13. ABSTRACT (Maximum 200 words) A design and VHDL implementation of a content-addressable memory (CAM) to exploit structural locality is the subject of this research. The concept of structural locality is that memory locations are referenced in the same order as they were previously referenced. Therefore, if memory locations that exhibit structural locality can be made available to the CPU through a fast data store, an increase in speed of the computer system can be realized. The CAM's purpose is to store memory references in the order they were used by the CPU and prefetch these locations to a smaller on-chip cache. The CAM uses a FIFO circular buffer algorithm to store the memory references. When the CPU references a location that is stored in the CAM, the CAM prefetches memory locations in a FIFO manner, thus allowing the on-chip cache to capture structural locality into its memory. Basic digital logic circuits were implemented in VHDL and were the building blocks for the cache model. From these, the controller, which controls the prefetching of structural locality, was then integrated onto the chip model containing a fully-associative CAM array.

Acknowledgments

This thesis document represents the hardest, most consistent work I have labored through during my AFIT tour. Designing a content-addressable memory chip for use in a modern computer was both exciting and challenging. Both of these factors made this a very rewarding experience.

Many deserve thanks for helping me through this trying time. I thank God foremost for listening to my prayers and encouraging me through his Word. These words were especially helpful to me: "The plans of the diligent lead surely to advantage, But everyone who is hasty comes surely to poverty" (Proverbs 21:5). When the workload seemed too great, He reminded me that diligence pays off. He provided me the strength to strive to completion.

To my thesis advisor, Major Bill Hobart, I thank for the undying support he gave me. His door was always open for me and he was willing to help whenever I needed it. I thank him for the freedom to approach the project in my own way and for the guidance that kept me on track. I sincerely thank my committee members for their help. Captain Mark Mehalic greatly assisted me with VHDL and the ZYCAD environment. He unloaded a burden from my shoulders at the inception of this project with the time he spent with me discussing VHDL. He made this seemingly monumental task look like a manageable project. Dr. Frank Brown helped me tremendously in the writing of this document. I asked him to be on my committee because of his background in computer hardware, but he quickly became an asset from the writing standpoint. I just regret not giving him drafts of this document sooner so he could have helped me even more.

Finally, I thank my family for their patience and understanding throughout this year and a half. I am so thankful for my wife, Theresa, and the support and love she offered me. She never lost sight of my goals; she worked hard for me so I could work hard

for our future. I thank my daughters, Laura and Christi, that though they were very young (5 and 4 years old, respectively, when I graduated), they understood that daddy had to work very hard. To my wonderful, loving family I dedicate this thesis. I love you.

Abstract

This research involved the design and VHDL implementation of a content-addressable memory to exploit structural locality. The concept of structural locality is that memory locations are referenced in the same order as they were previously referenced. Therefore, if memory locations that exhibit structural locality can be made available to the CPU through a fast data store, an increase in speed of the computer system can be realized.

A content-addressable memory (CAM) cache was used to supply data to an on-chip cache that acts as this fast data store. The CAM is described in this study and is a member of a two-cache memory hierarchy. Its purpose is to store memory references in the order they were used by the CPU and prefetch these locations to a smaller on-chip cache for fast processing. The CAM emulates an LRU stack by using a FIFO circular buffer algorithm to store the memory references. When the CPU references a location that is stored in the CAM, the CAM prefetches memory locations in a FIFO manner, thus allowing the on-chip cache to capture structural locality into its memory.

A fully-associative content-addressable memory was used in this study. This type of memory allows its contents to be searched in parallel. When a search is successful, the contents of the memory location are read and a top-of-stack pointer is incremented to read successive memory locations from the CAM array. A bottom-up design approach was used to build this cache. Basic digital logic circuits were implemented in VHDL and were the building blocks for the model. Using these basic components, the major components that make up the controller were made. The controller, which controls the prefetching of structural locality, was then integrated onto the chip model containing a fully-associative CAM array.

A CACHE DESIGN TO EXPLOIT STRUCTURAL LOCALITY

1. Introduction

Overview

A computer's main memory is very important in the support of the operating systems and the users. The technologies of the 1950s and 1960s made it very expensive to have an adequate amount of this main memory. Conversely, secondary storage is relatively inexpensive and has a much greater capacity than main memory. Unfortunately, secondary storage has a much slower access speed. As a result, the idea of a memory hierarchy was introduced. Initially, the hierarchy consisted of main memory and secondary storage. Main memory was used to store the instructions and data of an executing program, while secondary storage held programs and data that were not immediately needed. Since main memory was more expensive, it was generally smaller than secondary storage. (4:188)

Cache memory was introduced in the 1960s and formed additional levels of the memory hierarchy. Cache memory is very fast storage designed to increase the speed of running programs. The ideal memory system would be one that holds infinitely large files, has an infinitesimal access time, and is free! Unfortunately, this is not possible, but cache memory is the next best thing. Using the concept of locality (explained below), caches simulate a larger memory by storing data that are frequently used by the central processing unit (CPU). Although a zero effective access time is not technologically possible, caches are much faster than main memory and secondary memory. Also, since

caches are composed of faster, and thus more expensive memory, only relatively small caches are economical.

A side effect of memory hierarchies, to which caches add another level, is data shuttling. Shuttling occurs when data are transferred from one level of hierarchy to another. This decreases the efficiency of the CPU (4:188). If shuttling can be decreased and access time to memory can be significantly reduced, the CPU could be much more productive. Cache memories are used exclusively to reduce access time. This thesis will focus on caching between the CPU and main memory.

Although caches are small, the memory hit-ratio on these caches can be extremely high due to the concept of locality. The most widely recognized aspects of locality are *spatial* and *temporal*. Spatial locality implies that if a memory location is referenced, then it is likely that the memory locations nearby in the virtual memory address space will also be referenced. Temporal locality means that if a memory location is referenced, then it is likely to be referenced again in the near future. Exploiting locality results in an increase in efficiency of the CPU and faster turnaround of executing programs.

In addition to the well known spatial and temporal aspects of locality, Hobart has identified a third aspect, which he has called structural locality (9). This type of locality is defined as the tendency of an executing program to reference memory locations in the same order in which they were previously referenced. Thus, if memory references were placed on a stack in the order in which they were referenced, a reference to a particular memory location in the stack increases the probability of subsequent accesses to memory locations immediately above it in this stack.

A software model using VHDL (Very High Speed Integrated Circuit (VHSIC) Hardware Description Language) of a content-addressable memory (CAM) with an integrated structural locality cache (SLC) controller will allow further investigation into

structural locality with much greater flexibility than with a hardware prototype. The VHDL model can be changed to test a desired behavior, whereas an actual realization in hardware is much more difficult to alter. Although CAMs have previously been designed, this researcher has not found one that has been modeled using VHDL.

Problem Statement

The problem addressed in this thesis is the design of a prefetching memory system to exploit the aspects and benefits of structural locality. The goal of this thesis effort was to design a main system cache that supports structural locality prefetching to a smaller on-chip cache.

Scope/Limitations

This thesis includes developing a behavioral and structural description of an SLC controller integrated into a CAM cache. Therefore, the structure of a CAM cache with an integrated SLC controller was modeled using VHDL. The gate level was the lowest level modeled.

The implementation and fabrication of the cache were beyond the scope of this thesis. However, this thesis should enable fabrication of an actual CAM chip with an integrated SLC controller by a follow-on thesis.

