is intended only to identify obvious shortcomings of HEC-PRM, inexplicable results, or weaknesses that would render HEC-PRM unacceptable for further analyses. A perfect match of results was not expected. Indeed, the results should not be identical, as the models employ different simplifications of the real system and operate for different goals. The MRD model follows existing operation rules, and HEC-PRM operates to minimize total system penalty for the period. Furthermore, with a linear model, alternative optimal solutions may exist. That is, alternative allocations of flow to the network arcs may yield the same total penalty. The network solver will find only one of these solutions.

Results

Computed time-series reservoir storages values for Ft. Peck, Garrison, Oahe, and Ft. Randall are shown on Figure 3. Storages indicated by HEC-PRM are shown in green, and those indicated by the MRD model are shown in red. This same color scheme is used for all figures depicting the validation results. Figure 3 also shows the current allocation of reservoir capacity to the permanent pool, carry-over and multiple use, annual flood-control and multiple use, and exclusive flood control zones. Proposed releases from Ft. Peck, Garrison, Oahe, and Ft. Randall are shown on Figure 4. Downstream flows at Kansas City, Nebraska City, Kansas City, and Boonville are shown on Figure 5. All storage is shown in 1,000 acre-feet (KAF). All flow is shown in 1,000 acre-feet per month (KAF/MON). To convert flow from KAF/MON to 1,000 cubic feet per second (KCFS) multiply by .01653. To convert flow in KCFS to KAF, multiply by 60.5. The conversions assume 30.5 days/month.

The pattern of storage indicated by the two models for Ft. Peck on Figure 3 matches well. The seasonal cycles are identical. HEC-PRM proposes slightly less storage for 1967-1969. Some slight differences in the storages are attributable to HEC-PRM's approximation of the evaporation. At lower storages, the evaporation is overestimated. This is true for all reservoirs. Reservoir releases proposed by the two models on Figure 4 shows that the major difference in storage for 1967-1969 is a consequence of greater releases proposed by HEC-PRM for that period. These releases are constant at 847 KAF.

Inspection of the penalty functions for Ft. Peck release (Figure E-7, Appendix E) and Ft. Peck storage (Figure E-1, Appendix E) reveals why this value is critical. The reservoir release arcs are defined by two links located in series below each reservoir: (1) energy release link and (2) all other release purposes link. The Ft. Peck energy release link is defined by two arcs (Figure E-7). The unit penalty (or slope of the penalty function) for the first arc (release between 0 and 847 KAF/MON) is -2.48 thousand dollars/KAF computed as follows:

$$\text{unit penalty} = \frac{(P_2 - P_1)}{(R_2 - R_1)} = \frac{(1.091 - 3.191)}{(847 - 0)} = -2.48$$

where:

P_1, P_2 is penalty in thousands of dollar
 R_1, R_2 is reservoir release in KAF/MON

The unit penalty for the second arc is zero (no change in cost for releases greater than 847 KAF/MON). Similarly, the Ft. Peck storage link is defined by 4 arcs (Figure E-1). As an example, the unit penalty (or slopes of the penalty function) for July is computed as shown on Table 1.

TABLE 1
Ft. Peck July Penalty Function

<u>Arc</u>	<u>Storage (KAF)</u>	<u>Penalty (\$1,000)</u>	<u>Unit Penalty</u>
-	0	4.2	-
1	11,070	.627	-.323
2	14,900	.108	-.136
3	16,550	.137	+.0176
4	18,550	.539	+.201

If HEC-PRM must only decide between storing or releasing water from Ft. Peck and if there is sufficient water, then it will always release 847 KAF/MON because that arc has the least unit cost (-2.48). It will then try to store water until the reservoir contains 14,900 KAF. It will avoid storing water above that because the storage arcs 3 & 4 have unit costs (+.0176 and +.201) greater than that for energy release arc 2 (zero). HEC-PRM cannot always release that amount because there is either a shortage of water or there are other higher priority needs at other links in the network.

The Ft. Peck release proposed by HEC-PRM falls to zero in several months. This seems odd, but is not totally unexpected. Two complicating factors play a role in release selection with HEC-PRM. First, the solver finds a minimum-cost flow allocation by setting iteratively a set of releases, storages, and flows at their upper or lower bounds. Second, HEC-PRM looks ahead in time and downstream in space when making release decisions.

FIGURE 3 Reservoir Storages for Validation Analysis

FIGURE 4 Reservoir Releases for Validation Analysis

FIGURE 5 Downstream Flows for Validation Analysis

The first complication is illustrated with a simple one-month reservoir-operation problem. In this problem, the initial storage is 3 KAF, and the net inflow is 7 KAF. The reservoir capacity is 10 KAF and the outlet capacity is 10 KAF. The governing equation is the continuity equation:

$$S_f + R = S_i + I \quad (1)$$

in which:

- S_i = the initial storage;
- I = inflow volume;
- R = release volume; and
- S_f = final storage.

This equation is written so the variables representing decisions are on the left-hand side and the known quantities are on the right-hand side. Suppose that the unit penalty on storage is \$1000/KAF, and the unit penalty on release is \$1000/KAF. What is the minimum-cost operation? The answer is that no unique optimal solution exists. Any combination of release and final storage which totals 10 KAF is feasible (satisfies the continuity equation). Furthermore, any feasible combination will have exactly the same total penalty. The network solver (or any linear program solver) will pick an extreme-point solution: a solution in which at least one of the decision variables is at its upper or lower bound. In the example, it will select either $R = 0$ KAF and $S_f = 10$ KAF or $R = 10$ KAF and $S_f = 0$ KAF. In practice, a knowledgeable reservoir operator might select other values of R or S_f for reasons that are not represented by the model objective function. For example, the release selected might be approximately the previous-month's release. However, if this operation criterion is not represented explicitly by the cost-based or non-cost-based penalty functions, HEC-PRM will not consider it in selecting releases.

In the Ft. Peck case, the lower bound on release is zero, so the solver found one minimum-cost solution with the release set to zero. Intuition suggests that another solution may exist with the release set to 847 KAF, the optimum value for hydropower. To examine this further, HEC-PRM was run with the minimum release for Ft. Peck increased to 847 KAF. In that case, the model was not able to find a feasible solution for the 5-year analysis, given the feasible range of storage at Ft. Peck.

The second complicating factor in understanding easily a release selected by HEC-PRM is that HEC-PRM looks ahead in time and downstream in space when selecting that release. Consequently, a release that seems optimal on examination of short-term operation may, in fact, be suboptimal for the long-term. To illustrate this, HEC-PRM was run for only the first year of the five-year validation period. In that case, operation of Ft. Peck for future inflows and demands was not a consideration. The Ft. Peck releases for the one-year operation are shown on Figure 6. The proposed releases for the first year of the five-year period are shown on the same figure. In the one-year period, HEC-PRM proposed releases to reduce the hydropower penalty. With this short-sighted operation, the future value of water is ignored. On the other hand, the releases proposed for the first of five years result in holding water in storage for subsequent delivery.

FIGURE 6 One-year Validation Analysis

The storages for Garrison, again, shown on Figure 3, matches the general pattern well. The storage indicated by HEC-PRM from mid-1966 to early 1968 is about 20% less than that indicated by the MRD model. In that same period, HEC-PRM has proposed greater release, as shown by Figure 4. As with Ft. Peck, this is due to the energy penalty function: The advantage of releasing water for energy exceeds the advantage of storing it in these months, even for future use. Thus HEC-PRM draws down the reservoir. HEC-PRM calls for no release from Garrison several months in the validation period. No minimum release is mandated, and the value of water in storage exceeds the value of water released. The efficiency of this decision is clearer when the downstream flows are inspected.

The overall Oahe storage pattern, shown on Figure 3, follows the pattern of the MRD model. Inspection of Figure 4 reveals that the releases proposed by HEC-PRM again tend to be at extremes: They fluctuate from zero to approximately 3000 KAF. This is due, in part, to the energy penalty function. The penalty drops to zero at approximately 3000 KAF. Consequently, greater releases will not reduce the total system penalty.

Ft. Randall storages proposed by the two models are shown on Figure 3. These match well, with what appears to be a slight time lag in the HEC-PRM results. This time lag may be the result of the capability of HEC-PRM to incorporate knowledge of future inflows in making release decisions: If postponing releases will reduce the overall penalty, HEC-PRM will do so. Figure 4 shows the releases proposed by the models. In one of the 60 months, the release falls to zero.

Figure 5 reveals much about the upstream reservoir releases. This is plots of the flow at Sioux City, Nebraska City, Kansas City, and Boonville. The Kansas City flow penalty function is presented on Figure E-16 of Appendix E. The unit penalty is very high for flow less than approximately 500 KAF. The unit penalty is less between 500 and 2300 KAF. The unit penalty is zero between 2300 KAF and 3600 KAF, increases rapidly as flow increases to about 12300 KAF, and is greater still for flow in excess of 12300 KAF. Local inflow downstream of Gavins Point often exceeds 500 KAF, so no releases are necessary to avoid the penalty for low flow. In June 1967, the local inflow between Gavins Point and Kansas City was 7735 KAF. HEC-PRM, in analyzing all periods simultaneously, was able to foresee the downstream impact of releases during this period. Consequently, the releases were limited, and in some cases reduced to zero, to avoid a very high penalty at Kansas City and downstream.

Conclusion

As a consequence of the validation test, HEC-PRM is accepted for subsequent analyses. It is clear from the test results that the model does what it is supposed to do: It defines a minimum-penalty allocation of system water. However, the test reveals the sensitivity of the model to the penalty functions used. HEC-PRM will store water if the penalty functions are defined in such a manner that releases of zero do not incur penalties that exceed those for storing water instead.

MODEL APPLICATION

Two applications of HEC-PRM were completed: (1) analysis of the critical period for the system with the best-currently-available estimates of system penalty functions; and (2) analysis of the same critical period with a hypothetical navigation penalty function for Sioux City flow. The reservoir storage levels, reservoir releases, and downstream flows are shown on Figures 7, 8, and 9, respectively. The results of the analysis of the critical period for the system with the best-currently-available estimates of the system penalty functions are shown in red for all plots. The results of the analysis with inclusion of the hypothetical navigation penalty function is shown in green for all plots.

Critical Period With Best-currently-available Penalty Functions

The critical period for the system was identified by MRD staff as March 1930 - March 1949. This includes the 12 year (1930 - 1941) drought of record and the period required for refilling of reservoirs when following current operation policy. Hydrologic data for the critical period were provided by MRD. These data include reservoir inflows and local flows, depletions, and lake evaporation rates.

Penalty Functions and Operation Constraints. Composite, piecewise-linear penalty functions were developed for all purposes at all locations for which penalty functions were provided by IWR. Only economic (cost-based) penalty functions are used. Hydropower penalty functions were linearized by assuming a fixed head for the entire period. Maximum reservoir storage was limited to the top of the annual flood-control and multiple-use zone. Minimum storage was limited to the top of permanent pool.

Results. As a rule, energy generation dominates the operation. HEC-PRM proposes release of water to drive the energy penalty to zero if sufficient water is available. Otherwise, it proposes making no release and storing water for subsequent use. This is again a case of long-term verses short-term operation decision making. The model must choose between making minimum releases for hydropower now or storing water for later use. It chooses the latter based on total system penalty, as defined by the penalty functions. Although a skilled operator might choose a less drastic operation, the penalty functions used in this application do not indicate that another policy is better, although it may be as good.

Figure 9 shows channel flows at Sioux City, Nebraska City, Kansas City, and Boonville if the system is operated according to the policy found by HEC-PRM. At Sioux City, the penalty would be great if the flow is less than approximately 500 KAF in January or less than 1600 KAF in the remainder of the year. HEC-PRM has proposed releases that will meet this minimum. At Kansas City, the penalty would be great if the flow is less than 500 KAF in January or 2200 KAF in the remainder of the year. Again, HEC-PRM has proposed releases to meet this minimum. Similarly, HEC-PRM has proposed releases that will limit the channel flow at Sioux City to well below the discharge at which penalty again is great. This is 2500 KAF in January or 8000 KAF in the remainder of the year. In fact, most flows are in the range between the desired minimum and the desired maximum, thereby incurring little or no penalty. The same is true at Kansas City. The flow is frequently in the range 500 or 2200 KAF to 3600 KAF. The flow at Kansas City is clearly outside this range in 1947 and again in 1951. However, reservoir operation could do little to reduce these extreme flows, as they are the consequence of uncontrollable local inflow. For example, when the Kansas City flow reaches approximately 10000 KAF in 1951, the local inflow between Nebraska City and Kansas City is almost 9000 KAF.