Approach

The product of this thesis was a design of an SLC controller integrated with a fully-associative cache. The controller controls the prefetching of the cache contents immediately above the currently referenced CAM location and the writing of data into the CAM array.

A bottom-up approach for modeling the CAM cache was used. With the CAM as described by DeCegama (3:82-88), a gate-level structural description of a CAM cell was

modeled. The cell was tested to determine if its features were acceptable. After verifying that the cell performed as expected, copies of the cell were integrated to form the CAM array. The CAM array was then tested to verify its expected behavior.

After the VHDL model of the CAM array was complete, design of the SLC controller began. Again, a bottom-up approach was used. First, the functions of the controller were defined. Next, the structure of the controller was determined in the form of a schematic diagram. Finally, the structures of this controller were integrated with the CAM array.

To test and verify the CAM and controller as described by VHDL, the external hardware, with which the cache will interface, was modeled. The external hardware includes the CPU main memory. The CPU was modeled using actual virtual memory address traces. For a virtual memory reference resulting in a main cache miss, an appropriate delay simulated the fetching of the cache line from main memory. After testing all pieces of hardware individually, they were connected to form a closed system. This system was then used to test and verify the expected behavior of the CAM chip model.

Thesis Contents

Chapter 2 contains an overview of computer memory systems. Associative memories, in particular, are discussed. The various types of content addressable memories are presented. They include bit-slice, byte-slice, word-slice, and fully-associative memories. Several implementations of these types are shown and the advantages and disadvantages of CAMs are discussed. Most of the CAM cells in the literature are described at the transistor level; therefore, many transistor level designs are presented.

Chapter 3 describes the VHDL implementation of the main CAM cache (MCC) for the proposed memory subsystem. The design of the cache is described in detail. The methodology used to design the MCC is discussed as well as the building of the MCC

model in a hierarchical manner in VHDL. Since the cache was designed from the bottom up, the functionality of each component making up the cache is explained.

Chapter 4 discusses the testing and performance characteristics of the main CAM cache. It describes the overall behavior of the MCC as well as an analysis of the timing constraints during each activity the MCC performs. Suggestions on possible improvements to the MCC are proposed and areas where potential space savings can be made during fabrication are discussed. Other issues to consider during the hardware implementation of the chip are reviewed.

Finally, Chapter 5 summarizes this thesis effort with conclusions and recommendations for further study.

II. Background

Introduction

A major goal for computer architects is to increase the speed of executing programs. "One such technique is the use of memory hierarchies - in particular the cache store concept. This approach to computer memory speedup has been well proven in the large processor situations" and "is also applicable to smaller machines where the economic constraints are more severe" (1:75). As computer technology has grown in complexity, so have computer applications. As these applications become more complex, the need for speed becomes increasingly important. To increase speed and "in order to minimize bus traffic, cache memory is often placed between the processor and the shared bus" (17:218).

Since caches are expensive and small, many studies have tried to determine an optimal size for a cache to get the highest hit ratio possible. "These studies suggest that the single most important factor for improving the cache hit ratio is the size of the cache memory" (17:219). Quinones suggests that a variable-size cache can allow many cost/performance goals to be reached (17:219). Ackland (1:76) points out that the optimal cache size depends on the processor architecture and the software environment that is being used. Ackland also found through simulation results that "effective speed up can be gained from buffers ranging in size from 256 words to 1024 words" (1:76).

Content-addressable memories are used as caches and have been investigated since 1956 (15:453). A CAM's purpose is to locate data by its contents rather than by its address, thereby increasing the speed at which memory is accessed. Memory access to data is accomplished differently in CAMs than with conventional random access memories (RAMs). Data access in RAMs is done by decoding the address and then fetching the

data. In contrast, data in CAMs are located by their content. Minker (15:453) states that "the retrieval of any one item in such a store would be accomplished by performing a content search on all registers in parallel with but a single operation." Not only is a search performed based on contents, but magnitude relationships such as less than, between limits, next higher/lower, similarity, proximity, not equal, or minimum/maximum value can also be accomplished (2:52). Addressing by content eliminates the need for such operations as scanning, sequential searching, and counting.

CAMs help to overcome what is known as the "von Neumann bottleneck." This bottleneck is caused by the communications between the CPU and the memory. "To reduce the traffic on this data path, and thereby increase system performance, one may add limited processing capabilities to the memory side of the bottleneck" (8:537). Content-addressable memories contain these limited processing capabilities, thereby reducing the von Neumann bottleneck effect. "Associative processors go a step further, eliminating the bottleneck entirely by performing both data storage and processing functions in a single unit." (8:537)

Target Architecture

Hobart (9) proposed the SLC memory subsystem shown in Figure 1. Two CAMs are used in this three-level memory hierarchy. The first CAM, the main CAM, interfaces between main memory and the on-chip cache. The second CAM is the on-chip cache that interfaces between the main CAM and the CPU. This author has not found this type of architecture implemented with CAMs.

The purpose of the two-CAM system is to take advantage of structural locality (explained in Chapter 1). The main CAM emulates the top portion of a least recently used (LRU) stack thereby mapping the temporal locality of the virtual memory references

Figure 1. Proposed Memory Subsystem Design (9:98)

into spatial locality within the main CAM. Structural locality is then exploited by spatially prefetching from the main CAM into the on-chip cache. (9:97)

Hobart chose the main CAM to be fully associative because “if the simulated LRU stack can be realized in a cache with full associativity, then any position in the stack

can be referenced in constant time, and the references immediately above the stack position accessed can be prefetched into a smaller faster on-chip cache..." (9:96). The on-chip cache, or the SLC, requires that the main cache be fully associative to locate any memory location on the stack. This enables prefetching to the SLC based on structural locality. The main CAM cache is written to with a circular buffer replacement algorithm. Therefore, when this cache prefetches to the SLC, the data references received by the SLC will be in the order in which the main CAM cache received them. (9:97).

The Importance of Content-Addressable Memory

The importance of storing and retrieving data in parallel has been known for about 30 years (2:51). CAMs have been implemented in silicon as far back as 1966, but it hasn't been until recently, with advancements in VLSI technology, that any useful amount of CAM has been feasible (20:1003). Content-addressable memory, or associative memory, allows for this parallel access of data. CAMs can perform *read*, *write*, and *search* operations in parallel, thus substantially increasing the speed of data access.

A search operation is performed when a search pattern is sent to each cell of the CAM array. Each cell performs a comparison with this data and a match or mismatch is then signaled on the tag lines. In order to detect a match or mismatch on selected cells, it is necessary to temporarily "disconnect" cells from the tag line. This is known as "masking" off particular cells to search only selected cells. Those cells that are masked off do not affect the outcome of a search. (10:166)

A write operation writes data to cells of the CAM array. A unique feature of a CAM is that it is possible to write to all CAM words simultaneously. It is also possible to select any bit-column to perform a write operation. In doing so, only the selected cells are written to while the rest are masked off and unaltered. (10:166)

A read operation retrieves the contents of cells in a CAM array. Again, a certain bit-column can be masked so a read will not be performed in the cells of that column but only in the selected cells. (10:166)

The unique approach of memory access in CAMs can be used to increase efficiency in many application areas. Some examples are databases, pattern recognition, data correlation, speech recognition, spelling checking, language translation, neural networks, and data retrieval.