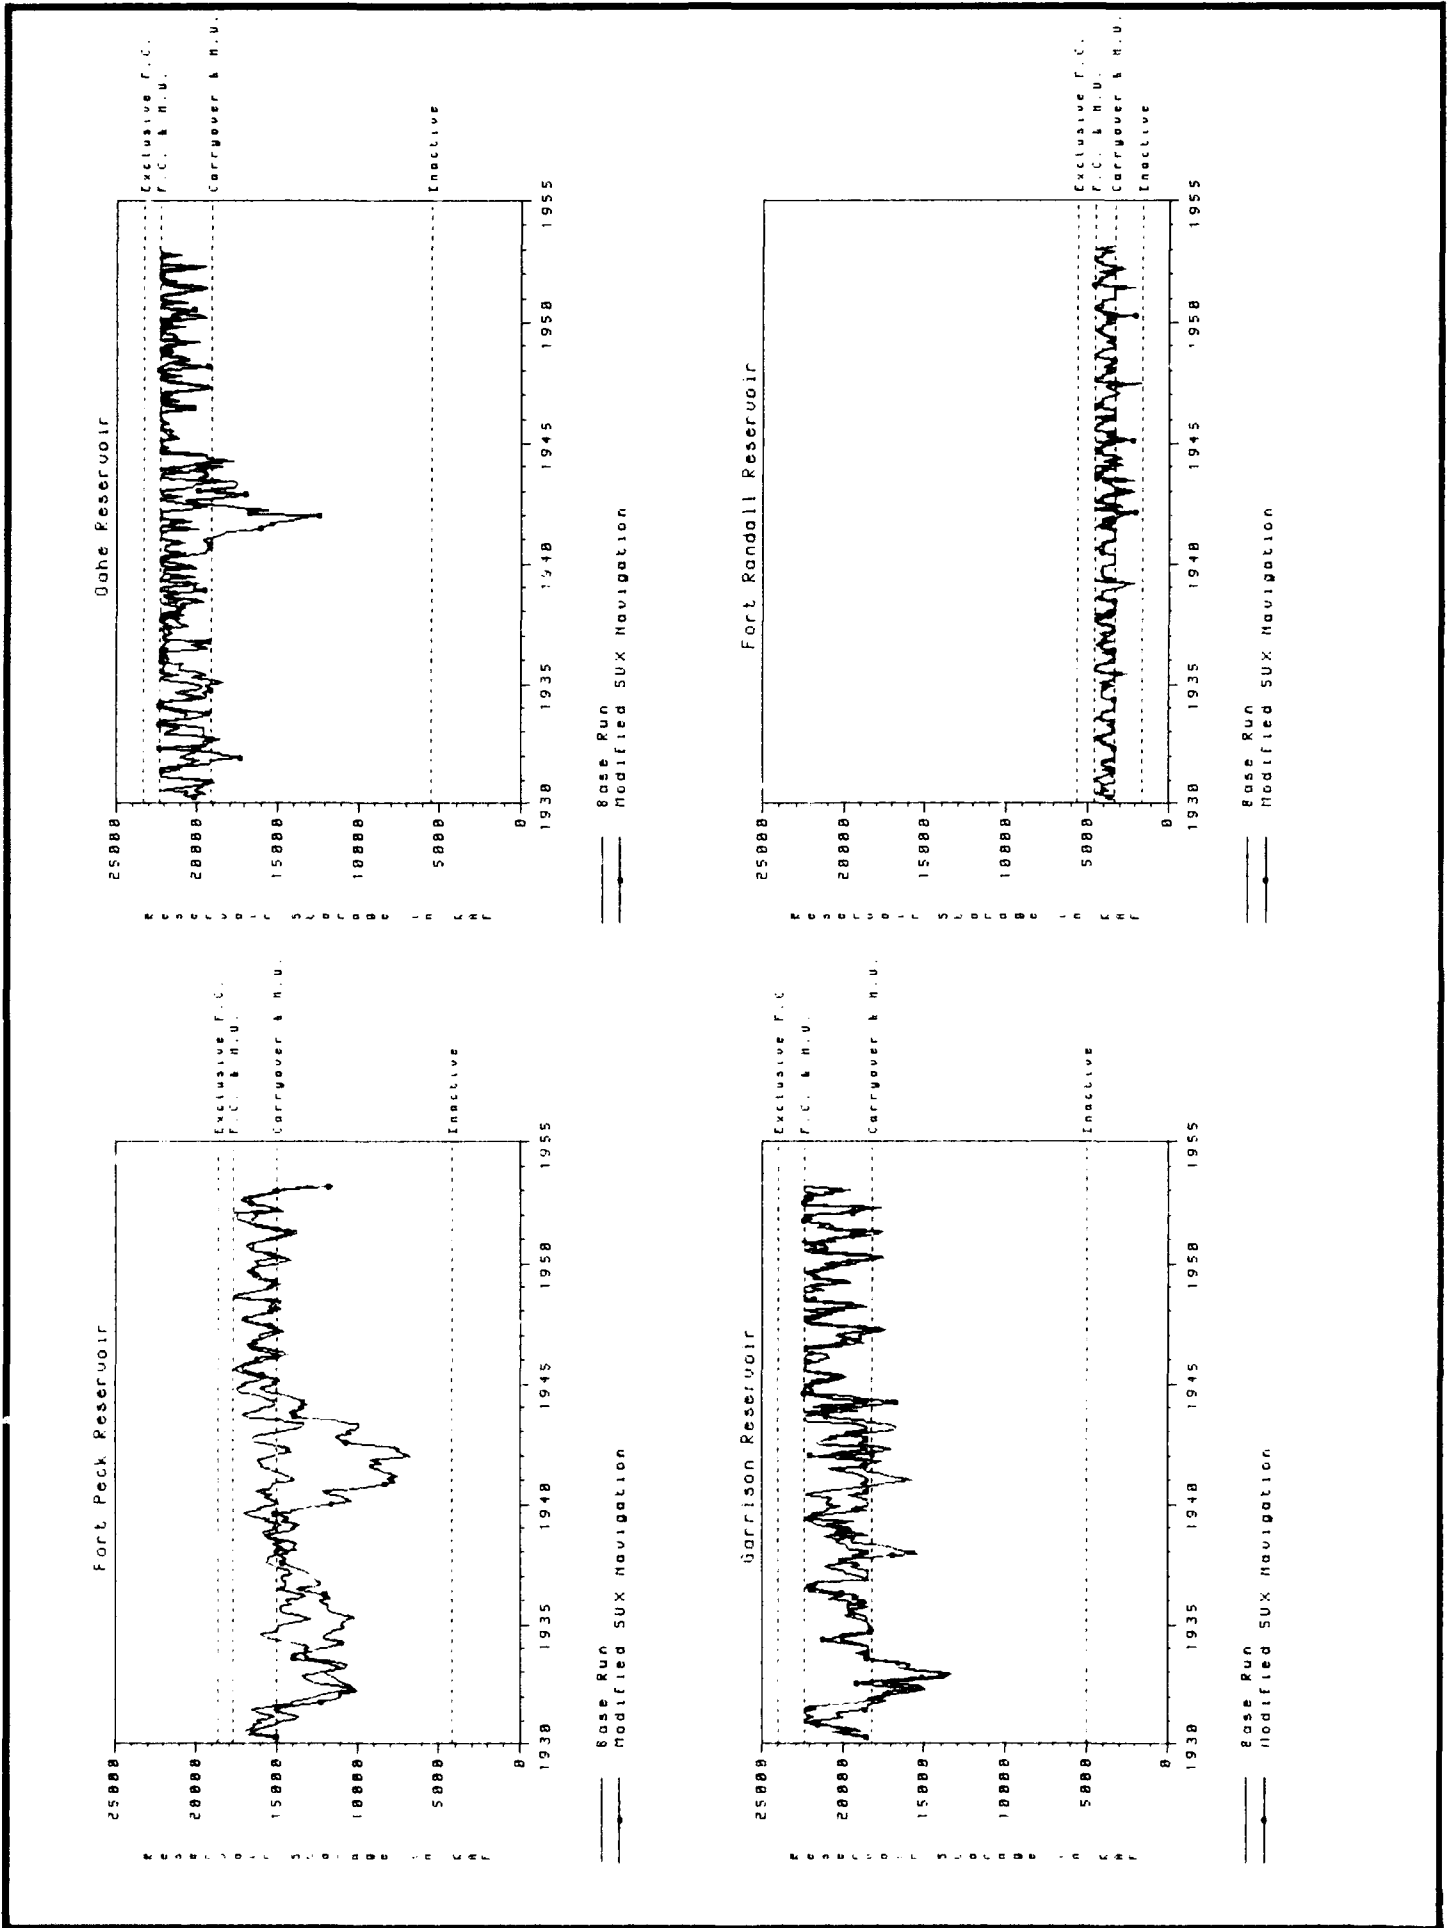

FIGURE 7 Reservoir Storages for Critical Period Analysis

FIGURE 8 Reservoir Releases for Critical Period Analysis

FIGURE 9 Downstream Flows for Critical Period Analysis

Critical Period With Hypothetical Navigation Penalty Function For Sioux City.

In the second application of HEC-PRM, operation was analyzed for the same period described in the previous section. A hypothetical navigation penalty function was added to demonstrate the impact of system operation for high-penalty downstream requirements.

Penalty Functions and Operation Constraints. As in the previous application, composite, piecewise-linear penalty functions were developed for all purposes at all locations for which penalty functions were provided by IWR. However, for the reach between Sioux City and Omaha for April-November, the function was replaced with the hypothetical navigation penalty function shown on Table 2.

TABLE 2
Hypothetical Navigation Penalty Function for Sioux City

Flow range, in KAF (1)	Penalty, in \$1000/KAF (2)
0 - 1875	10.7
1875 - 7200	0
7200 - 13900	0.149
13900 - 21000	2.67

Figure 10 depicts the June navigation penalty functions for Sioux City. Included are the best currently available navigation function and the edited hypothetical navigation penalty function.

Hydropower penalty functions were linearized by assuming a fixed head for the entire period. Maximum reservoir storage was limited to the top of the annual flood-control and multiple-use zone. Minimum storage was limited to the top of permanent pool.

Results. The hypothetical navigation penalty function causes the flow pattern at Sioux City to be smoother, as the range of flows there is reduced. Often the system has operated to provide exactly 1875 KAF during April-November. For December-March, the system has reduced releases to a bare minimum to conserve water to meet subsequent April-November demands. Even so, to satisfy the 1875 KAF minimum at Sioux City, the system must draw down Ft. Peck, Garrison, and Oahe, starting in 1939. For example, the January 1942 storage at Ft. Peck falls to 7000 KAF, whereas without the hypothetical function, it was approximately 15000 KAF. Earlier and later in the critical period, the Ft. Peck storages are approximately the same with and without the function. Then sufficient water is available to meet the demand without drawing on upstream storage.

FIGURE 10 Sioux City Penalty Functions for Critical Period (June)

PHASE II ACTIVITIES

As proposed by HEC, Phase II of this study begins in January 1991. In Phase II, HEC and IWR staff will (1) expand the system analyzed; (2) refine the penalty functions used; (3) improve HEC-PRM's user interface; (4) make technical improvements to HEC-PRM; and (5) perform selected production runs with HEC-PRM. These activities will be completed in January-June 1991. Phase II analyses are scheduled for June and July 1991. HEC and IWR staff will conduct a workshop for MRD staff in fall 1991. HEC will provide there a working version of HEC-PRM and draft user's documentation. HEC will provide a draft Phase II report in mid-November 1991. HEC-PRM software, complete user documentation, and final Phase II report will be provided to MRD staff by 31 December 1991.

Model Expansion

The Phase I model includes all six main-stem reservoirs, but includes non-reservoir control points only as far downstream as Hermann. As needed, additional downstream reaches will be added in Phase II. To model well the impact of system operation on navigation, the system will be extended at least to St. Louis. Mississippi River navigation targets will be imposed there. The period of analysis will be expanded, if possible, to the available period of record.

Penalty Functions Refinement

The penalty functions used in Phase I are based on the best currently available data. For Phase II, these functions will be refined, and functions will be added to permit modeling operation for all purposes.

One area in particular will require additional effort: definition of penalty functions for reservoir flood-control storage. In Phase I, no penalty was associated with storing water in the flood-control pools of the system reservoirs. As HEC-PRM considers simultaneously operation for all periods, the minimum-penalty allocation may call for storing water in the flood control pool to meet downstream water-supply demands some months in the future. To avoid this operation, HEC-PRM was constrained in Phase I to prevent use of the exclusive flood-control pool. For Phase II, a penalty for using reservoir flood-control storage will be developed.

As originally proposed, refinement of the functions will be undertaken as a task separate from model development.

User Interface Improvement

The HEC proposal indicated that staff would "... generalize input, output reporting, and user interface for the model ..." In doing so, HEC staff will focus on automating penalty-function derivation, on standardizing the presentation of results, and on improving user-model interaction for system definition.

Penalty-function Derivation. HEC-PRM requires the user to specify no more than one penalty function for each system link. This function must be convex and piecewise linear. Consequently, the user must pre-process penalty functions developed for various project purposes to derive this function. For the applications reported herein, this pre-processing was done manually by HEC and IWR staff. For each link, the flood-control, hydropower, navigation, water supply, and recreation penalty functions were added. The resulting function was stored with the HECDSS (USACE, 1990g). The function was plotted, and a convex, piecewise linear approximation was defined "by eye." For a complex system, this is tedious, time-consuming, and subject to operator error.

For Phase II, the process of deriving the penalty functions of the required format will be automated. However, human interaction will be included in the final selection of the functions. For example, an algorithm may be developed to sum the functions and suggest a convex, linear approximation of the results. However, the suggested function will be displayed for the user to accept or reject. If the user rejects the suggested function, he or she will be able to define an alternative. If feasible, this will be done interactively, using a mouse or other pointing device.

Presentation of Results. Results of solution of the network-flow programming representation of the reservoir operation problem are stored with the HECDSS. The HEC DISPLAY program is used to plot any of these results, as desired by the user. This provides maximum flexibility for a knowledgeable user, but is overwhelming for the novice user. Accordingly, HEC will select, with concurrence of MRD, a set of standard displays. These standard displays will show pertinent hydrologic variables at selected locations. The displays will be pre-programmed and included so they are directly accessible from the user interface. At a minimum, the displays will include the reservoir storages and downstream flows for the period of analysis.

In addition to displays of hydrologic variables, HEC will select performance indices for display. Likely candidates are the time series of hydroelectric energy generated, cost-based penalty, and non-cost-based penalty at selected locations. Additional performance indices may be computed from the results. For example, flow-duration curves can be computed with data stored in HECDSS. If MRD staff identify such indices, procedures for developing them will be pre-programmed and included so they are directly accessible from the user interface.

Currently, HEC-PRM provides a minimum of tabulated results. HEC will expand HEC-PRM to provide tabulations consistent with other HEC reservoir analysis software.

User-model Interaction For System Definition. In its current form, HEC-PRM is generalized. The system configuration is specified by the user. No assumptions are built into HEC-PRM regarding hydraulic interconnections, system inflows or outflows, or hydropower facilities. All system hydrologic and economic data are stored with the HECDSS. All results also are stored with the HECDSS.

Nevertheless, definition of the system may be simplified, especially through development of a graphical interface. Prof. J. Andreau of the Universidad Politecnica de Valencia (Spain) has developed such an interface for AQUATOOL, his reservoir system model. This interface uses the graphical interface tools of MS-Windows 3.0. Prof. Pete Loucks of Cornell University has developed a similar interface for his model, IRIS.

Loucks's interface uses CAPLIB routines from Resource Planning Associates. Both interfaces permit the user to "draw" a reservoir system on the PC monitor with a mouse. The system hydraulic linkages are inferred from the graphical representation. Both also feature "fill in the blanks" forms for specification of pertinent data. Working copies of AQUATOOL and IRIS are available at HEC. In Phase II, these and other user interfaces will be evaluated. An appropriate interface for HEC-PRM will be selected and implemented.

Capability for interactive data entry and editing of penalty functions, arc flow bounds, system constraints, and initial and final storages will be developed. Also, interactive control of HEC-PRM execution specifications, output reports, and displays will be developed.

Technical Improvement

HEC-PRM will be improved for Phase II studies. The hydropower algorithm will be fully-implemented. The execution time required will be reduced if feasible.

Hydropower Algorithm. For all applications in the Phase I study, hydropower penalty functions were simplified to express the penalty as a function of reservoir release only. For subsequent analyses, HEC-PRM will be improved to include the more complex relationship of hydropower penalty to release *and* head. A proposed algorithm for doing so is presented in the requirements document in Appendix C. Implementation of the algorithm will require some testing and additional development by HEC. The algorithm proposed is for hydropower value functions slightly different from the penalty functions provided by MRD.

Execution Time. The execution time of HEC-PRM is great by current standards for PC programs. For example, to analyze the critical period on a 25 MHz PC with 80486 processor requires 3.5 hours. If this is intolerable, execution time will be reduced by using a faster computer, reducing the number of arcs and nodes in the network, simplifying the formulation, or reformulating HEC-PRM to use a different solver.

(1) Using a Faster Computer. This is perhaps the simplest solution and may reduce the execution time as desired. Two possibilities exist: (1) Use a faster PC, such as a 80486 processor with a Weitek coprocessor; or (2) move the program from the PC to another USACE computer.

A shift to a PC with a Weitek coprocessor may solve the network faster. With a Weitek coprocessor, the execution time, according to published reports, may be halved. Other technical problems may arise if the Weitek coprocessor is used instead of the 80387. For example, certain programs that require a 80387 coprocessor will not use properly the Weitek coprocessor.

Much of the time required to solve the network problem is spent in simple calculations and in comparisons of parameters stored in arc-length arrays. The speed of these calculations and comparisons depends heavily on the speed with which these arrays can be addressed by the CPU. Under DOS, this is limited by the 640 kbytes directly-addressable memory. Beyond this limit, the operating system swaps pages of memory into and out of the 640 kbytes of memory. This is not required with other operating systems,

such as the UNIX system common on engineering workstations. With these operating systems, all memory is accessible directly from the CPU. Consequently, a shift to a machine with a less-restrictive operating system may solve the network faster. In addition, RISC chip based engineering workstations typically are substantially faster in processing speed than PC's.

Shifting HEC-PRM from DOS and the PC to another operating system or computer will require special attention to computer numerical accuracy. The algorithms used by the network solver are iterative algorithms. They rely on many thousands of comparisons of arc costs and arc flows. The accuracy of the computer plays a role in the accuracy of these comparisons. This numerical analysis problem must be addressed if a shift is made, and appropriate tolerances for the comparisons must be selected for each computer to be used.

(2) Reducing The Number of Arcs and Nodes in the Network. This is the nonstructural approach: If the solver takes too long, reduce the size of the problem. The most obvious way to do so is to limit the number of linear segments used in any piecewise approximation of the penalty functions. For example, the Missouri river system model has one reservoir-storage link for each month for each of the six reservoirs. If four arcs are required to represent the storage penalty function in each case, the total number of arcs required is 288 per year. If only three arcs are used, the number required is reduced by 25%. The same logic applies throughout the network: If the penalty functions are simpler, the network will be smaller, and the solution will be found quicker.

(3) Simplifying the Formulation. Significant execution time is required to account for the lake evaporation with currently-employed network solver. To reduce the execution time, this accounting may be simplified. One alternative is to specify the evaporation volume for each reservoir for each month prior to solution. In that case, the evaporation is treated as a diversion from the reservoir. The potential error is that the specified volume may be too large or too small for the computed lake surface area.

The alternative is to iterate to estimate the lake evaporation. In other words, HEC-PRM could estimate a fixed evaporation volume for each reservoir for each month, based on initial estimates of storage. These estimates are treated as diversions, and the network problem is solved. The fixed evaporation volume is compared then with the proper volume of evaporation from each reservoir each period. If the two are sufficiently close, iteration stops. Otherwise, the fixed volume is corrected, and the process is repeated. Even with three or four iterations, this may be faster than the network-with-gains algorithm.

A side benefit of simplifying the formulation as proposed is that it will be possible to use a faster network solver. A solver for a network with no gains (a pure network) may be 10 times faster than a solver for a network-with-gains (generalized network). Further, very large scale problems can be solved with the generalized network codes.

(4) Reformulating HEC-PRM to Use a Different Solver. This alternative requires reformulating HEC-PRM to use a different solver, such as a pure linear programming (LP) solver. This would require re-writing the code that sets up the arrays for the network solver. Instead of describing arcs and nodes, the code would specify the coefficients in a set of simultaneous linear equations. The code required would indicate the row and column number of each coefficient and the coefficient magnitude. The code would also specify the magnitude of the known right-hand side of each equation.

A variety of efficient LP solvers are available for the PC. Some, including the commercially-available CPLEX solver, are not limited at all by available computer memory. Others, such as the non-commercial XMP package used in program HEC-5Q, make efficient use of available computer memory.

Perform Selected System Analysis

In the interest of providing efficient analysis for the on-going Master Manual Update study, several key system analysis will be performed by HEC. System operation policy sets representing differing views will likely have surfaced by the time the full model capabilities are operational and prior to the development of the data input and output report components of the model. Three to four analysis are planned. One will be chosen to emphasize and illustrate operation for environmental goals such as sustaining endangered species. The results will be summarized for use in the Master Manual Update study.

APPLICATIONS GUIDE

HEC-PRM will be a tool for efficiently developing information about optimal allocation of water for the hydrologic record studied and the penalty functions specified. It is envisioned that successive executions of the model with systematic adjustments to the model constraints and penalty functions, will provide a substantive basis for deriving updated system operation rules. The rules inferred from study of HEC-PRM results would be tested and refined using the existing Missouri River reservoir simulation model. The strategy to employ in using HEC-PRM to develop the critical information and the appropriate analysis for inferring the operation rules will be developed and documented in the Applications Guide. The investigation will be a mutual undertaking with the MRD staff and will most likely evolve as a case study applications document.

CONCLUSIONS

From the activities of Phase I, HEC staff conclude the following:

- ▶ Network flow programming is an appropriate tool for analysis of long-term system operation. It is simple enough to understand in theory, yet sophisticated enough to account for most critical system characteristics and operation requirements.
- ▶ A usable model (HEC-PRM) has been implemented on the PC.
- ▶ The success of a prescriptive model such as HEC-PRM depends on the capability of the penalty functions to capture the essence of operation goals and constraints.
- ▶ Additional development is required before the results of HEC-PRM are "fit for public consumption." The work proposed for Phase II will yield a model and penalty functions that will provide useful information for making decisions regarding long-term operation rules for the MRD system.

SUMMARY

This proposal presents a plan to apply system analysis methods for the Missouri River Main Stem Master Water Control Manual Update study. We propose to:

- a. Prepare a document assessing the applicability of network-flow programming system analysis method for the study,
- b. On a trial basis, formulate and apply a network-flow model to the Missouri River main stem,
- c. Develop and document preliminary project output value functions (penalty functions) for use with the model, and
- d. Present the results in a Phase I summary report.

Following review and analysis of the trial model formulation and application, approval for Phase II would:

- e. Expand the conceptual and geographic scope of the network-flow model to the full Missouri River Main Stem system and issues,
- f. Refine the value (penalty) functions,
- g. Perform several system analyses for selected policy options and prepare summary report,
- h. Generalize input, output reporting, and user interface for the model,
- i. Develop preliminary user documentation, and
- j. Conduct workshop for MRD staff on model application.

Phase I will be completed in 6 months at a cost of \$66,500. Phase II will be completed 12 months following Phase I and is estimated to cost \$90,200 for a total cost of \$156,700. The Phase II cost is preliminary and will be finalized following Phase I. Table A-1 lists the tasks and estimated staff time to accomplish. Figure A-1 presents the proposed project schedule.

BACKGROUND

The Missouri River System Master Water Control Manual Review and Update study is described in the Draft Phase I Report dated May 1990. The report describes the objective of the study, identifies a range of water control operations alternatives, and briefly describes potential economic, social, and environmental impacts of alternatives that merit further study. The principal determinants of system operation are presented as four decision criteria: 1) allocating system storage among exclusive flood control, flood control and multiple use, carryover and multiple use, and permanent pool; 2) navigation season length; 3) minimum winter discharge; and 4) minimum summer discharge. Choices resulting from these decision criteria have profound impacts on the system's performance in meeting purposes of flood control, hydropower, water supply, recreation, and navigation.

The study strategy presented in the Draft Phase I report is that of identifying alternative operating plans, evaluating the impacts of alternative plans, and based on these impacts and views of others, selecting a plan. System analysis methodology poses the problem in a different context: given the system characteristics, system operation purposes, and impact relationships, develop the operating scheme that best accomplishes the system goals. The system hydrologic simulation, impact evaluation, and subsequent storage utilization and releases are formulated such that the computation results are the desired system operation.

System analysis methods develop information in a prescriptive rather than a descriptive manner. The results of the analysis are contingent on the ability to represent the essence of system performance and impacts such that the operation problem is formulated in a tractable structure and can be solved. The application proposed is to develop a tool that can provide information and insight into operation options and trade-offs that are not easily surfaced in the methodology currently being used. Implementing the system analysis model will not resolve the real conflicts that exist today - there is simply not enough water during drought years. It will assist in devising means for sharing negative impacts and developing long term strategies that are equitable among basin water resource system beneficiaries.

PROPOSAL

The tasks comprising the proposed work are described in following paragraphs.

- a. **System Analysis Applicability Assessment.** A number of successful system analysis applications to reservoir system operation problems are reported in the literature. Texts, (see for example Loucks, et. al. 1981) and journal articles (Yeh, 1985) present a wide range of methods and applications examples of system analysis technology. Proposed applications to water resources system operations are many and are reported on a continuing basis in the literature. Few have achieved the status of practical applications.

Based on literature review, experience with similar studies, and consultation with system analysis experts, we propose to develop and apply a network-flow programming model to the Master Manual Update study. This task will develop a document describing the strengths and weaknesses of the

selected method. The document will be written with MRD and HQUSACE management as the target audience. An assessment of the application of the network-flow model to the study will be performed as part of task d.

- b. **Formulate and Apply Preliminary Model.** Examples of successful applications to problems similar to that of the Missouri River system are described in (Sigvaldason, April 1976) and (Chung et al, March 1989).

Network-flow programming, a special case of linear programming, is the system analysis method proposed for trial application to the Missouri River main stem system. This is the method discussed in these papers and described more extensively in (Jenson and Barnes, 1980). The D2M2 model (HEC, 1984), applies network flow-modelling to the problem of optimal transport and disposal of dredged-material. D2M2 was successfully developed by HEC and continues in use by the Philadelphia District.

The network-flow model will provide for hydrologic simulation and prescriptive operation of the Missouri River system. The model will be formulated on a monthly time-step with aggregation to longer periods for seasons for which monthly detail is not warranted. A network-flow model represents the system as a series of nodes and arcs. Each reservoir and each demand point is represented by a node. Flow is conserved at nodes. The hydraulic interconnect of reservoirs and demand points is represented by arcs between the nodes. These arcs have specified capacity. Functions are developed to relate flow in an arc to a measure of the value of the system output. For this application, a penalty function that can be thought of as the cost of flow in the arc, will be used. A penalty function defines the per-unit penalty of flow in the arcs. By structuring a network with parallel arcs between nodes, complex penalty functions can be used. Figure A-2 is an example network for a single reservoir and a downstream control point with local inflow and a diversion. The network is duplicated for each time step and is connected to the previous time step with arcs representing carryover storage. The complete network model is a set of nodes and arcs with associated Missouri River system physical features, flow paths, flow limits, penalty functions, and system inflows for each time step.

A solution for flows in the network is developed by a network solver. The resulting flows in the network arcs are then interpreted to physically meaningful terms for tabulation and display. The solution to the network is the minimum penalty (e.g. maximum value) routing of flows and represents period-by-period discharge and storage utilization. This is in effect a simulation of the operation of the system for optimum operation based on the physical description of the system, constraints applied to the arcs, and penalty functions specified.

The test application will involve constructing a preliminary network and using a commercially available network solver for the solution. It will likely prove desirable to construct the network for a limited portion of the complete period-of-record and selected physical components. The solution for

network flows will be interpreted and recast into tabulations and displays for report presentation.

- c. **Develop Preliminary Penalty Functions.** The functions needed for the network model are relationships between flow in the arcs (releases/stream flow, reservoir storage) and penalty. The network is "solved", e.g. flow is routed, through the arcs to achieve an overall minimum penalty. We propose that the penalty functions be developed based on achieving desired or "optimum" service levels with a penalty for failing to do so. A penalty function may be estimated from failure cost. For example, for downstream water diversions for water supply and cooling water, the cost of extending intakes or acquiring an alternative water supply for flow less than full service flow is computed and related to the flow in the Missouri at the diversion location. Flow below the target service level result in a penalty being incurred. The penalties for each diversion are aggregated by stream reach and related to flow. Similar logic is applied for river flow for recreation, power generation, and navigation, and for reservoir storage for recreation and fisheries purposes. To reflect operations desirable for environmental purposes such as enhancing the habitat of an endangered species, a penalty function can be devised and adjusted to cause operation of the system to occur in the desired manner.

The project purposes described in the Draft Phase I report are hydropower, flood control, water supply, recreation, and navigation. For the trial application, we propose to develop preliminary penalty functions for all these purposes for the Missouri River system for which data are readily available. Figure A-3 presents stylized penalty functions for flood control, water supply, navigation, hydropower, and reservoir recreation as examples.

- d. **Phase I Summary Report.** The results of tasks a. - c. will be presented in a brief summary report. A technical appendix will describe the model development and application. Several experts in the field of system analysis will be asked to review the technical report and comment on the development and application of the network-flow model for the study.

The main report will describe the trial application and the model applicability to the full Missouri River system and issues assessed. The scopes of the remaining tasks for the successful accomplishment of Phase II will be refined from those presented in this proposal. The report will be written for the target audience of MRD, HQUSACE, and local agency managers and officials.

The Phase II tasks described below are contingent upon acceptance of the results of the Phase I effort. To a substantial degree, the efforts needed to successfully accomplish the tasks are dependent on findings of the Phase I studies. The assumption here is that the test application proves successful and that the test adequately demonstrates the usefulness of the model in the Master Manual Update study.

- e. **Expand Model to Full System and Issues.** This task will expand the model to include as needed, additional upstream reservoirs, intervening and downstream reaches, and system operation purposes. Should the linear approximations employed in the test application need refinement, additional arcs will be added to refine the function definition. The full-flow record will be implemented. Methods to account for depletions resulting from future diversions, and permit analysis of selected time windows of the historic record will be developed. The construction of the model and data preparation will be documented in a technical report.
- f. **Refine Penalty Functions.** The penalty functions used in the test application are based on available data. The functions will be expanded to include all purposes, all stream reaches, and all reservoirs. They will be refined based on specific research efforts undertaken to improve their reliability. These research efforts will be undertaken as a task separate from the model development project addressed by this proposal. The full scope of this task is highly dependent on the credibility of the functions adopted for the test application and the performance of the model regarding sensitivity of modelled system operations to changes in penalty functions.
- g. **Perform Selected System Analysis.** In the interest of providing efficient analysis for the on-going Master Manual Update study, several key system analysis will be performed by HEC. System operation policy sets representing differing views will likely have surfaced by the time the full model capabilities are operational and prior to the development of the data input and output report components of the model. Three to four analysis are planned. One will be chosen to emphasize and illustrate operation for environmental goals such as sustaining endangered species. The results will be summarized for use in the Master Manual Update study.
- h. **Develop Generalized Network Model Construction Capability and User Interface.** Construction of the network model for the Missouri River system to this point of the study will be crafted to the system, data, and issues initially defined. Modification of the model for additional and subsequent studies would require the services of a system analysis specialist to implement. To make the model generally usable for MRD staff and others, an automated network construction algorithm must be developed, and data input, output report development, and general user interface must be implemented. This will provide the capability for the user to describe the problem and data in commonly understood terms using familiar data without knowledge of the technical details of the network model. This concept was implemented by HEC for the D2M2 model and proved to be essential for the continued use of the model by the Philadelphia District.
- i. **Preliminary User Documentation.** A draft user's manual will be prepared as a companion to the technical report described above in the section "e. Expand Model to Full System and Issues." The manual will describe the capabilities and limitations of the model, summarize the technical methodology, provide an input description, output explanation, and include a

test example application. The manual will be prepared in the style of existing HEC user's manuals.

- j. **Workshop.** A two to three day workshop on model application will be formulated and presented to MRD and other interested local staff on-site in Omaha. The workshop will include presentations and discussions on data development, data entry, program applications, and output analysis. The model will be used in workshop sessions.

RESPONSIBILITIES, COORDINATION, AND MANAGEMENT

The system analysis model development and application project will be performed by the Hydrologic Engineering Center for the Missouri River Division. HEC will rely on the Institute for Water Resources for the development of the penalty functions. IWR will assist in the network construction and act as advisor on other aspects of the project. Oversight will be provided by HQUSACE engineering and planning divisions. The project will be coordinated on a continuing basis with check point meetings as shown on the schedule in Figure A-1. Attendance by all project participants will be encouraged. Substantial assistance will be required from the Missouri River Division in several areas.

MISSOURI RIVER DIVISION RESPONSIBILITIES

MRD will:

- * Provide detailed definition of the requirements of the system analysis application to the Master Manual Update study,
- * Furnish hydrologic data of monthly flows for system and local inflow,
- * Provide physical descriptive data on the reservoir system, Missouri River, system diversions, target flow requirements, etc. The specific needs will be agreed upon in consultation with MRD staff,
- * Provide cost data needed to construct the penalty functions, and
- * Provide consultation and guidance on a continuing basis during the performance of the project.

RELATIONSHIP TO ON-GOING STUDIES

We will make a concerted effort to avoid undue interference with ongoing Master Manual Update studies. Additional effort to that presently planned by Missouri River Division staff for the Master Manual Update study will likely be required for the system analysis methodology application project to make a meaningful contribution to the study.

**TABLE A-1
TASK SUMMARY
Phase I**

Task	Staff-days
a. Network-flow model applicability assessment	
b. Formulate/apply network-flow model	
- define preliminary system requirements	
- formulate network model	
- compile hydrologic, system data	
- generate network	
- secure, test network solver	
- apply test, interpret results	
c. Develop penalty functions	
- specify functions, define data needs	
- compile data, formulate functions	
- test functions	
- document development, application	
d. Prepare summary report, Phase II work plan	
* Management, travel, coordination, briefings	
SUBTOTAL PHASE I	110

*****Phase II*****

e. Expand model to full MRD system, issues	
- complete system requirements specification	
- expand network model - arcs, nodes, etc.	
- complete data compilation, data entry	
- test expanded model	
- prepare technical report	
f. Refine and finalize penalty functions	
- complete function specification	
- update and incorporate additional data	
- prepare technical, applications documentation	
g. Perform selected system analysis (assume 4)	
h. Network generator and user interface	
- specify/develop network generator	
- design user interface, reports	
- develop user interface	
i. Preliminary user documentation	
j. Workshop	
* Management, travel, coordination, briefings	
SUBTOTAL PHASE II	163
GRAND TOTAL	273

IS A NETWORK-FLOW PROGRAMMING MODEL THE RIGHT MODEL FOR ANALYSIS OF THE MISSOURI RIVER MAIN STEM RESERVOIR SYSTEM?

CONCLUSION

A network-flow programming model is appropriate for analysis of the Missouri River main stem reservoir system because it satisfies institutional, economic, environmental, and engineering criteria. A network model represents the system operation problem with a set of nodes and arcs. A network solver finds the optimal allocation of available water to the arcs, subject to absolute limitations on that allocation. The network model demonstrates what will happen if a particular operation policy is adopted, and will indicate the policy preferred, given a set of priorities for operation.

WHAT IS A NETWORK-FLOW MODEL?

A network model represents the pertinent characteristics of a reservoir system, the objectives of operation, and limitations on actions with a set of simultaneous linear equations. The variables in the equations represent decisions that must be made by system operators. For example, the reservoir releases and storages are represented by variables in the equations. The equations that describe relationships of these variables are of three types: (1) An objective function equation; (2) continuity equations; and (3) upper and lower bounds on the variables. For convenience, the set of equations and the decision variables can be represented by a graph of nodes connected by directed arcs. Nodes represent river or channel junctions, gage sites, monitoring sites, reservoirs, or water-demand sites. Flow is conserved at these nodes: The total volume of water in the arcs originating at any node must equal the total volume in arcs terminating at that node. Arcs represent river reaches or diversion channels. Water moves from node to node through the arcs. A penalty (cost) is incurred for each unit of water that moves through an arc. Each arc is capacitated. That is, each has a minimum and a maximum flow that it must carry.

The proposed network model of the Missouri River main stem system is a layered model, with each layer representing one time period (one month in the model proposed). To develop this model, the network representation is developed first for a single month. Figure B-1 illustrates a simplified version of this network. Node 3 is a reservoir. Node 4 is a downstream demand point. The arc from node 3 to node 4 represents the total reservoir outflow. Node 1 is a hypothetical node that provides all water for the system. The arc from node 1 to node 3 represents the reservoir inflow. The arc from node 1 to node 4 represents the local runoff downstream of the reservoir. Node 2 is the hypothetical sink for all water from the system. The arc from node 4 to node 2 carries water from the reservoir/demand point network to this sink.

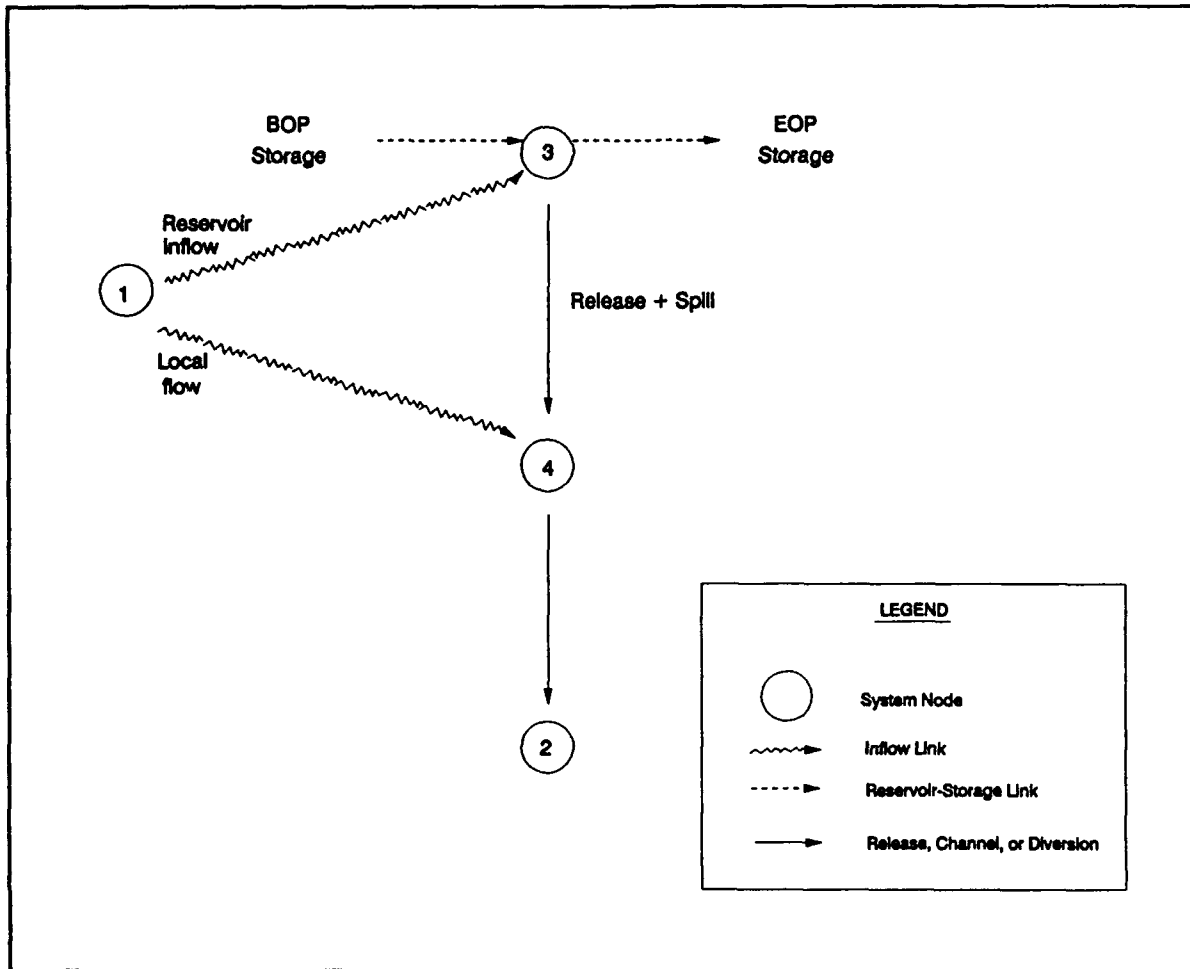

FIGURE B-1 Simplified Single-period Network

For each time period to be analyzed, the arc-node representation of the reservoir system is duplicated. Figure B-2 illustrates this. A single source node (node 1) and a single sink node (node 2) are included. The duplicate networks are connected by arcs that represent reservoir storage. For example, in Figure B-2, the arc connecting node 3 in period 1 to node 3 in period 2 represents the storage. The flow in this arc is the end-of-period 1 (beginning-of-period 2) storage. Likewise, the flow in the arc connecting node 3 in period 2 to node 3 in period 3 represents the end-of-period 2 storage. The single source node (node 1) and single sink node (node 2) are excluded from the figure for clarity.