Disadvantages and Advantages of CAMs

Disadvantages. Hanlon (6:519) points out that there are surprisingly few disadvantages found in the literature on content-addressable and associative memory systems. Chisvin (2:54) states that there are a number of obstacles to overcome before commercially successful associative memories are available. These obstacles are:

- functional and design complexity of the associative subsystem,
- relatively high cost for reasonable storage capacity,
- poor storage density compared to conventional memory,
- slow access time due to available methods of implementation, and
- a lack of software to properly use the associative power of the new memory systems.

Advantages. Although these disadvantages exist, advantages to CAMs abound. When searching a content-addressable memory for data, the time to access the data is independent of the size of the CAM; all searching is done in parallel. Sorting is unnecessary because the data can easily be found by its content. Using conventional memory, the time to perform a search and sort grows at a rate of $O(n \log n)$, where n is the number of items on the list. If only the maximum value is needed, the time to find it would increase

at least as fast as the size of the list. With content-addressable memories, the time to find the maximum value would be the same despite the length of the list. (2:54)

Another advantage is the "minimization or total elimination of many of the burdensome bookkeeping operations connected with the use of conventionally organized memories". CAMs would make this bookkeeping a much easier task on programmers. It could even reduce the operating time of functions that use slower I/O devices. (6:510)

A paper written by P. M. Davies and described by Hanlon (6:518) states that processing time for many operations can be reduced "because

- a) it is not necessary to store data in sorted order;
- b) lookups can be made on the basis of different keys at different times over the same data;
- c) records need to be stored only once;
- d) addresses are not needed to store records."

Organization of list structures is accomplished very quickly with a CAM system. On the other hand, RAMs use more execution time in forming the lists, searching the list, retrieving data from a large list, deleting a list, and transferring a list to another storage medium. These functions, which require more RAM access time, are performed by CAMs in constant time. (6:518)

The repetitive structure of a CAM array makes for ease of fabrication and testing. This is also true for RAM. The CAM cell can be laid out in an organized fashion; therefore, the interconnections are short and easily implemented in integrated circuit technology. (6:518)

CAMs can also be viewed as fault tolerant. If a cell fails, that cell can be masked off, never to be used again. Of course, fault tolerance is dependent on the application of the CAM. If the system can be fault tolerant, the maintenance task is decreased. (6:518)

The Organization of CAMs

CAMs have the basic organization depicted in Figure 2. Minor variations do exist but the general concept of the interfaces remains the same. The biggest difference lies merely in terminology. The layout of a CAM array is shown in Figure 3 and relates directly to Figure 2. The definitions below contain various terms (in parentheses) used to describe each component (the list of terms is not complete).

Figure 2. Organization of CAMs (3:85)

Data In (Argument Register, Data Input Register). These registers contain the data to be read or searched for as well as the data that will be written into the array. Figure 3 displays this as the Data Input Register. (3:84)

Bit Select Logic (Mask, Mask Register). This register is used to specify the bits of a word to be written to and searched for. A '1' in the bit select stream means that the

Figure 3. Associative Memory Array (3:83)

bit will be written to during a *write* operation. For a *search* operation, a '1' in the bit select stream means that a match is needed for that bit, while a '0' indicates a match is not needed (i.e., the bit is masked off). (3:84)

Word Select Logic (Decoder, Address Decoder). This register indicates which words are to be used in a *read* or *write* operation. (3:84)

Associative Memory Array (Memory Cells, CAM Array, Memory Array). This is the memory portion of the organization that contains CAM cells laid out in a 2-dimensional array, as shown in Figure 3.

Tag Register (Response Store). This register indicates that a selected word has matched the portions of the data input specified by the bit select register. (3:84)

Data Out (Output, Data Output, Data Output Registers). This register stores the data of the selected word from a *read* operation. The Data Output Register of Figure 3 contains the data that is output from the array as well as a "valid" field. The R_j field is the data while the P_j contains the valid bits. These are discussed in more detail in Chapter 3. (3:86)

Tag Reply. This contains a reply to the control unit that one or more set tags are in the tag register. (3:85)

CAM Data Word Arrangement

A common CAM data word arrangement is shown in Figure 4. The *Tags* field shows the type of data stored at that location (i.e., data or code) and whether the location is empty or used. The *Label* field is used in the comparison operation. Finally, the *Data* field is the storage area for the information to be retrieved or modified. Sometimes the *Label* and *Data* fields are treated as one if the *Label* field is part of the *Data*. (2:52)

Figure 4. CAM Data Word Arrangement (2:53)

The data word arrangement is flexible. The data word could be segmented in any way with any of the segments used for interrogation. Or it may not be segmented at all, in which case any choice of bits can be selected for an interrogation (this is the most general form of a CAM). (6:509)

Rowe (18:15) points out that various data-word sizes have been used by different people and organizations for diverse reasons. They range from 30 to 140 bits in length.

A 30-bit wide data-word does seem a bit strange but one reason cited for it was that it matched the CPU's word length.

Types of Architectures

Four different types of architectures exist for associative memories: bit-serial, byte-serial, word-serial, and distributed logic. The tradeoffs among these types of memories consist of the storage media, the communications between the cells, the type of retrieval logic, and the nature and size of external logic (such as registers and I/O ports). (2:58)

Bit-serial associative memories search the data a bit at a time, in parallel, in each word of the associative array. The search time, therefore, depends on the word width and is independent of the number of words, or word depth, of the array. After one bit-slice is searched, the next bit position in each word is inspected, and so on, until the entire field is searched. Likewise, byte-serial and word-serial associative memories search the data a byte and word at a time, respectively, in parallel for the depth of the memory.

Distributed-logic memories avoid the serial aspects of the bit-, byte-, and word-serial memories by placing the search, read, and write logic into each cell. This allows all memory cells to be accessed simultaneously in parallel. Since the logic is in each cell of the memory, the cell cycle time is longer in the distributed logic array than in the bit-serial architectures. (2:59)

Design considerations must be taken into account when deciding upon which architecture to choose. The bit-and byte-serial architectures work best on data and arithmetic computations. Distributed logic arrays work best on equality comparisons and multiprocessor control. Cost is another factor. The amount of logic in the distributed memory cell causes this type of memory to be physically larger and more expensive than

the bit- or byte-serial memories. The lack of cell logic in the bit- or byte-serial architectures allows these memories to be denser than the distributed logic arrays. (2:59)

Current CAM Cell Designs

Several CAM cell designs are available in the literature. The hardware implementation of these designs uses one of the following three options:

- 1) Static. Data are stored using two cross-coupled inverters acting as a flip-flop. The data remains in the cell as long as power is supplied. When power is taken away, the contents of the cell are lost.
- 2) Self-refreshing or pseudo-static. Data are stored by making use of the capacitance on the transistor gates. Over time, the charge will decay, but by asserting a control signal the charge can be restored. The consequence of this operation is increased power consumption.
- 3) Dynamic. Data are stored in much the same way as in RAM memory and requires external control logic to sense and refresh the data signals. The logic needed and the requirement to regularly refresh these cells results in a time penalty that may significantly slow down its operations. (10:167)

Gate Level CAM Designs. DeCegama (3:87) proposed the gate level design shown in Figure 5. A CAM chip can be modeled by collecting these cells into a 2-dimensional array, as shown in Figure 3.