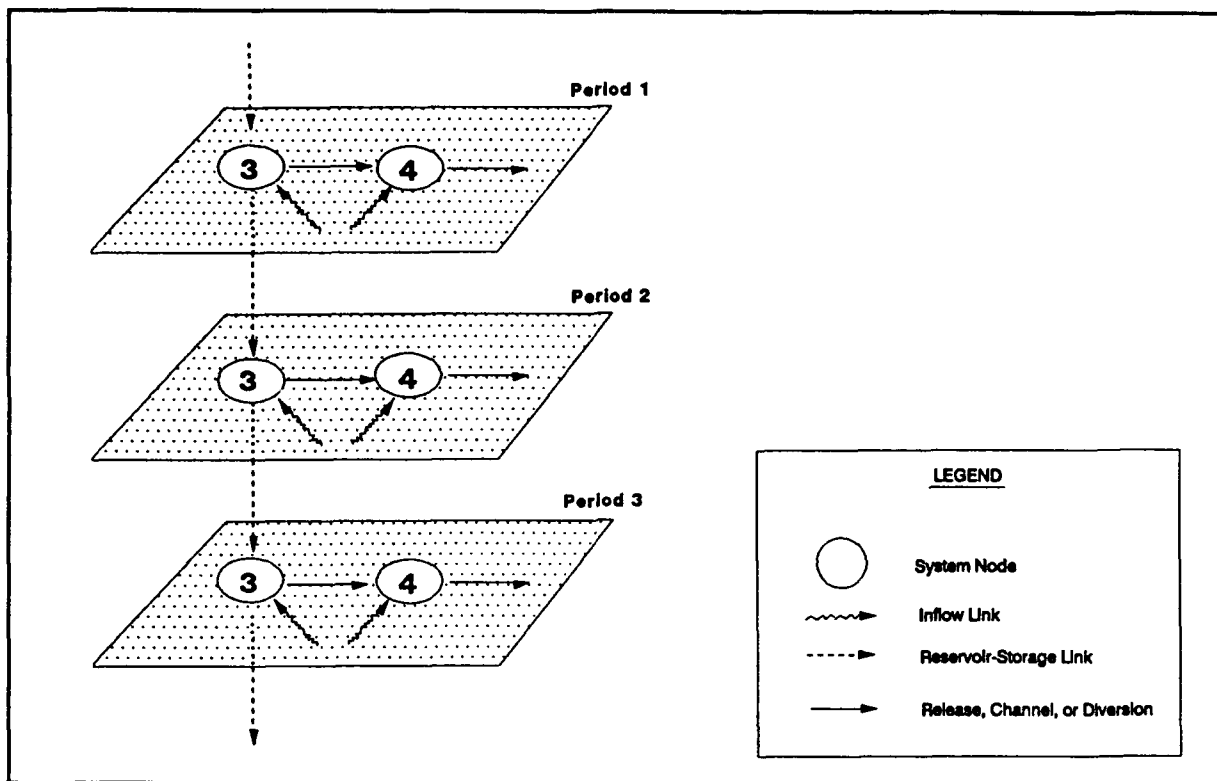

FIGURE B-2 Multiple Period Network

The optimal allocation of water in the layered network is determined with a network solver. The solver finds the flow in each network arc that yields the total minimum-penalty circulation for the entire network, subject to the continuity and capacity constraints. These flows may be translated into reservoir releases, hydropower generation, storage rates, diversions, and channel flows.

IS A NETWORK-FLOW PROGRAMMING MODEL THE RIGHT MODEL?

Institutional Criteria

Will the model solve the Missouri River main stem reservoir system operation problem? The network model proposed will provide information that will help solve the system-operation problem. However, the model itself will not solve explicitly the problem. No model can do that. The network model will help the policy makers and their staffs understand the consequences of proposed courses of action. For example, Hitch and McKean (1960) write, "casually selected or arbitrary constraints can easily increase system cost or degrade system performance manyfold, and lead to solutions that would be unacceptable to the person who set the constraints in the first place." The proposed model will demonstrate clearly the penalty for constraints (limitations) or degradation of system performance, as it is a penalty-driven model. This information will enable rational policy debate. The model will demonstrate what will happen if a particular policy is adopted, and will indicate the policy preferred, given a set of priorities for operation.

Can the model represent all system operation purposes fairly? Yes, the model can represent all operation purposes if system performance for those purposes is expressed in hydrologic terms. The penalties for flow in the network arcs are related to system releases, storages, and water deliveries. Likewise, the arc capacities are related to releases, storages, and water deliveries. Any purpose can be represented in the model in terms of these penalties and arc capacities. Solution of the network problem indicates how water is allocated for the various system purposes.

Can the model evaluate alternative priorities for system operation? Yes, alternative priorities can be evaluated by altering the arc penalties. The desirability of release, storage, and delivery dictates the magnitude of the penalty. The penalty factor is inversely associated with priority. For example, if storage in a reservoir is highly desirable, the penalty is low. If the storage is undesirable, the penalty is great. The relative magnitudes of the penalties dictate how water is allocated optimally in the network. To change priorities, the penalties are adjusted.

Will decision makers accept the results of this model? It is impossible to guarantee that decision makers will accept the results. However, the model has characteristics that increase the likelihood of acceptance. The first is simplicity. Woolsey (1975) suggests that people would rather live with a problem they cannot solve than accept a solution they cannot understand. The network approach is intuitive, and the solution procedure is straightforward. Consequently, decision makers should be able to understand the model. This should lead to acceptance of the results. The second important characteristic is realistic expectations. The results of the proposed model are not promoted as solutions to the operation problem. Instead, the results are promoted as information for rational policy debate. The third important characteristic is relevance. The proposed model will include, in some fashion, all purposes and priorities that can be identified. Finally, the model is flexible, and thus should be useful for answering, in a timely fashion, any "what-if" questions that may be raised by decision makers.

Can the model outputs be translated into terms that are readily understandable to users? Yes, the outputs can directly be translated to hydrologic terms. Further, the penalties can be used for direct, quantitative comparison of alternative operation priorities.

Can the model be modified or expanded easily as more information becomes available, as understanding of the system operation improves, and as the users become more sophisticated? The network structure of the model makes modification especially convenient. With alternative mathematical-programming tools, equations must be developed in a specific format. If the formulation changes, the equations change. When the equations change, computer code must be modified extensively to solve the resulting equations. This is not so with the network model. Modification of the network formulation requires only identification of new nodes and arcs and specification of the new arc parameters.

Can the model be used on the computer hardware available to users? The model will be developed specifically for use on the computer hardware available to MRD staff. Initial planning for the model indicates implementation on a state-of-the-art PC (80386 processor with expanded memory) may be possible. Such implementation would permit use of the model by interested government and nongovernment parties.

Can the model be implemented in time to provide information for decision making?

Yes, the model will be developed in time to provide the information. The technology proposed is not experimental. It has been tested thoroughly and applied to similar problems (see references that follow). The model developers, the Hydrologic Engineering Center (HEC) staff, are not novices in model development. They have a 25-year history of success. The system analysis specialists, again the HEC staff, are not tinkering with new tools. They previously have used network-flow programming to solve water management problems. The model users, the MRD staff, are not new to modeling. They have used computerized system analysis models to study the Missouri River main stem for years. These all point toward successful implementation in a timely manner.

Economic Criteria

Can the model evaluate accurately the economic impact of operation decisions? The network model will evaluate the economic impact of operation decisions to the extent that the penalties assigned to flow in the network arcs are related to economic costs. Otherwise, the evaluation is in terms of relative satisfaction of demands for water.

Can the economic data required for the model be obtained with reasonable effort? The data required for economic analysis with the network model are the same data that would be required for economic analysis with any model of the reservoir system. Costs and benefits must be related to hydrologic parameters. This task is difficult. However, it is not a task unique to application of the network model.

Environmental Criteria

How can the model treat non-quantifiable operation purposes, such as fish and wildlife protection? The model treats non-quantifiable operation purposes through assignment of the penalties for flow in the network arcs. These penalties are not direct dollar costs. Instead, they are units of relative dissatisfaction, related to hydrologic phenomena. The penalty magnitude is assigned by the analyst. Consequently, the analyst can assign a penalty as large as required to achieve desired flows or storages for fish and wildlife protection. The model will demonstrate the trade-offs with other purposes as these penalties are adjusted.

Alternatively, the flow in network arcs can be constrained absolutely as required, for example, for fish and wildlife protection. This is accomplished by specifying discharge or storage requirements as upper or lower bounds on flow in appropriate network arcs. The network solver will find the optimal allocation of flow, given the absolute constraints, if a solution is possible. The difference in total system penalty with the constraint and without the constraint is the penalty for maintaining flow at the required level.

Can the model represent adequately the requirements for endangered species? The network model can represent the requirements in terms of monthly average discharge or storage. As described above, the requirements can be expressed in terms of penalties or as absolute limitations.

Engineering Criteria

System analysis is no longer restricted to "either it's linear or I can't do it," so why chose a linear model? A model may be developed with one of two alternative approaches. The first approach is to develop the model with realism uppermost, trying to simulate the real world to perfection. The alternative approach, followed here, is to keep relevance uppermost. This permits the questions asked, as well as the processes to be modeled, to determine what will be in the model. Of course, it is true that all engineering, economic, and environmental relationships are not linear in the Missouri River system. Nevertheless, a linear model will provide information about trade-offs amongst purposes and impacts of institutional, engineering, economic, and environmental limitations. These are the questions of interest.

Does the model use existing data or data that can be obtained with reasonable effort? The network model, as presently proposed, requires much of the same data as the existing MRD reservoir system simulation model. For example, reservoir characteristics, channel capacities, and diversion requirements must be defined. These data are readily available. Likewise, the flow data required are the same as required by the existing MRD simulation model.

Can alternative future inflow or demand sequences be studied conveniently? The network model will be developed so inflows and demands are defined with input. Alternative sequences can be studied by changing only input. The network configuration will remain unchanged.

Can the model account for risk? The network model does not account for risk explicitly. However, it is possible to account for risk implicitly by analyzing the frequency of various network-model results. For example, the network model may be applied to determine the optimal allocation of water for the 92-year historical record, given a set of penalty functions. As a consequence of this application, the monthly-average channel discharge time series is computed. The channel discharge-frequency curve can be computed with this time series. The frequency curve will account for risk of failing to meet discharge demands. Similar frequency analyses can be made for reservoir release, power generation, diversion flow, or other pertinent variables. To increase the reliability of the statistical analyses, alternative inflow and demand sequences can be developed with a stochastic-hydrology model and analyzed with the network model.

Is the technology dependable? Yes, the technology for formulating and for solving network-flow programming problems is dependable. Representation of water-management problems as network-flow problems is well-known. The Texas Water Development Board (TWDB) developed network models for studying alternative state water plans in the 1970's (TWDB, 1974). Sigvaldason (1976) used a network model to plan operation of the Trent river system, Canada. The California Department of Water Resources uses network models for planning (Chung, Archer, and DeVries, 1989) and for real-time operation of the State Water Project (Sabet, et al., 1985). Ikura and Gross (1984) formulated a network model for scheduling operation of a hydroelectric system. HEC formulated a "leaky" network and employed a network-with-gains algorithm to analyze dredged-material disposal management (Corps of Engineers, 1984; Ford, 1986).

Network solvers were introduced in the 1960's (Ford and Fulkerson, 1962; Durbin and Kroenke, 1967) and have been widely used. Subsequent research has yielded solvers that are faster than the original solvers (Barr, Glover, and Klingman, 1974) and solvers for more general network problems (Jensen, Bhaumik, and Driscoll, 1974; Jensen and Barnes, 1980).

Is the network-solver fast enough? Network solution algorithms are amongst the fastest mathematical-programming algorithms. Even on the PC, these algorithms have the reputation of solving problems in one-tenth the time required for solution with a linear-programming algorithm. Jensen, Bhaumik, and Driscoll (1974) show results that indicate for some problems the network-with-gains solves some problems in one-hundredth the time required for an linear-programming algorithm.

SUMMARY

A network-flow programming model is proposed for analysis of operation of Missouri River main stem reservoir system operation. This model represents the relevant institutional, economic, environmental, and engineering features of the system with a set of nodes and arcs. Penalties are assigned for flow in the arcs. A network solver finds the minimum penalty allocation of water to the arcs.

The model proposed will represent all relevant project purposes. It will use readily-available hydrologic data. It will use economic data consistent with those that must be collected for any evaluation. Model results can be translated easily into terms that are understandable to users.

The proposed model will quantify the impacts of alternative operation priorities, and it will quantify the impacts of absolute limitations on discharge and storage. In this manner, it will provide information for rational policy debate.

REQUIREMENTS FOR PRESCRIPTIVE MODEL OF MISSOURI RIVER MAIN STEM RESERVOIR SYSTEM OPERATION

SUMMARY OF REQUIREMENTS

The Missouri River main stem reservoir system operation problem will be addressed as a problem of optimal long-term allocation of available water. A prescriptive model will be developed to solve this problem. The model will identify the allocation that minimizes poor performance for all defined system purposes. Performance will be measured with analyst-provided penalty functions of flow or storage or both.

To determine the optimal water allocation, the physical system will be represented as a network, and the operating problem will be formulated as a minimum-cost network flow problem. The objective function of this network problem is the sum of convex, piecewise-linear approximations of the penalty functions. An off-the-shelf solver will be used to define the optimal allocation of water within the system. The results of the solver will be processed to report and display reservoir releases, storage volumes, channel flows, and other pertinent variables.

To the extent possible, the software to implement the model will be general purpose. Accordingly, the software will include the following model-building components:

1. Inflow link;
2. Initial-storage link;
3. Diversion link;
4. Final-storage link;
5. Channel-flow link;
6. Simple reservoir-release link;
7. Hydropower reservoir-release link;
8. Reservoir-storage link; and
9. Node.

An analyst can specify the characteristics of and the configuration of these components to represent any system.

PROBLEM STATEMENT

The problem addressed by the proposed system model is identification of the optimal long-term operation plan for the reservoirs of that system. This plan will identify the priorities to be assigned to conflicting objectives of operation. For example, the plan will identify whether water should be released from a system reservoir if a demand exists for downstream flow for wildlife protection and a conflicting demand exists for continued storage of the water for reservoir recreation.

The model will quantify system performance for various purposes in multi-objective terms. The economic cost of operation will be considered. Also, the social and environmental cost will be considered. These costs will be expressed in commensurate terms to permit display of trade-offs in operation for various purposes.

Constraints on the physical system will be included. For example, the outlet capacity of the reservoirs will be modeled explicitly. However, inviolable constraints on system operation will be used frugally. This will avoid the problem described by Hitch and McKean (1960) when they wrote "...casually selected or arbitrary constraints can easily increase system cost or degrade system performance manyfold, and lead to solutions that would be unacceptable to the person who set the constraints in the first place." Instead, operation limitations will be imposed through value functions. This will permit clear evaluation of the impacts of limitations. For example, instead of specifying maximum flow requirements for flood control, the system model will represent this requirement through high costs of failure to meet the requirement.

PROPOSED SOLUTION

The proposed solution considers the reservoir operation planning problem as a problem of optimal allocation of available water. The proposed solution to this water allocation problem is as follows:

- (1) Represent the physical system as a network;
- (2) *Formulate the allocation problem as a minimum-cost network flow problem;*
- (3) Develop an objective function that represents desirable operation;
- (4) Solve the network problem with an off-the-shelf solver; and
- (5) Process the network results to define, in convenient terms, system operation.

Represent System as a Network

For solution of the water allocation problem, the reservoir system will be represented as a network. A network is a set of arcs that are connected at nodes. The arcs represent any facilities for transfer of water between two points in space or time. For example, a natural channel transfers water between two points in space and is represented by an arc. A reservoir transfers water between two points in time; this transfer is represented by an arc.

Network arcs intersect at nodes. The nodes may represent actual river or channel junctions, gage sites, monitoring sites, reservoirs, or water-demand sites. Flow is conserved at each node: the total volume of water in arcs originating at any node equals the total volume in arcs terminating at that node.

Figure C-1 illustrates a simple network representation. Node 3 represents a reservoir. Node 4 represents a downstream demand point. Two additional nodes with associated arcs are included to account completely for all water entering and leaving the system. Node 1 is the source node, a hypothetical node that provides all water for the system. Node 2 is the sink node, a hypothetical node to which all water from the system returns. The arc from node 1 to node 3 represents the reservoir inflow. The arcs shown as dotted lines represent the beginning-of-period (BOP) and end-of-period (EOP) storage in the reservoir. The BOP storage volume flows into the network from the source node. The EOP volume flows from the network back to the sink node. The arc from node 3 to node 4 represents the total reservoir outflow. The arc from node 1 to node 4 represents the local runoff downstream of the reservoir. The arc from node 4 to node 2 carries water from the reservoir/demand point network to the sink.

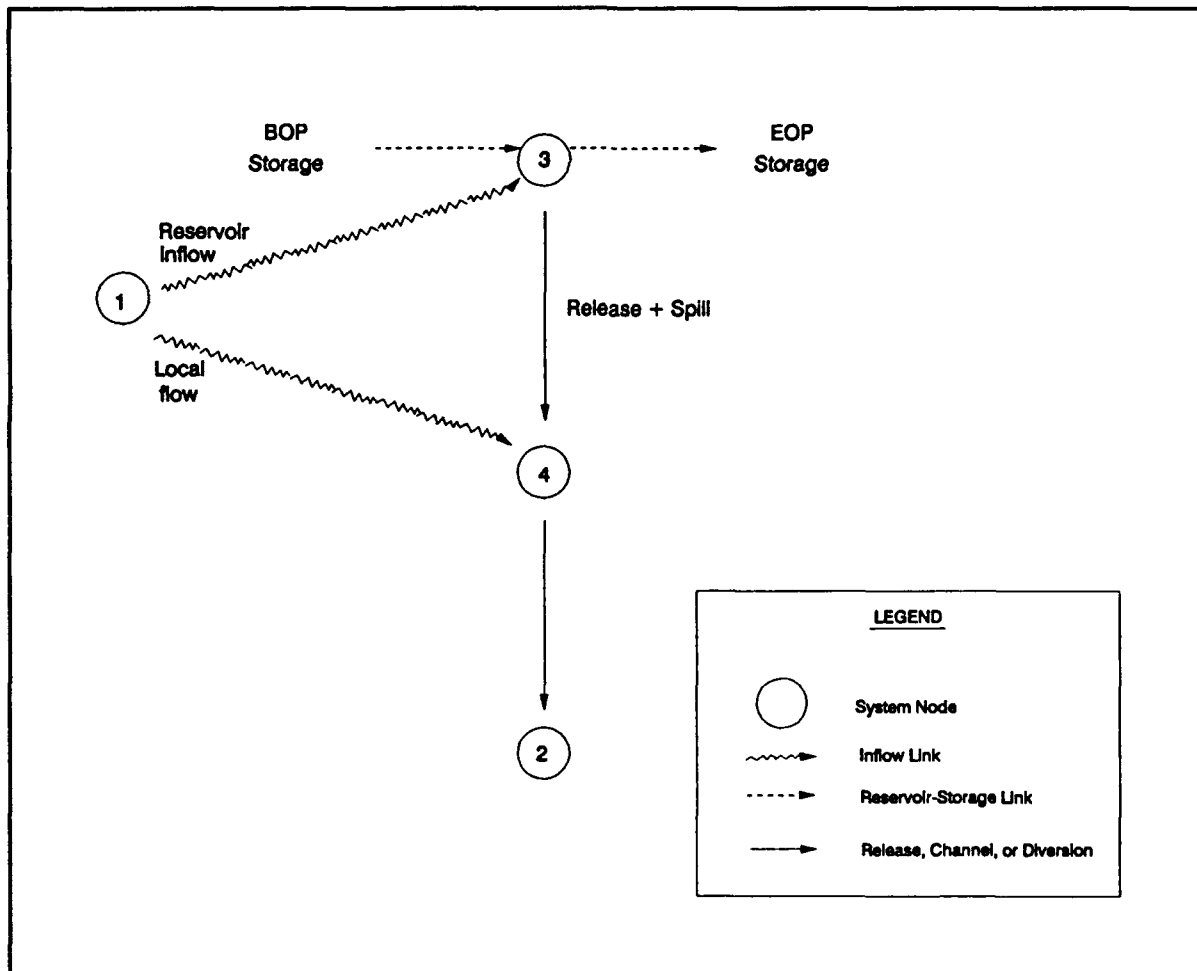

FIGURE C-1 Simplified Single-period Network

To analyze multiple-period system operation, a layered network will be developed. Each layer represents one month. To develop such a layered network, the single-period network representation is duplicated for each time period to be analyzed. Figure C-2 illustrates this. A single source node and a single sink node are included. For clarity, these have been omitted from the figure. The duplicate networks are connected by arcs that

represent reservoir storage. For example, in Figure C-2, the arc connecting node 3 in period 1 to node 3 in period 2 represents the storage. The flow along this arc is the end-of-period 1 storage. This is equivalent to the beginning-of-period 2 storage. Likewise, the flow along the arc connecting node 3 in period 2 to node 3 in period 3 represents the end-of-period 2 storage. This also is the beginning-of-period 3 storage.

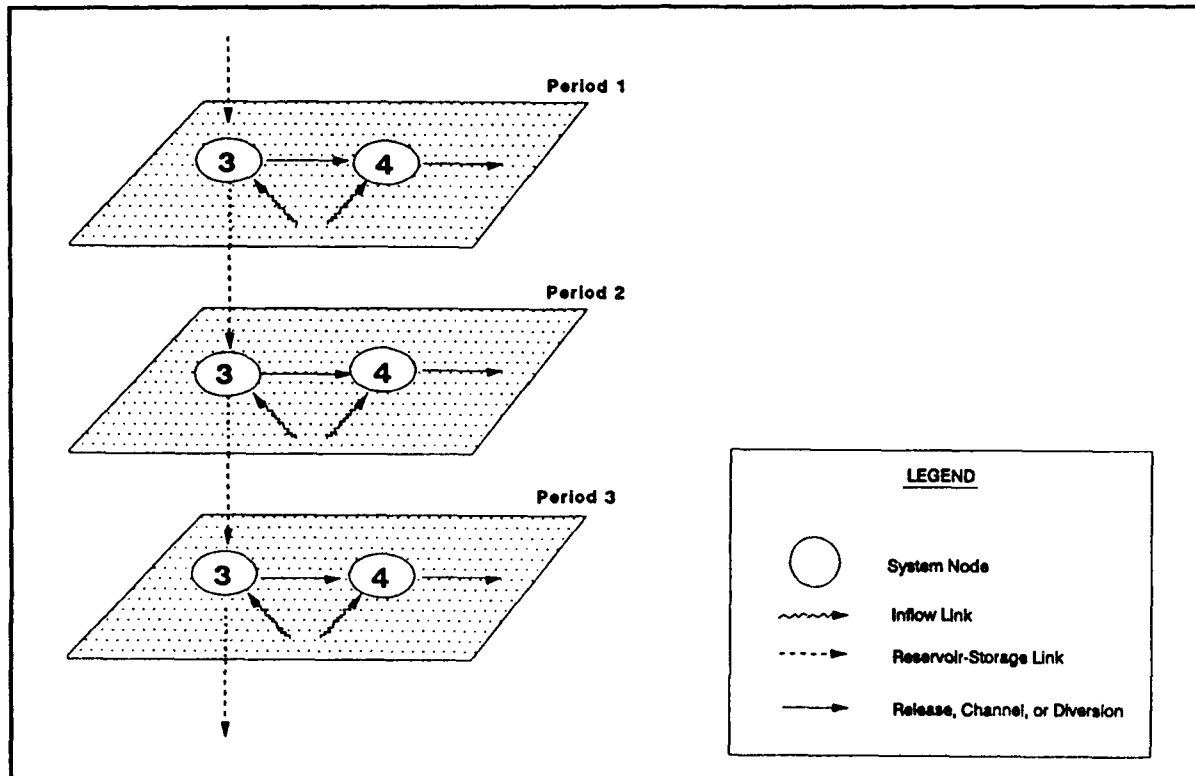

FIGURE C-2 Multiple Period Network

Formulate the Allocation Problem as a Minimum-cost Network-flow Problem

The goals of and constraints on water allocation within the reservoir system can be represented in terms of flows along the arcs of the network. If a unit cost is assigned for flow along each arc, the objective function for the network is the total cost for flow in all arcs. The ideal operation will be that which minimizes this objective function while satisfying any upper and lower bounds on the flow along each arc. The solution also must maintain continuity at all nodes.

Minimum-cost Objective Function. A network solver finds the optimal flows for the entire network simultaneously, based on the unit cost associated with flow along each arc. The functions that specify these costs are defined by the analyst.

The simplest cost function is a linear function, such that shown in Figure C-3. This function represents the cost for flow along one arc of a network. The cost increases steadily as the flow increases in the arc. The unit cost is the slope of the function. Here, it is positive, but it may be positive or negative. The total cost for flow along the arc represented is the product of flow and the unit cost.

FIGURE C-3 Simple Linear Cost Function

The simplest linear function may be too simple to represent adequately many of the goals of reservoir operation. Instead, nonlinear functions, such as those shown in Figures C-4(a-c), may be required.

Piecewise-linear Approximation. If the cost functions are convex, as are those in Figures C-4(a-c), they can be approximated in a piecewise linear fashion for the proposed network model. Figure C-5 illustrates piecewise approximation of a complex cost function. Linear segments are selected to represent the pertinent characteristics of the function. The analyst controls the accuracy of the approximation. More linear segments yield a more accurate representation. However, the time required for solution of the resulting network-flow programming problem depends on the number of arcs included in the network. Thus, as the approximation improves, the time for solution increases. Jensen and Barnes discuss this approximation in detail (1980, pgs. 355-357).

FIGURE C-4 Nonlinear Penalty Functions

FIGURE C-5 Piecewise Linear Approximation of Nonlinear Penalty Function

With a piecewise linear approximation, the physical link for which the function applies is represented in the network by a set of parallel arcs. One arc is included for each linear segment of the piecewise approximation. For example, suppose the cost function in Figure C-5 represents the cost of release from the reservoir represented by node 3 in Figure C-1. In the proposed network model, four parallel arcs will connect node 3 to node 4. Characteristics of the arcs are shown on Table C-1.

**TABLE C-1
Example Network Model Arc Characteristics**

<u>Arc Number</u> (1)	<u>Lower Bound</u> (2)	<u>Upper Bound</u> (3)	<u>Unit Cost</u> (4)
1	0	100	$(1-4)/100 = -0.03$
2	0	$200-100=100$	$(0-1)/100 = -0.01$
3	0	$300-200=100$	$(1-0)/100 = 0.01$
4	0	$400-300=100$	$(4-1)/100 = 0.03$

Arc 1 has the least marginal cost. Therefore, as flow is increased from node 3 to node 4, flow will pass first through arc 1. When the capacity of this arc is reached, flow begins to pass through arc 2. Arc 3 will have non-zero flow if and only if arc 2 is at its upper bound. Finally, arc 4 will have non-zero flow only when arcs 1, 2, and 3 are flowing full. Because the objective is to minimize cost, if two or more arcs are parallel, the one with the lowest unit cost is used first.

Develop Objective Function Representing Desirable Operation

Penalty Functions. All goals of system operation cannot be represented adequately with economic costs. Some of the goals are socially, environmentally, or politically motivated. Consequently, the objective function for the proposed model is formed from penalty functions, rather than cost functions. These penalty functions are in commensurate units, but those units are not necessarily dollars. The penalty functions represent instead the relative economic, social, environmental, and political penalties associated with failure to meet operation goals. Thus, even if failure to meet, for example, an environmental operation goal has no measurable economic cost, the penalty may be great.

Flow Penalty Functions. All operation goals related to reservoir-release, channel-flow, or diversion-flow flow are expressed with flow penalty functions. These functions may represent operation goals for navigation, water supply, flood control, or environmental protection.

Figure C-6 is an example of a flow penalty function. This function represents the relative penalty for diverting flow when the minimum desired diversion is 100 cfs. Less diversion is undesirable. More diversion is acceptable, but that water does not reduce further the penalty.

FIGURE C-6 Typical Flow Penalty Function

The penalty function of Figure C-6 is represented in the network by two parallel arcs. The characteristics of these arcs are shown on Table C-2.

TABLE C-2
Penalty Function Arc Parameters

<u>Arc Number</u> (1)	<u>Lower Bound</u> (2)	<u>Upper Bound</u> (3)	<u>Unit Cost</u> (4)
1	0	100	$(0-100)/100=-1.00$
2	0	$1000-100=900$	0.00

The first arc represents flow up to the desired rate. As the flow increases from 0 cfs to 100 cfs, the total penalty decreases. At 100 cfs, the unit penalty is 0.00. As the flow increases beyond 100 cfs, the unit penalty remains 0.00.

Similar penalty functions can be developed for reservoir release and channel flow.

Storage Penalty Functions. All reservoir operation goals uniquely related to storage are expressed through penalty functions for arcs that represent reservoir-storage. These functions may represent operation goals for reservoir recreation, water supply, or flood control.

Figure C-7 is an example of a reservoir storage penalty function. For this example, the top of the permanent pool is 200 kaf, the top of the conservation pool is 800 kaf, and the top of the flood-control pool is 1000 kaf. The function represents penalty for storage when the reservoir operation goal is to keep the inactive and conservation pools full and the flood control pool empty.

FIGURE C-7 Typical Storage Penalty Function

The function of Figure C-7 is represented in the network by three parallel arcs. The flow along one arc represents storage in the permanent pool. Increasing the flow along this arc reduces the penalty rapidly. Flow along the second arc represents storage in the conservation pool. Increasing flow along this arc also decreases the penalty, but not as rapidly as does flow along the inactive-pool arc. The third arc represents storage in the flood-control pool. Increasing flow along the flood-control pool arc increases the penalty. The solver will allocate flow to the arcs to minimize the total system penalty: first to the inactive-pool arc, then to the conservation-pool arc, and finally to the flood-control pool arc.

Storage and Flow Penalty Functions. Certain system operation goals depend on both storage and flow. The most significant is hydroelectric energy generated at a reservoir. This is a function of the product of release and head on the turbine. Head is the difference in reservoir-surface elevation and downstream water-surface elevation. Reservoir-surface elevation is a function of reservoir storage, and downstream water-surface elevation is a function of release. Thus, the energy generated is a complex function of storage and flow.

Figure C-8 illustrates a typical energy penalty function. Here, penalty is measured in terms of reduction in value of the energy produced, when compared to the firm energy target. Additional energy generated has a value, but that value is less than firm energy. Thus the slope is less.

FIGURE C-8 Typical Hydropower Penalty Function

Solve the Network Problem with an Off-the-shelf Solver

Mathematical Statement of Problem. The optimization problem represented by the network with costs associated with flow can be written as follows (Jensen and Barnes, 1980):

$$\text{Minimize: } \sum_k h_k f_k \quad (1)$$

subject to

$$\sum_{k \in M_O} f_k - \sum_{k \in M_T} a_k f_k = 0 \quad (\text{for all nodes}) \quad (2)$$

$$l_k \leq f_k \leq u_k \quad (\text{for all arcs}) \quad (3)$$

in which:

- m = total number of network arcs;
- h_k = unit cost for flow along arc k ;
- f_k = flow along arc k ;
- M_O = the set of all arcs originating at a node;
- M_T = the set of all arcs terminating at a node;
- a_k = multiplier for arc k ;
- l_k = lower bound on flow along arc k ; and
- u_k = upper bound on flow along arc k .

Equations 1, 2, and 3 represent a special class of linear-programming (LP) problem: the *generalized minimum-cost network-flow problem*. Solution of the problem will yield an optimal allocation of flow within the system.

Network Solvers. Jensen and Barnes (1980) describe a variety of solutions to the generalized minimum-cost and other network-flow programming problems. One solution is the flow-augmentation algorithm developed by Jensen and Bhaumik (1974). This algorithm determines the minimum-penalty flow in a generalized network by iteratively performing two computations. In the first computation, at the first iteration, the algorithm solves a shortest-path problem. That is, it determines a set of arcs that provide the minimum-penalty path from the source node to the sink node. In each successive iteration, the shortest-path computation deletes an arc with flow at upper bound from the path. It then adds the most promising available arc to create a new path. The second computation determines the maximum flow that can be directed from source to sink through the current shortest path. It increases flows in the arcs to achieve the maximum possible flow at the sink. If this flow equals an analyst-specified flow requirement at the sink, the algorithm terminates. Otherwise, the algorithm continues with the first computation. FORTRAN routines implementing this algorithm were published by Jensen and Bhaumik and used by Martin (1982). These routines are available at HEC.

If $a_k = 1.00$ for all k in Equation 2, the resulting problem is a *pure network-flow programming problem*. For this class of problem, faster solution algorithms are available. The well-known out-of-kilter (OKA) algorithm (Fulkerson, 1961) solves this pure network problem. A FORTRAN routine implementing the OKA has been available as shareware since 1967 (SHARE). Barr, Glover, and Klingman (1974) presented an improved formulation of the OKA and developed a FORTRAN code to implement their algorithm. They present results showing that the reformulated algorithm is faster than the share routine by a factor of 4 to 15 on large problems. This code, designated SUPERK, is published by the Texas Department of Water Resources (1975) and used by the California Department of Water Resources (Chung, et al., 1989). FORTRAN code for SUPERK is available at HEC.

Karney and Klingman (1976) present a special-purpose in-core, out-of-core code for solving capacitated transshipment and transportation network problems. They report that this code has solved problems with 50,000 nodes and 62 million arcs on a UNIVAC 1108 for the U.S. Treasury Department. They also report solution of networks with 625,000 arcs on machines with less than 30,000 words of central memory. This code, designated I/O PNET-I, is available commercially.