Another CAM cell design is given by Hayes (7:452), and is shown in Figure 6. This design uses a D-type flip-flop for storing the data. Its match circuitry is composed of an exclusive-NOR gate. Other circuitry is present for the reading and writing functions.

Figure 5. Gate Level Design of CAM by DeCegama (3:87)

Figure 6. Gate Level Design of CAM by Hayes (7:452)

Transistor Level CAM Designs. The CAM cells described above were designed at the gate level. Several more cells can be found in the literature that are designed at the transistor level. One such design is the AFIT CAM designed by Shinn (19:13), shown in Figure 7. This is a general purpose CAM that can search the cell contents on the basis of equality, between limits, greater than, less than, etc.

Figure 7. Gate Level Design of CAM by Shinn (19:50)

Another transistor level design is shown in Figure 8. This CAM cell was developed for large-bit-capacity CAM LSI to realize a partial-WRITE operation. "The associative-memory cell circuit is composed of seven/nine n-MOS transistors and two high-resistive poly-Si load devices." (16:1014)

Figure 9 shows a five-transistor dynamic CAM cell. This cell can store three states: ZERO, ONE, and the DON'T CARE state. "A cell in the DON'T CARE state is unable to discharge the match line." (20:1006)

A slightly different design than the one in Figure 9 is shown in Figure 10. This content-addressable parallel processor (CAPP) uses only 5 transistors. It has three states, with the DON'T CARE state "being useful in logical inferencing and pattern-matching applications." (8:537)

Figure 10. Transistor Level Design of CAM by Herrmann (8:538)

A 12-transistor CAM cell is shown in Figure 11. This is an addressable CAM that functions as a normal CAM even though its data store is RAM-based. It is made up of three sections: 1) a six-transistor static RAM, 2) four-transistor XOR, and 3) a two transistor parallel write pull-up disable gate (DISABLE). "It was designed primarily for address translation in a high-speed packet switching network." (13:257, 258)

Weste (21:351) briefly describes a transistor-level CAM cell designed by J. C. L. Hou. This cell nine-transistor cell is shown in Figure 12.

Figure 11. Transistor Level Design of CAM by McAuley (13:258)

Figure 12. Transistor Level Design by Weste (21:351)

Finally, Jones (10) presents four different transistor-level CAM designs. Jones discusses the design constraints, trade-offs, and implementation issues involved in deciding which design to choose for a VLSI CMOS high-speed CAM architecture. The designs are shown in Figures 13 through 16. (10)

Figure 13. CAM A Transistor Level Design by Jones (10:167)

Figure 14. CAM B Transistor Level Design by Jones (10:168)

Figure 15. CAM C Transistor Level Design by Jones (10:169)

Figure 16. CAM D Transistor Level Design by Jones (10:169)

Figure 13 shows the simplest design considered by Jones. The cell is “pseudo-static in that when the *RW* line is driven high, the cell acts as a static nMOS flip-flop” (10:168). This cell needs to be refreshed frequently so data will not be lost. (10)

Figure 14 is very similar to Figure 13 but the data are stored in two cross-coupled CMOS inverters. This design does not require refreshing. (10)

Figure 15 is an enhancement of Figure 14. This design “avoids the need to rely on the positive feedback between the cross-coupled inverters to maintain the data contents of the CAM cell...” (10:168). This design reduces power consumption on the ‘write X’ operation. (10)

Figure 16 is different from Figures 13 - 15 in that it has ‘capacitive’ loading on the data lines. “The design relies on the positive feedback between the two cross-coupled inverters to complete the write operation” (10:168). In contrast to Figure 15, both drive transistors are switched off during a ‘write X’ operation, which reduces power consumption. (10)

Jones chose CAM A based on power consumption and chip area. Jones found “the ‘search’ and ‘read’ operations, being based on a precharge/discharge mechanism, consume relatively little power. It is during the ‘write’ operations that the designs exhibit different, and often quite large, power consumption figures” (10:169,170). Table 1 shows that CAMs B to D (the CMOS designs) have a much higher power consumption during the ‘write 0 and ‘write 1’ operations than CAM A. Conversely, CAMs C and D consume very little power during a ‘write X’ operation compared to CAM A, with CAM B consuming the most.

An interesting result occurs when these CAMs are introduced into their working environment. Table 2 reveals that CAM A has the highest power consumption. “This is caused by the predominance of ‘write X’ operations, and the need to refresh the memory

Table 1

CAMs A through D Power Consumption in Isolation (10:169)

	CAM area (μm^2)	Write 0/1 (μW)	Write X (μW)
CAM A	1944	51.0	99.8
CAM B	2980	149.0	120.6
CAM C	4160	165.4	<1
CAM D	5240	173.8	<1

Table 2

CAMs A through D Average Power Consumption in Working Environment (10:170)

Name	Power (μW)
CAM A	64.7
CAM B	53.6
CAM C	10.6
CAM D	11.2

at regular intervals" (10:170). Relative to CAM A, CAMs C and D consume little power since the 'write 0' and 'write 1' operations are performed infrequently. Figure 17 shows the chip power dissipation of each CAM design. (10:170, 171)

The other consideration in the selection of CAM A was the chip area used by each design. Figure 18 shows the chip area needed for each CAM. Notice that the more sophisticated CAMs (C and D) require the largest die size. The smallest area required by the four CAM designs came from CAM A, which was a major factor in its selection. (10:171)

Summary

The goal of content-addressable memories is to access data in parallel based on content rather than by address. The memory subsystem of Figure 1 will use CAMs to increase the speed of memory accesses over that of conventional hierarchies. A brief

Figure 17. CAMs A through D Power Dissipation (10:171)

Figure 18. Chip Area Needed for CAMs A through D (10:171)

overview of the organization of CAM chips was presented. Several different CAM implementations were shown, none of which has been previously used in a two-level cache memory architecture.

III. The Design of the Main CAM Cache that Exploits Structural Locality

Overview

This chapter covers the design of the main CAM cache (MCC). The MCC performs two basic functions: *read* and *write*. Upon activating the MCC to perform these functions, a search operation is performed on the address that is made available to the MCC. After the search is complete, one of four distinct states exists: *Read Hit*, *Read Miss*, *Write Hit*, and *Write Miss*.

The Read Hit state is the most important state the MCC can be in. It is in this state that the prefetching of structural locality of memory references is performed. The state is entered when the CPU requests that the MCC perform a read on the requested address. If the address is stored on the MCC, a read hit (i.e., the search operation found the address) occurs. This triggers the prefetching of data in a first-in-first-out (FIFO) manner.

The Read Miss state is also entered during a read cycle. First, a search is performed on the CAM array. If the search is unsuccessful, the Read Miss state is entered. Since the address was not found (i.e., "missed"), the FIFO replacement algorithm is used to write the data into the cache. These data come from main memory over the data bus. Thus, temporal locality is captured by the MCC.

The Write Hit state is entered during a write cycle. Again, the first operation performed by the MCC is the search operation. If the address used in the search was found, then that location in memory will be replaced by the new data.

The Write Miss was the easiest state to deal with. If the search operation produced no matches, the MCC does nothing but wait until the next operation is requested of it.

The remainder of this chapter describes the VHDL implementation of the MCC. Since a bottom-up approach was used to design the cache, it is appropriate to describe the MCC in a bottom-up fashion. First, the method used to design the MCC is briefly described. Then, a brief look at the basic components that make up the MCC are discussed. Next, the heart of the cache, the CAM cell, and the inner workings of the CAM array are described in detail. The brains of the MCC, the controller, is then explained. Finally, the MCC is viewed as a whole and its functionality is presented.

Design Methodology

The first step taken in this thesis effort was to choose a logic design of a CAM cell. The CAM cell designed by DeCegama (3:87) was used. After implementing the CAM cell in VHDL, the CAM array was built using the VHDL *generate* function.

Once the CAM array was tested thoroughly, the controller was designed. The four states described above were used to logically decide upon the components, gates, and signals that must be used in order for the MCC to function properly. A schematic diagram was drawn of the entire cache and it was broken into two major sections. The first was the CAM array and its associated logic and the second was the controller. The controller was further broken out into its major components so it could be built in a hierarchical manner. This allowed for the separate sections to be tested before being integrated into the controller portion of the MCC.

The next step taken was the building, in VHDL, of all the basic components needed in the MCC. These were the building blocks for the major components that make up the controller. Once these basic components were built, the major components of the controller section were created from them. The controller was then put together from these sections and the final step was the integration of the controller onto the MCC with the CAM array and its logic.

Basic Components

This section contains the basic components that make up the major components of the controller. The VHDL code for each of the basic components is in Appendix B. They are organized in alphabetical order.

BINARY_COUNTER: This synchronous binary counter is a slightly modified version of the binary counter in Mano (12:278). It is the only reason the MCC requires a dual-phased clock. The version shown in Figure 19 uses JK-type flip-flops with RESET (these JK-type flip-flops are described later in this section). It is also of generic size. The size, `Bits_In_Counter`, is defined in `chip_pkg.vhd` (see Appendix E).

Figure 19. Schematic Diagram of BINARY_COUNTER (12:278)

CHANGE_DETECTOR (14): The purpose of this circuit is to detect a change from '0' to '1' and from '1' to '0' in any input signal. The circuitry is very simple and is shown in Figure 20. Refer to Figure 21 during the following explanation of how it works. Suppose a '0' is on both inputs of the XOR gate. This causes the output to be '0' ($0 \text{ XOR } 0 = 0$). Now, if a '1' is input into the change detector, a '1' is on one of the XOR inputs.

Figure 20. Schematic Diagram of CHANGE_DETECTOR (14)

Figure 21. Timing Diagram for CHANGE_DETECTOR Operation

The other XOR input is still a '0' for as long as it takes for the signal to go through the buffer (BUF_Delay in the figure). This causes the XOR output to be a '1' ($1 \text{ XOR } 0 = 1$). After the buffer delay, the second XOR input gets '1' and the XOR output becomes a '0' again ($1 \text{ XOR } 1 = 0$). The circuit works the same way with a signal transition from '1' to '0'.

EDGE_TRIGGERED_DFF: This is a D-type positive-edge triggered flip-flop taken from Mano (12:214) and slightly modified. The logic diagram is shown in Figure 22. The only change was the addition of a RESET port to allow the flip-flop to be asynchronously reset to '0'.

Figure 22. Schematic Diagram of EDGE_TRIGGERED_DFF (12:214)

MS_JKFF: This is a clocked master-slave JK-type flip-flop taken from Mano (12:213) and slightly modified. The schematic diagram of this component is shown in Figure 23. A RESET port was added to allow it to be asynchronously reset to '0'. In addition, the CP port was modified to allow a dual-phased clock to be used and, as a result, a NAND gate was deleted from Mano's design.

PREFETCH_COUNTER: This component is very similar to the word-time signal generator found in Mano (12:285) and is shown in Figure 24. It uses the BINARY_COUNTER of Figure 19 to count upward from zero to Prefetch_Block_Size-1 (as defined in chip_pkg.vhd of Appendix E). When the circuit is "started", the output signal of the RS-type flip-flop, Counting, produces a '1' and the binary counter begins to count. The XNOR gates are used to compare the outputs of the binary counter and Prefetch_Register. When they are equal, the output of each XNOR gate becomes '1' and

Figure 23. Schematic Diagram of MS_JKFF (12:213)

the RS-type flip-flop is reset to zero. Counting then becomes '0' and its complement is able to clear the binary counter to set up for the next prefetch cycle.

RS_FLIPFLOP: This is an RS-type flip-flop found in Mano (12:206). The logic diagram is shown in Figure 25.

SHIFT_REGISTER: This component is a circular shift register with parallel load. The design came from Mano (12:267) and was implemented with some modifications. This register is a unidirectional shift register, whereas Mano's is bidirectional. Therefore, 2x1 multiplexers were used as opposed to Mano's 4x1 multiplexers. Also, SHIFT_REGISTER is of generic size whose depth is defined in the chip_pkg.vhd of Appendix E. SHIFT_REGISTER is shown in Figure 26.

TOS_SHIFTER: This shift register is very similar to that of Mano's shift register (12:264). It uses the EDGE_TRIGGERED_DFF with RESET and is shown in Figure 27. It is cleared upon initialization of the MCC with Master_Reset and loads the bottom flip-flop with a '1'. The Master_Reset signal is connected to the CLEAR port of TOS_SHIFTER. When it goes high, all flip-flops are reset except for the bottom one. An OR gate is connected to the D input of this flip-flop and the OR inputs are the topmost

Figure 24. Schematic Diagram of PREFETCH_COUNTER

Figure 25. Schematic Diagram of RS_FLIPFLOP (12:206)

flip-flop's output and the CLEAR port. Therefore, the circular shift can be accomplished with the top flip-flop's output, and the CLEAR port can load the bottom flip-flop with a '1' when Master_Reset is '1'. The CLEAR port is also ORed with CP and input into the CP port of the bottom edge-triggered D-type flip-flop. Thus, upon initialization, the bottom flip-flop clocks in a '1', which can then be shifted in a circular manner.

The CAM Cell

The fully-associative CAM cell was selected over the bit-slice, byte-slice, and word-slice associative memories for the implementation of the structural locality cache memory subsystem. Its advantages far outweighed its disadvantages for the purpose of this research. Speed during memory accesses is the most important issue (outweighing the fact that more logic is needed to form each cell) and the fully associative array is fast. Each cell of the CAM array performs its comparison simultaneously, thus increasing the speed of the entire memory subsystem.

The CAM cell proposed by DeCegama (shown in Figure 5) was used in the implementation. It is a fully associative CAM cell with all the features necessary to be integrated onto a cache used to prefetch memory references. This design was chosen for this thesis not because of its robust functionality but simply because it was familiar to the

Figure 26. Schematic Diagram of SHIFT_REGISTER (12:267)

Figure 28. Naming convention for CAM cell gates and signals

The CAM cell performs three functions: *search*, *read*, and *write*. The RS-type flip-flop, consisting of gates AND1, AND2, NOR3, and NOR4, is used to store the contents (C) of the cell. Table 3 shows the inputs to the CAM cell to perform the desired operation.