Post-process Network Results

The optimal allocation of water in the layered network is determined with a network solver. The solver finds the flow along each network arc that yields the total minimum-penalty circulation for the entire network, subject to the continuity and capacity constraints. These flows must be translated into reservoir releases, hydropower generation, storage volumes, diversion rates, and channel flows to be useful to the reservoir system operators.

For convenience, the results after translation will be stored with the HEC data storage system (HECDSS). Then the results can be displayed or processed further as needed to provide information required for decision making.

MODEL-BUILDING SOFTWARE

To the extent possible, the software to implement the network model will be general-purpose software. With this software, an analyst will be able to define the layout of any existing or proposed reservoir system. Further, the analyst will be able to describe the physical features of the system reservoirs and channels and the goals of and constraints on their operation. The operation goals will be defined by penalty functions associated with flow, storage, or both.

To permit representation of any reservoir system as a network, the software will include the following model-building components:

1. Inflow link;
2. Diversion link;
3. Channel-flow link;
4. Simple reservoir-release link;
5. Hydropower reservoir-release link;
6. Reservoir-storage link;
7. Initial-storage link;
8. Final-storage link; and
9. Nodes at which links are connected.

By selecting the appropriate links and the manner in which they are interconnected, the analyst can describe any system. By describing the characteristics of the links and the penalties associated with flow along the links, the analyst can define operating constraints and goals.

Inflow Link

An inflow link brings flow into the reservoir-system network. It originates at the source node and terminates at any other system node. In Figure C-1, the link from node 1 to node 3 is an inflow link. It originates at the source node, node 1, and carries flow into the system at node 3.

The flow along the arc representing the inflow link is an input to the model. This known inflow may be an observed inflow from the historical record, or it may be an inflow from a sequence generated with a statistical model. To insure that the link carries the specified flow, the arc upper and lower bounds are equal, and the unit penalty is zero.

Initial-storage Link

An initial-storage link is a special case of an inflow link. It originates at the source node and terminates at a node that represents a reservoir in the first period of analysis only. It introduces to the network the volume of water initially stored in the reservoir. In Figure C-2, the storage link terminating at node 3 in period 1 is an initial-storage link; it represents the beginning-of-period 1 storage.

As an initial-storage link carries a specified flow, no decision is represented by this link. To insure that the link carries the specified flow, the arc upper and lower bounds are equal, and the unit penalty is zero.

Diversion Link

A diversion link carries flow out of the system. It originates at any system node and terminates at the sink node. In Figure C-1, the arc from node 4 to node 2 is a diversion link. It originates in the system at the downstream control point, node 4. It carries flow out of the system to the sink, node 2.

The flow along a diversion link is a decision variable, selected to minimize total system penalty. The diversion penalty function is specified by the analyst as a convex piecewise approximation of the true penalty associated with deviating from the diversion desired. This function may vary by month. The software will define appropriate arc bounds and unit costs to represent the function.

The analyst may specify also inviolable minimum and/or maximum flow for a diversion link. If the analyst specifies both minimum and maximum, and if these values are the same, the diversion link will be represented in the network by a single arc. The upper and lower bounds of the arc are equal. In that case, the only feasible solution is one in which flow equals the specified value, regardless of cost. Any penalty function defined by the analyst for the link is ignored in that case, as it has no impact on the solution.

If the analyst specifies only a lower bound or only an upper bound, the software will impose the bound on the appropriate network arcs. If the penalty function is a simple function, like that of Figure C-3, the bound is applied to the single arc representing that function. For example, if the analyst specified a lower bound of 25 cfs and an upper bound of 800 cfs, the network arc will have $l_i = 25$ and $u_i = 800$ (see Equation 3).

For more complex penalty functions, the software must include an algorithm to determine the proper network arcs on which to impose the bound. For example, the penalty function of Figure C-6 is represented by two parallel arcs, with bounds and cost. If the analyst specifies an inviolable lower bound of 25 cfs and an upper bound of 800 cfs, the network arcs must be adjusted to have parameters shown on Table C-3.

TABLE C-3
Diversion Link Arc Characteristics

<u>Arc Number</u> (1)	<u>Lower Bound</u> (2)	<u>Upper Bound</u> (3)	<u>Unit Cost</u> (4)
1	25	100	-1.00
2	0	800-100=700	0.00

For the first arc, the lower bound increases from 0 to 25. The upper bound remains 100. The unit cost does not change. For the second arc, the lower bound remains 0, and the upper bound now is $800 - 100 = 700$. The unit cost does not change.

Final-storage Link

A final-storage link is a special case of a diversion link. It carries flow out of the system, but only from a reservoir in the last period of analysis. The final storage link thus originates at any system reservoir and terminates at the sink node. In Figure C-2, the storage link originating at node 3 in period 3 is a final-storage link. The final-storage link is included in the system model to permit assignment of a future value for water in system reservoirs. Otherwise, the network solver will be indifferent regarding final storage. The solver may chose any storage state, including empty or full, without regard for future use.

Just as with the diversion link, the flow along a final-storage link is a decision variable, selected to minimize total system penalty. The penalty function is specified by the analyst as a convex piecewise approximation of the true penalty associated with deviating from the an ideal final storage. The software will define appropriate arc bounds and unit costs to represent this function.

As with the diversion link, the analyst may specify also inviolable minimum and/or maximum storage for a final-storage link. The software will impose these constraints on the appropriate network arcs.

Channel-flow Link

A channel-flow link originates at any non-reservoir node, terminates at any other network node, and represents the flow in a channel reach. The flow along the link is a decision variable, selected to minimize total system penalty.

As with the diversion link, the analyst may specify inviolable minimum and/or maximum flow for a channel-flow link. The software will impose these constraints on the appropriate network arcs.

The analyst may specify also a multiplier for flow along a channel-flow link. The multiplier is a_k of Equation 2 for all arcs representing the link. If the multiplier is greater than 1.00, it represents increase of flow in the channel. If the multiplier is less than 1.00, it represents loss of flow.

Simple Reservoir-release Link

The reservoir-release link originates only at a non-hydropower reservoir node, terminates at any other node, and represents the total outflow from a reservoir. This includes release and spill. The flow along a reservoir-outflow link is a decision variable, selected to minimize total system penalty. In Figure C-1, the link from node 3 to node 4 is a simple reservoir-release link. It originates at a node representing a reservoir and terminates, in this case, at a node representing a demand point.

The analyst may specify inviolable minimum and/or maximum flow constraints. The analyst may specify also a multiplier for flow along a reservoir-release link. The software will apply the multiplier and impose the constraints on the appropriate network arcs.

Hydropower Reservoir-release Link

Link Description. A hydropower reservoir-release link (hydro-release link) originates only at a hydropower reservoir node, terminates at any other node, and represents the total outflow from the reservoir. This includes release and spill.

The flow along a hydro-release link is a decision variable, selected to minimize total system penalty. As hydroelectric energy is not a linear function of flow, however, determination of the release that minimizes total penalty requires consideration of storage.

Hydropower Computation From Link Flow. The nonlinear hydro-release problem will be solved via iterative solution of linear approximations. Such successive linear programming techniques are described by Martin (1982), Grygier and Stedinger (1985), and Reznicek and Simonovic (1990). In summary, these techniques convert the energy penalty functions to release penalty functions by assuming a value of reservoir storage. Given the storage, head can be estimated. Given this head, the unit penalty for release is used, and the flow allocation problem is solved. Then the head assumption is checked, using the storage computed for the optimal allocation. If the assumption is not acceptable, the heads corresponding to the computed storages are used, and the process is repeated.

The algorithm proposed by Grygier and Stedinger (1985) will be employed in the proposed model. This algorithm solves the hydro-release problem as follows:

1. Set ITER, an iteration counter, equal zero. Assign a value to ΔS_{\max} , the maximum allowable storage deviation.
2. For each hydro-release link for each period, estimate the beginning-of-period (BOP) and end-of-period (EOP) storage for penalty calculation. Note that this may be a reservoir other than that upstream of the link.
3. Determine the BOP and EOP head corresponding to the storage. Given the head, convert the energy penalty function to a flow penalty function. Assign the appropriate linear costs and bounds to the release arcs. Add constraints to the storage arcs so the storage does not vary by more than ΔS_{\max} .
4. Solve the resulting network flow programming problem.
5. For each hydro-release link for each period, determine the average storage with the optimal network solution. Compare the computed values with the values used in step 2. If all values are accurate within a user-specified tolerance, stop. Otherwise, go to step 6.
6. If the objective function value is worse than the value found in the previous iteration, go to step 7. Otherwise, accept this solution. Determine from the optimal solution the BOP and EOP storage for each hydro-release link for each period. Set $ITER = ITER + 1$ and decrease ΔS_{\max} . Repeat the computations, beginning with step 2.
7. Decrease ΔS_{\max} . Repeat the computations, beginning with step 3, without updating the storage estimates.

Other Release Penalties. Due to the special nature of the hydro-release link, all other release-related penalties must be defined as a function of flow downstream. This is accomplished by defining a "dummy" node downstream of the hydropower reservoir. The hydro-release link connects the reservoir and this dummy node, and the hydropower penalty function is associated with this link. A channel-flow link connects the dummy node with the next downstream node. All penalty functions normally defined in terms of reservoir release are defined in terms of channel flow instead.

Reservoir-storage Link

Link Description. A reservoir-storage link originates at any reservoir node in a layered, multiple-period network. It represents the volume of water stored in the reservoir at the end of the period. The reservoir-storage link terminates at the node representing the same reservoir in the period following. The flow along a reservoir-storage link is a decision variable, selected to minimize total system penalty.

For example, in Figure C-2, the arc from node 3 in period 1 to node 3 in period 2 is a reservoir-storage link. Flow along the arc leaving the period-1 layer represents reservoir storage at the end of period 1. Flow along the arc entering the period 2 layer represents reservoir storage at the beginning of period 2.

Evaporation Computation With Link Flow. To approximate reservoir evaporation, a fraction of flow entering the reservoir-storage link may be "lost". For the network model, the relationship of storage and evaporation is given by

$$S_t = S_{t-1} - EV_{t-1} \quad (4)$$

in which:

S_t = reservoir storage at beginning of period t ;
 S_{t-1} = reservoir storage at end of period $t-1$;
 EV_{t-1} = volume of reservoir evaporation. The evaporation volume is related to reservoir surface area with the following equation:

$$EV_{t-1} = (ED_{t-1}) (A_{t-1}) \quad (5)$$

in which:

ED_{t-1} = evaporation rate in period $t-1$; and
 A_{t-1} = reservoir surface area in period $t-1$.

The quantity ED_{t-1} is input to the model. It may be an historically observed evaporation rate, or it may be generated with a statistical model. The relationship of surface area and storage can be approximated with a linear function as

$$A_{t-1} = \beta S_{t-1} \quad (6)$$

in which: β = a linear coefficient. The value of β is found from analysis of specified reservoir characteristics. Substituting Equations 5 and 6 into Equation 4 and simplifying yields

$$S_t = (1 - ED_{t-1} \beta) (S_{t-1}) \quad (7)$$

The quantity $(1 - ED_{t-1} \beta)$ is an arc multiplier. The flow out of the reservoir-storage arc, S_t , is the flow into the arc, S_{t-1} , multiplied by $(1 - ED_{t-1} \beta)$. This multiplier is the arc multiplier a_t of Equation 2.

If the magnitude of $(1 - ED_{t-1} \beta)$ is approximately 1.00 for all periods of analysis, $S_t = S_{t-1}$. That is, reservoir storage at beginning of period t = reservoir storage at end of period $t-1$. In that case, the network-flow programming is no longer a generalized network problem. Instead, it is a pure network problem. Faster solvers may be used.

Nodes

Nodes are included in the model to permit joining the appropriate links. Two or more of the links described may join at a node. The nodes represent system reservoirs, demand points, channel junctions, or diversion points. These may be existing facilities or proposed facilities. Additional nodes may be included in the network for convenience of description.

In addition to the analyst-defined nodes, the software will incorporate in the network a source node and a sink node to satisfy the mathematical requirements for defining a network. All water entering the system flows from the source node. All water leaving the system flows to the sink node. These hypothetical nodes have unlimited capacity.

TYPICAL PENALTY FUNCTIONS

The goals of reservoir system operation are identified by the analyst via penalty functions. The functions define, as a function of flow, storage, or both, the economic, social, and environmental cost for deviating from ideal operation for each of the system operation purposes. These purposes include flood control, navigation, lake and stream recreation, water supply, environmental protection, and hydropower.

Flood-control Penalty Function

A flood-control penalty function defines the cost of deviating from ideal flood-damage-reduction operation. This function typically will relate penalty to channel-link flow or reservoir release link flow.

Figure C-9 is a typical flood-control penalty function. In this example, no penalty is incurred for flows less than 600 cfs, the channel capacity. Between 600 cfs and 1100 cfs, the penalty is slight, increasing to 100 units. The penalty is much greater for flows exceeding 1100 cfs. This represents significant damage incurred as the flow moves out of the 10-25 year floodplain and into surrounding property.

FIGURE C-9 Typical Flood-control Penalty Function

Navigation Penalty Function

A navigation penalty function defines the cost of deviating from flows desired for vessel traffic in a system channel.

Figure C-10 is a typical navigation penalty function. In this example, the penalty is great for flows less than 400 cfs; this represents the minimum desired flow for towing barges in the channel. Between 400 and 600 cfs, the penalty is zero, as this is the desired flow for navigation. Between 600 and 1100 cfs, the penalty increases slightly, representing the increased effort required for navigation. Finally, the penalty increases rapidly if the flow exceeds 1100 cfs. This is the upper limit on desired flow for navigation.

FIGURE C-10 Typical Navigation Penalty Function

Recreation Penalty Functions

A recreation penalty functions may represent the relationship of recreation to reservoir storage or channel flow. Figure C-11 is an example of a typical lake recreation function. In this example, the desired range of active storage for recreation is 40 to 80 kaf. If the reservoir storage is less than 40 kaf, the boat ramps are inaccessible, and recreation is hazardous. If the reservoir storage is more than 80 kaf, the reservoir is in flood operation, and recreation is hazardous. Consequently, the function is shaped as shown.

FIGURE C-11 Typical Lake Recreation Penalty Function

Figure C-12 is a typical river recreation penalty function. In this example, the desired range of flow for boating, swimming, and fishing is 400 to 500 cfs. If the flow rate is less than 400 cfs, boating and swimming are dangerous due to shallow depths and fishing is poor. If the flow rate exceeds 500 cfs, recreation is hazardous.

FIGURE C-12 Typical River Recreation Penalty Function

Water-supply Penalty Function

A water-supply penalty function describes desired operation for supply of water for municipal and industrial use or for irrigation. A water-supply penalty function may relate to channel-link flow, simple reservoir-release flow, or diversion flow. Figure C-13 is a typical water-supply penalty function. In this function, the desired flow for water supply is 100 cfs. If the flow is less, demands are not met, so the penalty is great. If the flow exceeds the desired rate, the water is used, but the benefit is not great, as it is not dependable supply.

FIGURE C-13 Typical Water-supply Penalty Function

Environmental Penalty Function

An environmental penalty function represents the desired operation for environmental protection. The function may define penalty for flow or penalty for storage or penalty or both. A typical case is illustrated by Figure C-14. In this example, an average monthly flow of 100 cfs is required to preserve wildlife habitat. If the flow is less or more, the habitat is destroyed. In that case, only the desired value is assigned zero penalty. For all other flows, the penalty is positive.

FIGURE C-14 Typical Environmental Penalty Function

Hydropower Penalty Function

A hydropower penalty function is assigned to a hydro-release link only and defines the cost of deviation from desired system operation for energy production. For the proposed model, Figure C-15 illustrates the acceptable form of the function. This function defines penalty as a function of release for a specified head (storage). If the head is less than the optimal head for the generator, the penalty is positive. Likewise, if the release is less than optimal for a specified head, the penalty is positive.

FIGURE C-15 Typical Hydropower Penalty Function

Combined Penalty Functions

If two or more penalty functions apply to a single stream reach or to a single reservoir, the functions are combined to yield a single penalty function. The combined penalty function then is used in the optimization. For example, a reservoir hydropower capacity penalty function, a reservoir recreation penalty function, and a water supply reservoir penalty function may apply for a reservoir. To combine the functions, the various penalties for a given storage are added. The resulting function is then edited or smoothed to yield a convex function. This convex function then is represented in a piecewise linear fashion for the network. Figure C-16 illustrates this.