Table 3

CAM Cell Inputs for Desired Operation

	Bit Select (B)	Word Select (W)
search	1	0
read	0	1
write	1	1

During a *search*, the datum to be searched for (D) is placed on the *Data In* line, as shown in Figure 28. Simultaneously, the *Bit Select* line (B) is set to '1' and the *Word Select* line (W) is set to '0'. Since B = '1', both *Read Outputs*, RX and RY, produce a '0' from gates NOR7 and NOR6, respectively. If D and C are equal, then a '1' will go into the NOR1 and NOR2 gates producing a '0' as their outputs. Since these outputs go into gate NOR5 and W = '0', then Match Line (M) becomes a '1'. Conversely, if D and C are not equal, either gate NOR1 or NOR2 will produce a '1' as its output, forcing the output of NOR5 (M) to go to '0'. Logically, M is derived as follows:

$$M = [(D + B' + C')' + (D' + B' + C)' + W]'$$

but B = 1 (or B' = 0) and W = 0, so

$$\begin{aligned} &= [(C' + D)' + (C + D')]' \\ &= [CD' + C'D]' \\ &= (C' + D)(C + D') \\ M &= CD + C'D' \end{aligned}$$

During a *read* operation, W is set to a '1' and B is set to a '0'. Note that D does not affect the result of the *read*. The output M goes to '0' from gate NOR5 since W is a '1'. The content of the cell is output through NOR6 onto RY and its complement is output through gate NOR7 onto RX. Logically, RY and RX are described as follows:

$$\begin{aligned} RY &= (B + C' + W)' \\ &= B'CW \end{aligned}$$

but B = 0 (or B' = 1) and W = 1, so

$$RY = C$$

and

$$\begin{aligned}RX &= (B + C + W)' \\ &= B'C'W\end{aligned}$$

or

$$RX = C'.$$

During a *write* operation, both B and W are set to '1'. Since W is a '1', M becomes a '0', and since B is a '1', RX and RY become '0'. The cell content C will become D as proven below:

$$C = [(DBW + C)' + (D'BW)]'$$

now since B and W are both '1',

$$\begin{aligned}C &= [(D + C)' + D']' \\ &= [C'D' + D']' \\ &= [D']' \\ C &= D.\end{aligned}$$

After the cell was completely tested, an array of cells was organized to form the CAM array.

The CAM Array

VHDL has a useful function called *generate*. Using this feature, an *m* by *n* array of CAM cells was generated. This allows the decision about the size of the array to be delayed to a later time when details about the fabrication technology and chip size are considered. In the VHDL description of *chip_pkg.vhd* (Appendix E), *m* is the length of the word (*Word_length* in the code) and *n* is the depth (*Depth* in the code) of the array (see Figure 29).

Figure 29. Dimensions of the CAM Array

The organization of the CAM array is shown in Figure 30. It functions as follows. The `Address_Buffers` and `Data_Buffers` accept incoming data from the MCC's `Address_In` and `Data_In` ports, respectively. These buffers in turn provide the buffered data to the `Data_In_Bus`. The buffers act to amplify the data before going into the CAM array. The `Bit_Select_Bus` and the `Word_Select_Bus` get data from the controller. This arrangement allows selected bits of a word to be compared during a search operation, and multiple words to be written to and read during the write and read operations.

The resolution functions, `Wired_Or` and `Wired_And`, are used to resolve signals along selected buses inside the CAM cache. The VHDL code for these resolution functions came from Lipsett (11:103-105) and can be found in `chip_pkg_body.vhd` of Appendix E. The implementation into hardware is technology dependent. The VHDL description would be modified to match the specific hardware technology used to realize the design.

When a certain bit is to be compared during a search, a '1' is placed on the `Bit_Select_Bus` to select that bit in all words of the array. If a match is successful, an M output of '1' from each matched cell is placed on the `Resolved_Signal_Tag` line. If a match is unsuccessful, a '0' is placed on the line. This line is a wired-AND that resolves

Figure 30. Organization of the CAM Array

the match lines from each cell. If a match is found on all selected bits of a word, then the Resolved_Signal_Tag becomes a '1'. If any of the selected bits do not match the cell

contents, then Resolved_Signal_Tag becomes a '0', meaning the word did not match the data input.

To write to a particular word of the array, a '1' is placed on that word's Word_Select_Bus line. Also, '1's are placed on the Bit_Select_Bus to write to the desired bits of the word.

During a read operation, a single word or multiple words can be read. If a single word is to be read (as will always be the case in the MCC), a '1' is placed on its Word_Select_Bus and all Bit_Select_Bus lines are set to '0'. The word is transported over the Resolved_Signal_Data_Out lines to the Data_Out_Buffers and its complement is transported over the Resolved_Signal_Data_Check line. This line is important during a multiple read because if two or more words are selected to be read, they may not have the same data. The Resolved_Signal_Data_Out performs the wired-OR function for each bit of the word being read. The complement of each bit is resolved on the Resolved_Signal_Data_Check line, which also performs the wired-OR function. The Resolved_Signal_Data_Out and the Resolved_Signal_Data_Check are compared, using exclusive-OR gates, to determine their validity. If the signals are different, then the Resolved_Signal_Data_Out is valid; if the signals are the same, they are invalid. This may more easily be seen in Table 4 below.

Table 4
Truth Table for Validity of Data

RX	RY	P = RX xor RY	
0	0	0	N/A
0	1	1	valid
1	0	1	valid
1	1	0	invalid

For example, suppose a multiple read were performed on the following two 4-bit words (the left-most bit is the most significant bit, bit 3).

1010

0010

The Resolved_Signal_Data_Out of bit 3 would be a '1' ($1 + 0 = 1$). Resolved_Signal_Data_Check would also be a '1' ($1' + 0' = 0 + 1 = 1$). Exclusive-ORing the two results produces a '0' ($1 \text{ XOR } 1 = 0$), i.e., not valid. On the other hand, Resolved_Signal_Data_Out of bit 2 would be a '0' ($0 + 0 = 0$) and Resolved_Signal_Data_Check would be a '1' ($0' + 0' = 1 + 1 = 1$). Exclusive-ORing these two produces a '1' ($0 \text{ XOR } 1 = 1$), i.e., valid.

Designing the Controller

Before getting into the details of how the MCC as a whole works, an overview of the MCC controller in an hierarchical fashion is in order. This will allow the reader to learn the terminology used and the figures can then be referenced during the discussion of the operation of the MCC.

Figure 31 shows the highest hierarchical level of the MCC. Appendix D contains the VHDL code describing the interconnects for Figure 31. The cache can logically be viewed as having two parts; 1) the CAM array and its corresponding logic and 2) the controller.

The controller controls the performance of the MCC by communicating with the CAM array. The controller accepts inputs from the array and the MCC's ports and produces outputs to be used by the array. The controller ports are shown in Figure 31. A brief description of each port is presented in Table 5. The ports are in alphabetical order and are identified as either input or output ports.