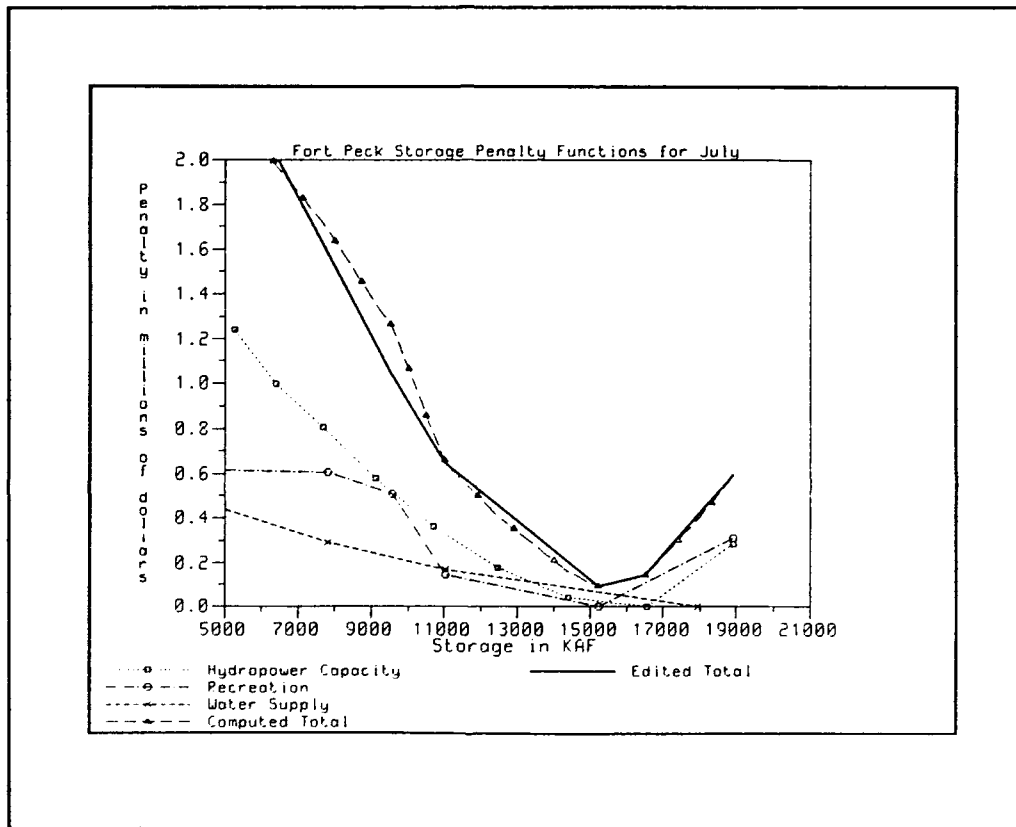

FIGURE C-16 Penalty Functions Combined

GLOSSARY

arc Connects two nodes of a network. In network-flow programming, each arc has three parameters: a lower bound, which is the minimal amount that can flow along the arc; an upper bound, which is the maximum amount that can flow along the arc; and a cost for each unit that flows along the arc.

channel-flow link Represents the flow in a channel reach. A channel-flow link originates at any non-reservoir node and terminates at any network node.

constraint Limit the decision variables to their feasible or permissible values.

convex function A function $f(X)$ for which the following is true for any two distinct points X_1 and X_2 and for $0 < \lambda < 1$: $f(\lambda X_1 + (1-\lambda)X_2) < \lambda f(X_1) + (1-\lambda)f(X_2)$

decision variable The unknowns which are to be determined from the solution of the model.

diversion link Carries flow out of the system. A diversion link originates at any system node and terminates at the sink node.

final-storage link Carries flow out of the system, but only from a reservoir in the last period of analysis. It originates at a reservoir node and terminates at the sink node.

hydropower reservoir-release link Represents the release from a hydropower reservoir. The penalty function for a hydropower reservoir-release link depends on both the release from the reservoir and the storage in the reservoir.

inflow link Brings flow into the reservoir-system network. An inflow link originates at the source node and terminates at any system node.

initial-storage link Introduces to the network the volume of water initially stored in a system reservoir. The initial-storage link originates at the source node and terminates at a reservoir node in the first period of analysis only.

network A collection of arcs and nodes.

network-flow programming An optimization procedure for allocating flow along the arcs of a network. Network-flow programming is a special class of linear programming.

node The junction of two or more network arcs. The node may represent a system reservoir, demand point, channel junction, diversion point. The sum of flow in arcs originating at a node equals the sum of flow in all arcs terminating at the node.

objective function Defines the overall effectiveness of a system as a mathematical function of its decision variables. The optimal solution to the model yields the best value of the objective function, while satisfying all constraints.

penalty function Defines the penalty for less-than-perfect operation as a function of flow, storage, or both.

piecewise linear approximation Is an approximation in which a non-linear function is represented by linear segments, arranged sequentially.

reservoir-storage link Represents the volume of water stored in a reservoir at the end of a period. The link originates at any reservoir in a layered, multiple-period network and terminates at the node representing the same reservoir in the period following.

simple reservoir-release link Represents the total outflow from a non-hydropower reservoir. Flow in the link includes release and spill.

sink node Is the hypothetical absorber of all flow in the network. All diversion links and final-storage links terminate at the sink node.

solver Finds the minimum-cost allocation of flow to the network arcs, subject to the upper and lower bounds on arc flows and to continuity at the network nodes.

source node Is the hypothetical provider of all flow in the network. All inflow links and initial-storage links originate at the source node. No user-defined links terminate at the source node.

APPENDIX D

MISSOURI RIVER NETWORK MODEL DESCRIPTION

MISSOURI RIVER SYSTEM DESCRIPTION

The Missouri River main-stem reservoir system consists of six reservoirs: Ft. Peck, Garrison, Oahe, Big Bend, Ft. Randall, and Gavins Point. These reservoirs and the area they service are shown in Figure D-1.

According to the reservoir regulation master manual (USACE, 1979), the main stem system is operated "...for flood control, navigation, irrigation, power, water supply, water quality control, recreation, and fish and wildlife." Current operation priorities in operating the reservoirs to meet these objectives are described as follows in the regulation manual (pg. IX-1, IX-2):

First, flood control will be provided for by observation of the requirement that an upper block of this intermediate storage space in each reservoir will be vacant at the beginning of each year's flood season...

Second, all irrigation, and other upstream water uses for beneficial consumptive purposes ... will be allowed for. This allowance also covers the effects of upstream tributary reservoir operations ...

Third, downstream M&I water supply and water quality requirements will be provided for.

Fourth, the remaining water supply available will be regulated in such a manner that the outflow from the reservoir system at Gavins Point provides for equitable service to navigation and power.

Fifth, ... the efficient generation of power to meet the area's needs ... will be provided for.

Sixth, insofar as possible without serious interference with the foregoing functions, the reservoirs will be operated for maximum benefit to recreation, fish and wildlife.

A review of these priorities was prompted by the following (USACE, 1990a):

- 1. It has been 10 years since the last update.*
- 2. The current (3 year) drought has pointed out that parts of the existing Master Water Control Manual may require change...*
- 3. Recreation on the reservoirs and the river downstream is becoming an increasingly important industry...*

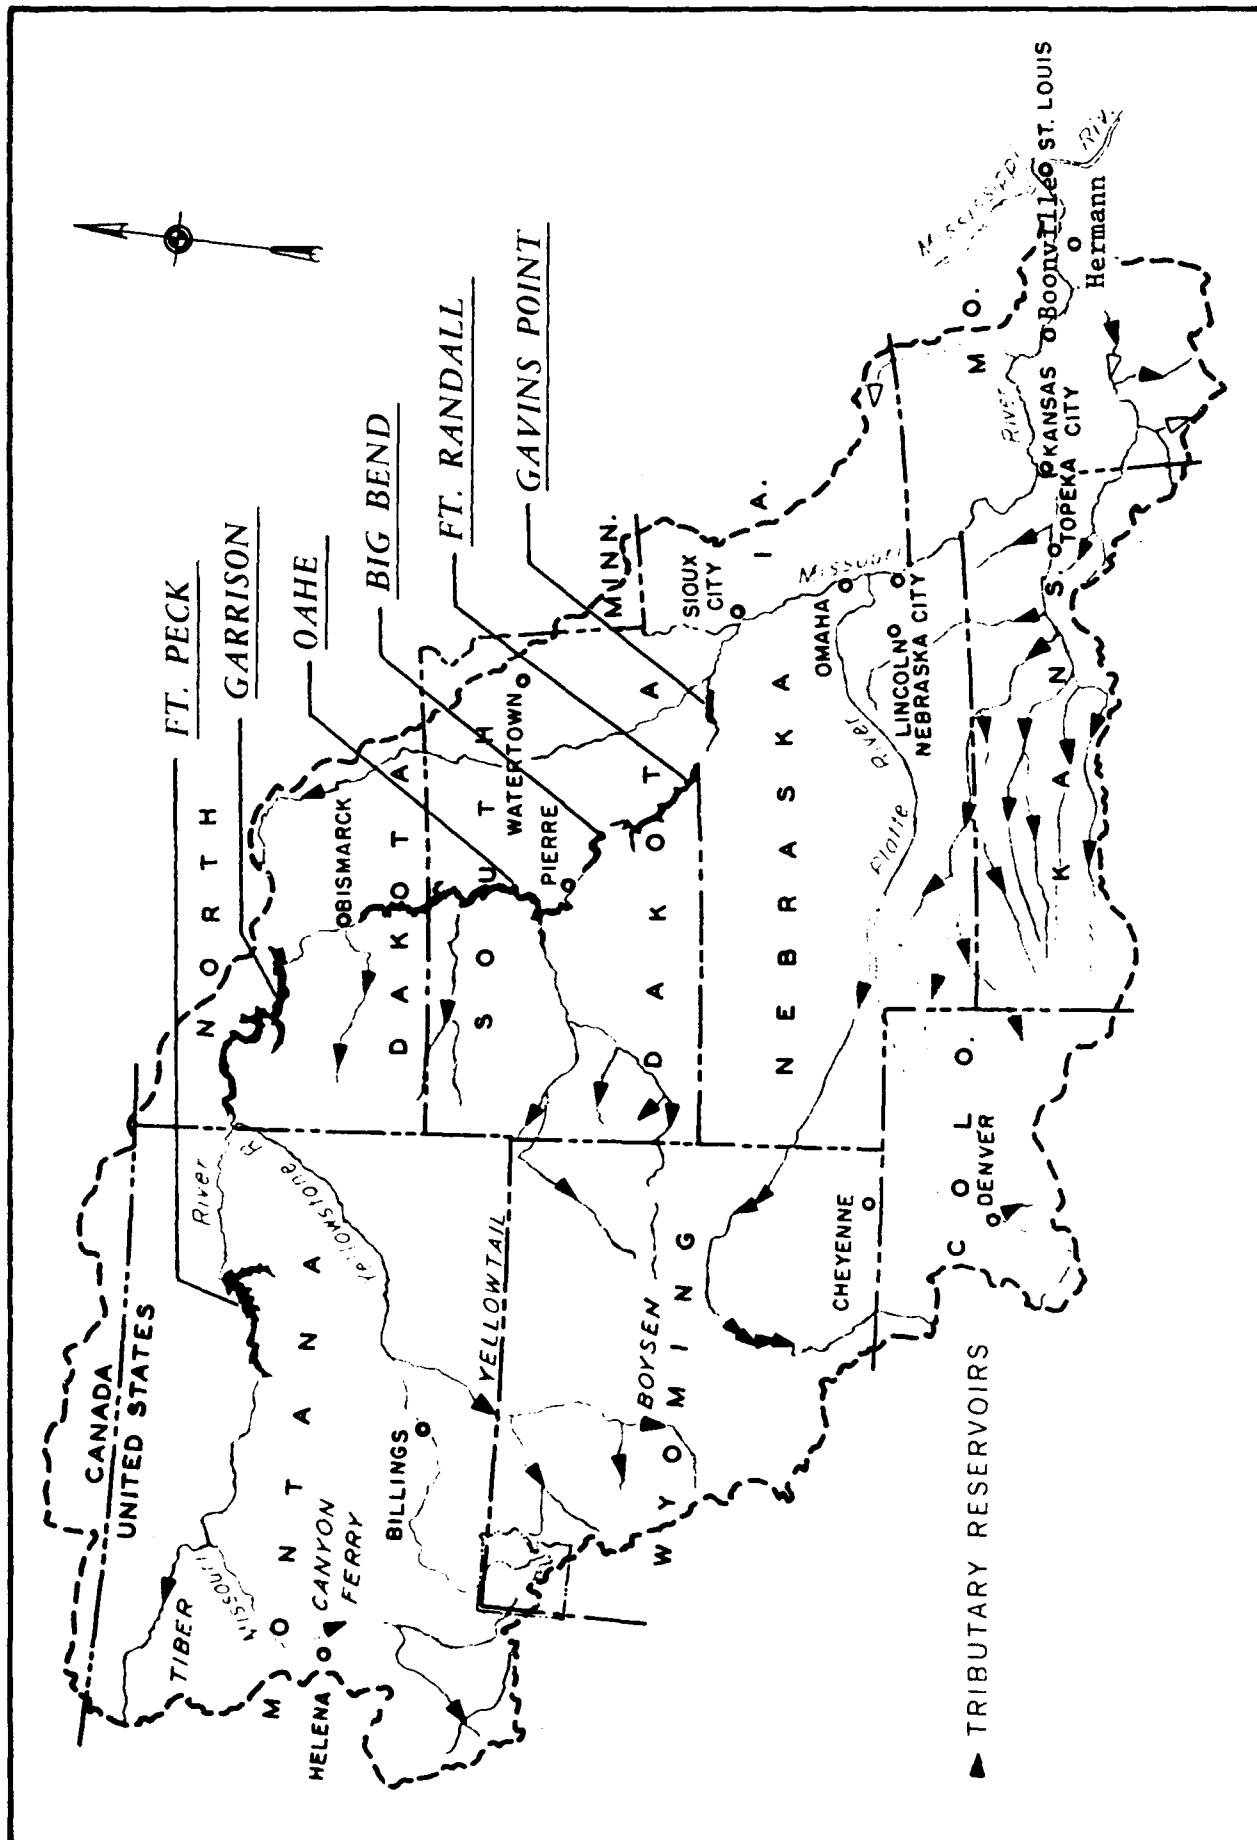

FIGURE D-1 Missouri River Reservoir System

4. *The current drought has demonstrated the importance of Missouri River water to commercial navigation...*

5. *The Master Water Control Manual needs to be updated to include regulation criteria for endangered and threatened species, new data collection methods, and flood history which has occurred since the last update.*

NETWORK REPRESENTATION

Summary

To provide quantitative information for the review, a prescriptive model of the system will be developed. The model will identify the water allocation that minimizes poor performance for all defined system purposes. Performance will be measured with analyst-provided penalty functions of flow or storage or both. The physical system will be represented as a network, and the allocation problem will be formulated as a minimum-cost network flow problem. The objective function of this network problem is the sum of convex, piecewise-linear approximations of the penalty functions.

Figure D-2 is a diagram of the network-model of the Missouri River system for the Phase I study. The system ends at Hermann, and thus does not consider Mississippi River supplies and demands. For analysis of multiple-period operation, this network is duplicated and layered, as described in *Requirements for a System Model of Missouri River Main Stem Reservoir System* (USACE, 1990b). In the proposed Phase I study, the network is duplicated 276 times to analyze monthly operation for the 23 year critical period resulting from the drought of the 1930's.

Network Nodes

The review of system priorities is divided into two phases. For Phase I of the study, the network representation includes six reservoir and six non-reservoir nodes. The reservoir nodes represent Ft. Peck, Garrison, Oahe, Big Bend, Ft. Randall, and Gavins Point. The non-reservoir nodes represent Sioux City, Omaha, Nebraska City, and Kansas City, Boonville, and Hermann. All network links either originate or terminate at one of these nodes.

Network Links

For Phase I of the study, the network representation includes the following links:

Inflow Links. An inflow link terminates each period at the Ft. Peck, Garrison, Oahe, Ft. Randall, and Gavins Point reservoir nodes. No inflow link is included for Big Bend reservoir. An inflow link terminates each period at all non-reservoir nodes. Thus, the network includes eleven inflow links per period. For the critical period analysis, the network includes $23 \times 12 \times 11 = 3036$ inflow links. Each of these links is represented by a single network arc. The upper bound and lower bound of the arc equal the monthly inflow.

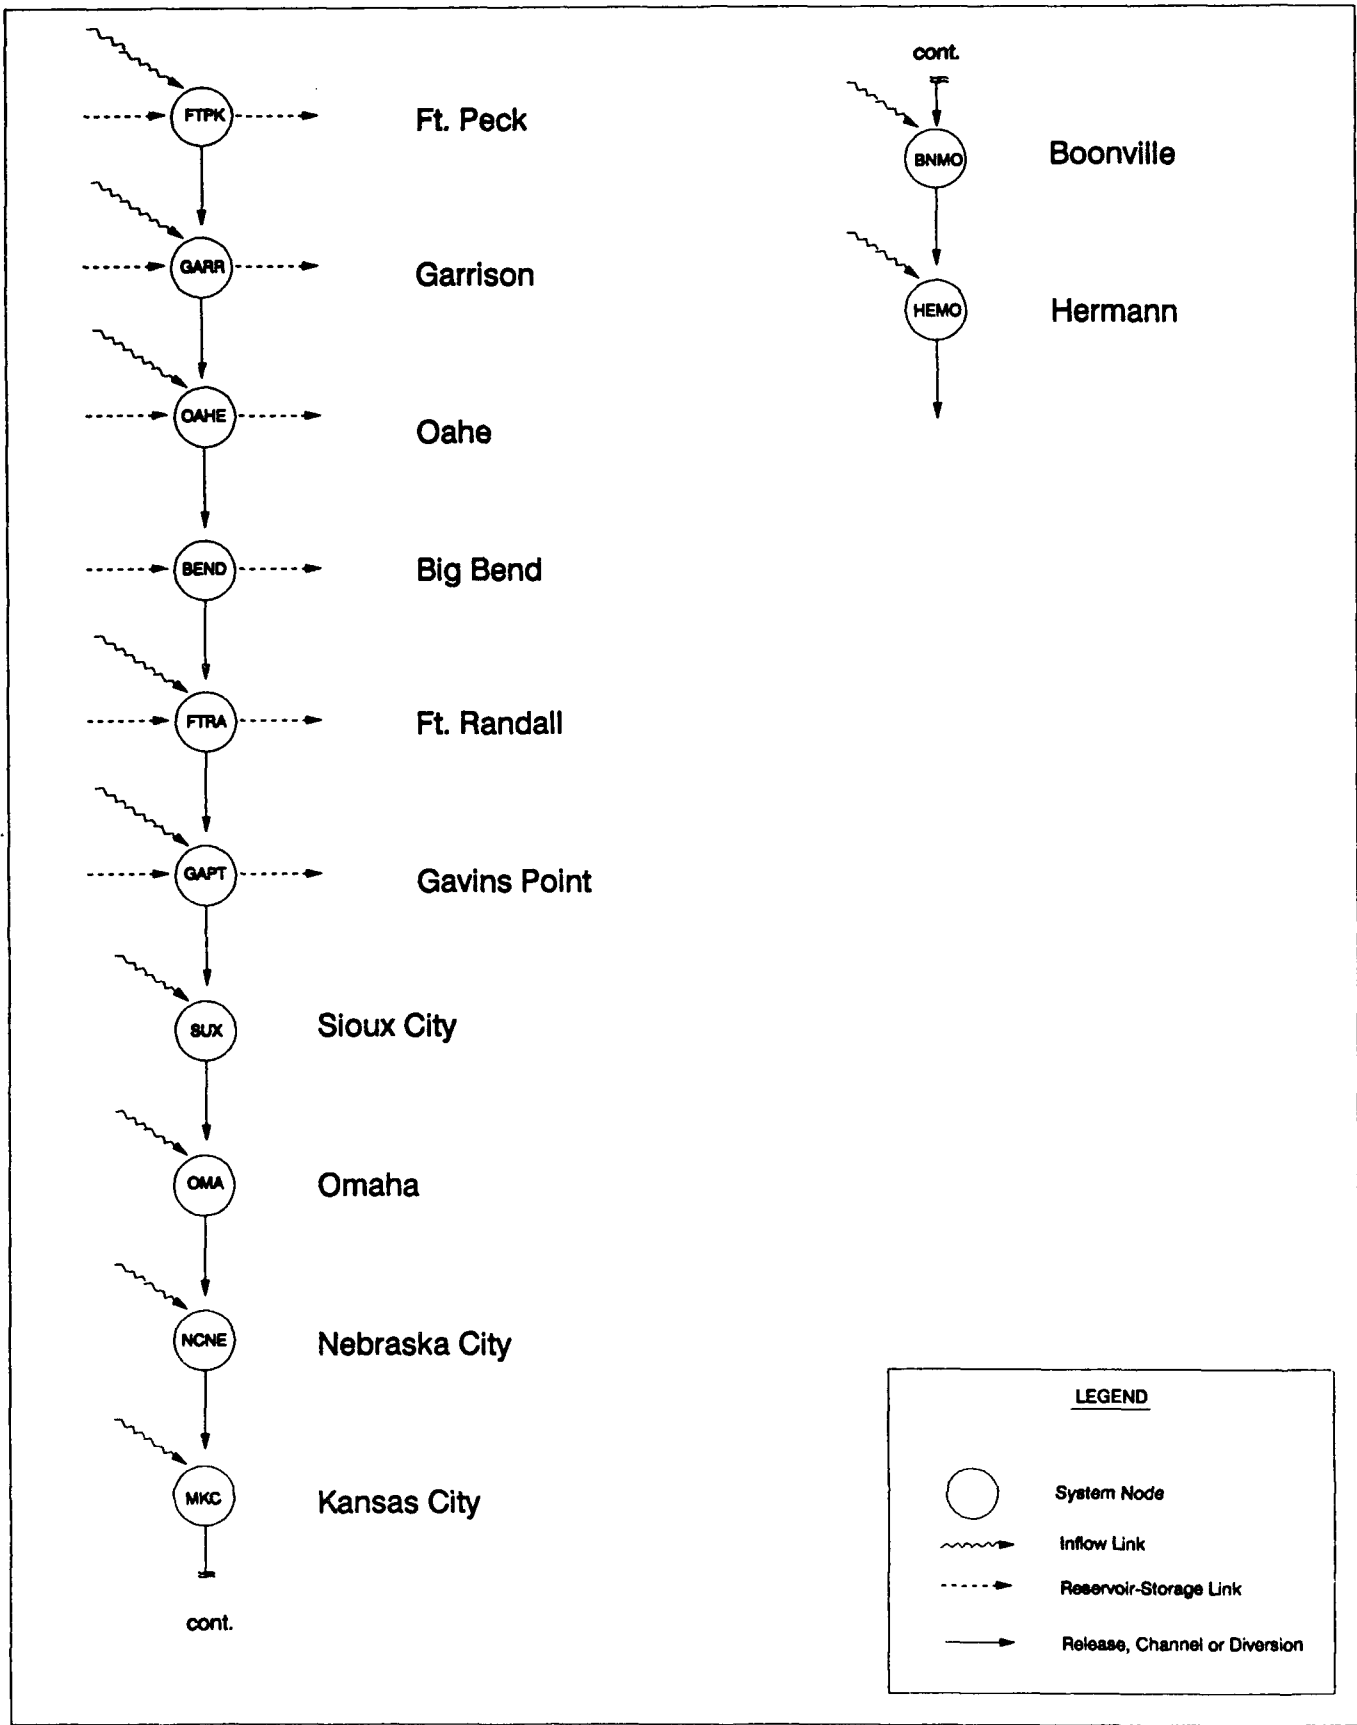

FIGURE D-2 Network Diagram of Missouri River Main Stem Reservoir System

Initial-storage Links. An initial-storage link terminates at each reservoir node in the first period of analysis. These links establish the initial storage for the analysis. For the Phase I analysis, the network includes six initial-storage links. Each of these links is represented by a single network arc. The upper bound and lower bound of the arc equal the desired initial storage.

Diversion Links. The network ends with a diversion link at Hermann City for each period. This link carries flow out of the network at its downstream end. The Phase I network includes $23 \times 12 = 276$ diversion links. Each link is represented by network arcs as necessary to model the penalty function for flow downstream of Kansas City.

Final-storage Links. A final storage link originates at each reservoir node in the final period of analysis. The network includes six final-storage links. As described in *Requirements for a System Model ...* (USACE, 1990b), a special penalty function should be specified for these links, and an upper and lower bound also may be specified. For the Phase I model, only the upper and lower bounds are implemented.

Channel-flow Links. Five channel-flow links connect the six non-reservoir nodes each period. For the 23-year critical period, the network includes $23 \times 12 \times 5 = 1380$ channel-flow links. Each of these links is represented by network arcs necessary to model the penalty function.

Simple Reservoir-release Links. For the Phase I model, a reservoir-release links connects each reservoir node with the next downstream node each period. For all reservoirs except Gavins Point, this next downstream point is another reservoir. The node downstream of Gavins Point represents Sioux City. The critical-period network includes $23 \times 12 \times 6 = 1656$ simple reservoir-release links.

For the Phase I analysis, all hydropower-release links are represented as simple reservoir-release links. This is accomplished by assuming a constant head at the reservoir. Energy penalty functions can then be expressed as release penalty functions. This assumption eliminates the need for iteration solution of the hydropower-release problem.

Reservoir-storage Links. Storage in each reservoir each period is represented with a reservoir-storage link. Each of these storage links has an amplification factor to represent lake evaporation as a linear function of storage. The network includes $(23 \times 12 - 1) \times 6 = 1650$ reservoir-storage links plus six links in place of the final storage links. Each link is represented in the network by arcs necessary to model the storage penalty functions.

SYSTEM DATA

Reservoir-inflow and Local-flow Data

Reservoir-inflow and local-flow data are provided by the Missouri River Division (MRD), USACE, in computer-readable form. Flows are provided for all reservoirs except Big Bend and for the six downstream nodes. The flow data are in units of 1000 acre-feet per month. These data are included as Exhibit D-1 of this Appendix. MRD developed the inflow data using historic stage and discharge records. Some of the data were recorded

daily and some were recorded continuously. Streamflow measurements at the present stations on the main-stem of the river were started in 1928.

Reservoir-inflow and Local-flow Depletions

According to MRD, the reservoir-inflow and local-flow data must be adjusted to account for depletions. Depletions include irrigation diversions, evaporation from major impoundments other than the six main-stem reservoirs, fish and wildlife use, land treatment, minor impoundments, rural domestic water supply, municipal and industrial water supply, and forestry use (USACE, 1979, pg. III-16). The MRD has provided a machine-readable record of historical depletions. The depletions are in units of 1000 acre-feet per month. A negative depletion indicates water was removed from the system whereas a positive depletion indicates water was added to the system. These data are included as Exhibit D-2 of this Appendix. Water use for all purposes has expanded significantly during the study period. The depletions are adjusted to represent a common level of water resource development in order that the flow data would be directly comparable from year to year. While any development level could have been selected, the 1975 level was used for the Phase I study.

Adjusted Inflow

HEC-PRM utilizes adjusted inflow (or "net" inflows) as input data rather than directly using reservoir inflow, local-flow, and depletions. The adjusted inflow is computed by adding the "reservoir-inflow" and "local-flow" to the corresponding "local-flow depletions". The adjusted inflows are in units of 1000 acre-feet per month. These data are included as Exhibit D-3 of this Appendix. On a network model, all links have a direction definition - flow can go in only one direction. For inflow links, flow starts at the super source and ends at a node. This corresponds to a positive "adjusted inflow". A negative "adjusted inflow" indicates flow would start at a node and end at the super source. However, this violates a network flow programming rule and cannot be done. To facilitate solution, HEC-PRM sets all negative "adjusted inflow" to zero.

Reservoir Evaporation Data

According to the master manual (USACE, 1979, pg. VIII-12), "[e]vaporation from the surface of the main stem reservoirs is a major water loss. Annual evaporation from the reservoirs is estimated to average about three million acre-feet..." This evaporation is accounted for in the network by arc multipliers for each storage arc each period. These multipliers are given by $(1 - ED_{t-1} \beta)$ in which ED_{t-1} = evaporation rate, in inches, in period $t-1$; and β = linear coefficient defining area as function of storage. The linear coefficients for the system reservoirs are shown on Table D-1:

TABLE D-1
Linear Coefficients for Reservoir Storage

<u>Reservoir</u> (1)	<u>Linear Area- Storage Coefficient</u> (Acre/Acre-inches) (2)	<u>Linear Area- Storage Coefficient</u> (Acre/Acre-feet) (3)
Ft. Peck	0.0011	0.0132
Garrison	0.0013	0.0156
Oahe	0.0012	0.0144
Big Bend	0.0024	0.0288
Ft. Randall	0.0013	0.0156
Gavins Point	0.0033	0.0396

These coefficients are the slope of a linear approximation to the area-storage relationship. Plots of the area-capacity relationships with the linear approximations are included as Exhibit D-4 of this Appendix. The linear approximation is fitted "by eye".

Annual evaporation depths are provided in machine-readable form for the six reservoirs. The resultant depths are tabulated in Exhibit D-5 of this Appendix. These annual values are distributed to monthly values using the distribution shown on Table D-2.

Hydraulic Capacities

For the network model, physical limitations on flow and storage must be defined explicitly. For the reservoirs of the Missouri River main stem system, release capacities are given on Table D-3.

TABLE D-3
Maximum Release Capacities of Main Stem Reservoirs

<u>Reservoir</u> (1)	<u>Max. Spillway Discharge, in cfs</u> (2)	<u>Max. Outlet Discharge,⁽¹⁾ in cfs</u> (3)	<u>Max. Power Discharge, in cfs</u> (4)
Ft. Peck	230,000	45,000	16,000
Garrison	660,000	98,000	38,000
Oahe	80,000	111,000	54,000
Big Bend	270,000	0	103,000
Ft. Randall	508,000	128,000	44,500
Gavins Point	345,000	0	36,000

(1) Non power releases

The maximum possible release from each reservoir each period for the network model is the sum of cols. 2, 3, and 4. *Requirements for a System Model ...* (USACE, 1990b) describes how these limitations would be imposed as inviolable constraints on network arcs. For the Phase I model, these limitations can be imposed through the penalty functions.

The reservoir storage capacities are on Table D-4. The reservoir elevation-storage relationships are graphically depicted in Exhibit D-2.

TABLE D-4
Reservoir Storage Information

<u>Reservoir</u> (1)	<u>Top Inactive Storage, in 1000 Acre-ft</u> (2)	<u>Top Carry-over, Multiple-use Storage, in 1000 Acre-ft</u> (3)	<u>Top Flood-Control & Multiple-use Storage, in 1000 Acre-ft</u> (4)	<u>Top Exclusive Flood-control Storage, in 1000 Acre-ft</u> (5)
Ft. Peck	4,211	14,996	17,714	18,688
Garrison	4,990	18,210	22,430	23,924
Oahe	5,451	19,054	22,240	23,337
Big Bend	1,696	-	1,813	1,873
Ft. Randall	1,568	3,267	4,589	5,574
Gavins Point	340	-	432	492

These storage values are gross storage defined in the master manual. MRD has divided the storage in individual reservoirs into operational zones in order to obtain the maximum possible service to all of the multipurpose functions consistent with the physical and authorizing limitations of the projects. The reservoir regulation master manual (USACE, 1979, pages V-1 and V-2) describes these operational zones as follows:

5-2. Operational Zones. The operational zones, and governing criteria for operation in these zones considered necessary to achieve the multipurpose benefits for which the reservoirs were authorized, are as follows:

a. Exclusive Flood Control Reserve. A top zone in each reservoir reserved exclusively for flood control. The storage space therein is utilized only for detention of extreme or unpredictable flood flows, and is evacuated as rapidly as feasible within limitations imposed by considerations of flood control. These considerations include project release limitations, status of storage in the other main stem projects and the level of system releases being maintained, as designated by criteria discussed in Sections IX and X.

b. Annual Flood Control and Multiple-Use Capacity. An upper "normal operating zone" is reserved annually for retention of normal flood flows and for annual multiple-purpose regulation of the impounded flood waters. The capacity in this zone, which is immediately below the top zone of exclusive flood control reserve, will normally be evacuated to a predetermined level by about 1 March to provide adequate storage capacity for the flood season. This level will remain more or less fixed from year to year. During the flood period, water will be impounded in this space as required by consideration of flood control and in the interests of general conservation functions on an annual basis. The evacuation of flood control and multiple-use storage capacity is scheduled to maximize service to the conservation functions. Schedules are limited by the flood control function in that the evacuation must be completed by the beginning of the next flood season, provided such evacuation is possible without contributing to serious downstream flooding.

c. Carry-Over Multiple-Use Capacity. An intermediate zone provides a storage reserve for irrigation, navigation, power production, and other beneficial conservation uses. At the major projects (Ft. Peck, Garrison and Oahe) the storage space in this zone will provide carry-over storage for maintaining downstream flows through a succession of well below normal runoff years. It will be used to provide annual regulation in the event the storage in the annual flood control and multiple-use zone is exhausted. Storage space assigned to this zone in the Ft. Randall project serves a different purpose. A portion of the Ft. Randall space will be evacuated each year immediately preceding the winter season to provide recapture space for upstream winter power releases. The recapture operation results in complete refill of the space during the winter months. Deliberate long-term drawdown into the Ft. Randall carry-over zone is not contemplated. While a minor amount of space in the big Bend and Gavins Point projects was initially provided in this zone, deliberate drawdown into these projects has been reassigned into the lower inactive storage zones.

d. Inactive Capacity. A bottom inactive zone provides minimum power head and sediment storage capacity. It also serves as a minimum pool for recreation, fish and wildlife, and an assured minimum level for pump diversion of water from the reservoir. Reservoir drawdown into this zone will not be scheduled except in an unusual emergency.

Storage limitations ideally will be imposed as inviolable constraints on network arcs that represent storage links. For the Phase I model, these limitations can be imposed through the penalty functions, upper, and lower bounds.

Initial Storage

Initial storage must be specified for each system reservoir. For the critical-period analysis, the starting storage for each reservoir is set to values provided by MRD. The initial storage values are provided on Table D-5.

TABLE D-5
Initial and Ending Storage Values

<u>Reservoir</u> (1)	<u>Initial Storage, in 1000 Acre-ft</u> (2)
Ft. Peck	14,626
Garrison	17,778
Oahe	18,804
Big Bend	1,697
Ft. Randall	3,473
Gavins Point	432

SYSTEM PENALTY FUNCTIONS

Goals of and constraints on Missouri river reservoir system operation are represented with system penalty functions. These functions represent the economic, social, and environmental costs associated with failure to meet operation goals. The costs are related to flow or storage or both at selected system locations. For the Phase I study, functions were developed by the Institute for Water Resources (IWR). These functions are presented in a separate document (USACE, 1990c).

APPENDIX E

PENALTY FUNCTIONS USED IN PHASE I ANALYSIS

INTRODUCTION

The following plots depict the edited penalty functions used in Phase I of the study. The penalties are in millions of dollars and the storage or flow in 1,000 acre-feet per month. These edited composite penalty functions were derived by combining the original individual penalty functions supplied by IWR and then manually editing the computed function. Appendix E contains the convex, composite functions used as input to HEC-PRM.

From the standpoint of network flow programming, the reservoir storage arcs contain flow volume per month. The beginning-of-period storage comes into a node through arcs connected to the same node in the previous time period and the end-of-period storage leaves the node through arcs connected to the same node in the next time period.

The graphs are plotted on 3 scales: (1) reservoir storage, penalty from 0 to \$25 million, storage from 0 to 25 million acre-feet per month; (2) reservoir release, penalty from 0 to \$10 million, release from 0 to 7 million acre-feet per month; (3) channel flow, penalty from 0 to \$20 million, flow from 0 to 20 million acre-feet per month.

For each reservoir, there are actually 2 reservoir release links: (1) a hydropower energy release link, and (2) all other functions release link. The hydropower energy function was separated to facilitate an iterative solution to the non-linear energy penalty function. The hydropower energy penalty is a function of both head and discharge. In Phase I, it was assumed that head was constant for all releases. The most conservative (lowest head) energy function was selected and is plotted on the reservoir release link penalty function in this appendix. They are plotted with the "all other" reservoir release penalty functions even though energy is treated as a separate link.