Figure 31. The MCC's Highest Hierarchical Level

Table 5
Description of Controller Ports

Port	Type	Description
Bit_Select	Output	directly connected to Bit_Select_Bus
CP	Input	receives the system clock pulse
CPnot	Input	complement of CP
Data_Avail_MEM	Input	used to signify when the data are available from main memory when a read miss occurs
Data_In	Input	receives the address from the Address_In port
Data_Out	Input	receives the Data_Out vector
Data_Out_Available	Output	signifies that data are present on output port during Read Hit state
Master_Reset	Input	receives MCC's Master_Reset signal that resets the entire chip model
Read	Input	signifies that data are requested of the MCC by the CPU
Read_Miss	Output	signifies that data are not stored on the cache during read function
Resolved_Signal_Tag	Input	receives Resolved_Signal_Tag vector of CAM array signifying which word of CAM array was matched during search operation
Resolved_Tags	Input	receives the Resolved_Tags bit signifying the data searched for are present in the CAM array
Select_Word	Output	outputs data to Word_Select_Bus
Write	Input	signifies when the CPU desires to write data into the MCC
Write_Hit	Output	signifies that data are stored on the MCC during a write function
Write_Miss	Output	signifies that data are not stored on the MCC during a write function

The interconnections between the components that make up the controller are shown in Figure 32. The VHDL code for each of the major components that make up the controller is presented in Appendix C. The purpose of each of these components will now be specified. They are listed in alphabetical order.

Figure 32. The Controller Components and Interconnections

FUNCTION_CHANGE_DETECTOR: This component determines if the Read or Write ports of the MCC have changed. Figure 33 shows the schematic diagram of the component and Appendix C contains its VHDL code.

Figure 33. Schematic Diagram of FUNCTION_CHANGE_DETECTOR

The input ports are Read and Write, and the output port is called Function_Change. When Read or Write transitions from '0' to '1' or vice versa, the change detectors detect the change and output a '1' onto the Rd_out or Wt_out signals. These signals are ORed together to produce Function_Change. As a result, if either Read or Write transitions, Function_Change will become a '1'. This is shown in the truth table, Table 6. Function_Change remains a '1' for the time called Change_Detector_Delay. This time is a constant and is defined in chip_pkg.vhd in Appendix E.

OPERATION_STATUS: This component indicates the state the MCC is in. It takes in the incoming signals and from them can determine the state the MCC is in, whether it be the Read Hit, Read Miss, Write Hit, or Write Miss state. The Read Hit state is coded in a less obvious way than the other states. The Data_Out_Available port is asserted high when the data on each read operation in a prefetch cycle is present on the

Table 6

1	1	N/A

MCC's Data_Out port when a read hit occurs. The logic diagram of the OPERATION_STATUS is shown in Figure 34. The VHDL code describing this circuit is in Appendix C.

Figure 34. Schematic Diagram of the OPERATION_STATUS Component

The output ports are defined as follows.

- **Data_Out_Available:** The Data port takes in the Data_Out data of the MCC. Each bit of the Data_Out is connected to a change detector that determines if the bit has changed. The resulting vector is Data_Change. This vector is resolved, using the wired-OR, into one bit, Data_Out_Change. This bit signifies if any of the Data_Out bits have changed. It is ANDed with the signal Prefetching. The AND result is Data_Out_Available, which signifies when the output data of the MCC are available on the MCC's ports. In other words, data are available when new data are available on the MCC's output ports and the MCC is in the prefetching cycle .

- **Read_Miss:** The Read Miss state is denoted by the AND result of three signals: Read, Resolved_TagsNot, and Search_Complete. Therefore, a read miss occurs when a read is requested, a match was not found (i.e., Resolved_Tags = '0'), and the search for the data is complete.

- **Write_Miss:** The Write Miss state is denoted by the AND result of the Search_Complete, Resolved_TagsNot, and Write signals. Therefore, a write miss occurs when the search for the data is complete, a match was not found, and a write function was requested.

- **Write_Hit:** The Write Hit state is denoted by the AND result of the Write, Search_Complete, and Resolved_Tags signals. In other words, a write hit occurs when the write function is requested, the search is complete, and a match was found.

PREFETCH_STATUS: This component produces a '1' on its output port, Counting, only when a read hit has occurred. It remains a '1' for the number of clock cycles required to read the Prefetch_Block_Size (defined in chip_pkg.vhd in Appendix E) from the CAM array. Figure 35 shows the PREFETCH_STATUS component and Appendix C contains its VHDL code.

Figure 35. Schematic Diagram of the PREFETCH_STATUS Component

The component PREFETCH_COUNTER counts to the number of clock cycles equal to the Prefetch_Block_Size. While counting, it produces a '1', which is put onto Counting port. It starts this counting cycle after a search is complete, the data are found, and a read is requested of the cache. The systems clock (CP) then clocks the counter inside PREFETCH_COUNTER. When Prefetch_Block_Size is reached, Counting becomes a '0' and the prefetch cycle is complete.

SEARCH_STATUS: This component provides enough delay to accomplish a search and produces a '1' on its output port, Search_Complete, until it is reset to '0'. The schematic diagram is shown in Figure 36 and its VHDL code is in Appendix C.

This is how SEARCH_STATUS works. The input into the D-type flip-flop is the signal Search_Done. Search_Done is defined as:

$$\text{Search_Done} = (\text{Resolved_Signal_Address_Change})(\text{Read} + \text{Write}).$$

Thus, when the address portion of the Data_In_Bus changes and a Read or a Write is requested of the MCC, a '1' is clocked into the D-type flip-flop. Notice that Search_Done clocks itself into the D-type flip-flop.

Figure 36. Schematic Diagram of the SEARCH_STATUS Component

The D-type flip-flop is reset with the OR result of three signals: AND_out, Reset_DFF, and Counting. AND_out is defined as:

$$\text{AND_out} = (\text{Function_Change})(\text{Read} + \text{Write})'.$$

This causes the D-type flip-flop to be reset only when the Read or Write signal transitions from a '1' to a '0'. Thus, the D-type flip-flop is reset at the end of a Read or Write request.

The second way the D-type flip-flop can be reset is with the Reset_DFF port. This port is connected to the MCC's Master_Reset port. Therefore, when Master_Reset is high, the D-type flip-flop is reset to '0'.

The third way to reset the D-type flip-flop is with the Counting signal. When Counting is '1', the MCC is in the prefetch cycle. If the prefetch cycle ends and Search_Complete is still a '1', the prefetch cycle will start again. To avoid this situation, the D-type flip-flop is reset to '0' upon activation of the prefetch cycle.

SELECT_WORD_SELECT: This component is used to select the register of the **WORD_SELECT** component that will be connected to the Word_Select_Bus. It outputs a '0' or '1', which is ported to the multiplexers that select the data to be put onto the Word_Select_Bus (see **WORD_SELECT** below). The schematic diagram is shown in Figure 37 and the VHDL code is in Appendix C.

Figure 37. Schematic Diagram of the SELECT_WORD_SELECT Component

When the output of this component, WSR_Select, is '0', the SHIFT_REGISTER outputs of WORD_SELECT are connected through the multiplexers to the Word_Select_Bus. SHIFT_REGISTER shifts upward on the prefetch cycle during a read hit to prefetch the desired block of data. It is also used to write to a particular word of the CAM array on a write hit.

When WSR_Select is a '1', the TOS_SHIFTER's output is connected through the multiplexers of WORD_SELECT to the Word_Select_Bus. This register is used to keep track of where the top of the stack is so data can be written into the MCC in the order

they are used by the CPU. Therefore, on a read miss, the data are written into the CAM array using TOS_Shifter output.

Thus, we have seen that the SELECT_WORD_SELECT selects which register's outputs will go onto the Word_Select_Bus. The SELECT_WORD_SELECT's output, WSR_Select, is connected to the multiplexers of the WORD_SELECT component. A D-type flip-flop stores the value used as the WSR_Select. The only time WSR_Select is a '1' is when a read miss has occurred and data from main memory will be written into the CAM array. This occurs when Read, the complement of Resolved_Tags, and Search_Complete are high. The one thing still missing is a signal from the main memory telling the MCC that data are available on the data buses. This signal is Data_Avail_MEM. When this signal is asserted high, the D input of the D-type flip-flop gets a '1' from the output of the AND1 gate, which is also used as the clock input. Therefore, when a read is requested, a read miss occurs, the search is complete, and the data are available from main memory, the WSR_Select output becomes a '1'.

WSR_Select is a '0' at all other times. As the MCC is initialized, the Master_Reset port is asserted high. This signal is connected to the RESET port of the D-type flip-flop and is therefore reset to '0'. Also, the Function_Change port is connected to the output of FUNCTION_CHANGE_DETECTOR. Therefore, when this port is asserted high, the D-type flip-flop is reset to '0'.

WORD_SELECT: This component is the most complex of the controller components. Its purpose is 1) to output data onto the Word_Select_Bus and 2) provide data to the Bit_Select_Bus. The schematic diagram is shown in Figure 38 and its VHDL code is located in Appendix C.

Figure 38. Schematic Diagram of WORD_SELECT Component

One thing to notice about the operation of this MCC is that in order to write to the TOS in the Read Miss state, the TOS position must be held from the previous write operation. Also, in the Read Hit state, a pointer is shifted upward to prefetch the data in the order in which they were written in order to capture structural locality. These two states are in direct conflict for the CAM pointer. The problem is solved by placing not one shift register on the MCC but two. One is used to keep track of the TOS position for writing into the cache during the Read Miss state. The other is used to locate the data during a Read Hit and to shift upward to prefetch the contents of the CAM array. 2x1 multiplexers are used to select which shift register's output is used as the word select input for the CAM array.

The TOS_SHIFTER is used to store the top-of-stack position for the write operation during the Read Miss state. The SHIFT_REGISTER is used to update data during the Write Hit state and also to shift upward during the prefetch cycle in the Read Hit state. The outputs of these two shift registers are connected to a series of multiplexers, with the In0 ports of each multiplexer connected to the bits of the SHIFT_REGISTER output and the In1 ports connected to the bits of the TOS_SHIFTER output. The Sel ports of the multiplexers are connected to the WSR_Select port, which determines the shift register that will be connected to the Word_Select_Bus. WSR_Select is connected to the output of the SELECT_WORD_SELECT component.

The operation of WORD_SELECT is fairly straightforward when TOS_SHIFTER is selected. This register is only selected during the Read Miss state. It is during this state that the CAM array does not contain the data asked for by the CPU. When this occurs, main memory will provide the CPU with the required data and the MCC will intercept these data and write them into the CAM array. The Clear_TOS port of the TOS_SHIFTER clears the register and initializes one of the flip-flops to '1' to act as the

first entry of the top-of-stack. It is cleared and initialized only with the MCC's Master_Reset. After initialization, the register is shifted on the clock pulse. The inputs into CP and CPnot come from the component WORD_SELECT_CLOCK described later.

The operation of WORD_SELECT is much more complicated in the Write Hit and Read Hit states when the SHIFT_REGISTER is selected. This register has a port called Sel0 that determines whether it will load incoming data or shift upward. During both Write Hit and Read Hit states the register will load data. During the Read Hit state, the register first loads the data then enters the prefetch cycle when it is shifted upward to read the desired prefetch block size. It is critical at the end of the prefetch cycle that the Bit_Select port not change to '1' until after SHIFT_REGISTER is cleared and Select_Word becomes all zeros. If it does change to '1', an inadvertent write will occur. To avoid this, the Select_Word port's data are resolved, using wired-OR, into a single bit. When this bit changes to a '0' (i.e., Word_Select_Bus is all zeros) and SR_Select is stored as a '0' (i.e., Counting is a '0' and no prefetching is occurring) in D-type flip-flop DFF1, SR_Select (currently '0') is clocked into DFF2. The output of DFF2 is NORed with the output of DFF1 (SR_Select) and the result is ported to the Bit_Select_Bus. The result in this case is '1' since '0' NOR '0' is '1'. Therefore, since Select_Word is connected to the Word_Select_Bus (currently all zeros), the write operation is disabled.

SHIFT_REGISTER is cleared only when the prefetch cycle is not occurring, i.e., when SR_Select = '0' is stored in DFF1. The Clear2 port is connected to the signal Function_Change. So, as long as Counting is '0' (i.e., the Qnot output of DFF1 is '1'), the AND4 output is a '1' after either the Read or Write ports change. The output of AND4 is connected through OR3 into the Clear port of SHIFT_REGISTER, thus clearing the register. SHIFT_REGISTER is also cleared promptly after the prefetch cycle. When SR_Select changes to a '0', it is clocked into DFF1. The output of DFF1 will then

change causing the CD2 output to go to '1' for a period of time. Qnot of DFF1 is ANDed with the output of CD2, and this signal is connected through OR3 to the clear port of SHIFT_REGISTER.

We saw above how Bit_Select becomes a '1' after the Read Hit state is completed. Now let's discuss how it becomes a '0' during that state. When the output of PREFETCH_STATUS, Counting, becomes a '1', we want Bit_Select to become a '0' to allow for the read operation. As discussed above, Counting is connected to the SR_Select port of WORD_SELECT. When Counting changes to '1', it is clocked into DFF1 and the output of DFF1 is connected to NOR2. Thus, NOR2 produces a '0' and is output onto the Bit_Select port, which in turn forces the Bit_Select_Bus to become '0's.

Let's summarize this complicated circuit. The reader may refer to the VHDL code of THE_CONTROLLER in Appendix D for the port connections of WORD_SELECT. The circuit is initialized when Master_Reset is asserted high. The Clear port of TOS_SHIFTER is connected to Master_Reset through Clear_TOS port. Therefore, when Master_Reset goes high, TOS_SHIFTER is cleared and one flip-flop is set to '1' to act as the TOS pointer. At the same time, SHIFT_REGISTER is cleared to all zeros. Clearing this register is a bit more complex than initializing TOS_SHIFTER. The first thing that must be done is to reset DFF1. This is accomplished with Master_Reset. After resetting, Qnot of DFF1 is '1' and is ANDed with OR1 output. One of the inputs to OR1 is Master_Reset so the AND result is '1'. This signal is then connected to OR3 and the OR3 output is connected to the Clear port of SHIFT_REGISTER. Thus, SHIFT_REGISTER is cleared. The other way SHIFT_REGISTER is cleared is when the signal, Function_Change, is asserted high when the prefetch cycle is not occurring. The signal, Function_Change, is connected to the Clear2 port of WORD_SELECT. If it is '1', then the output of OR1 is '1'. This signal is ANDed with the Qnot output of

DFF1. Qnot is a '1' as long as the MCC is not in the prefetch cycle. Therefore, the AND result is a '1', which goes through OR3 to clear SHIFT_REGISTER.

If a read miss occurs, the MCC will write the data into the CAM array when it is available from main memory. In this case, the WSR_Select port becomes a '1' selecting the TOS_SHIFTER and shifting it upward using the CP and CPnot inputs. The Bit_Select port is already a '1' from initialization or from the previous state change. Thus, the CAM array is set up for a write and the write is accomplished.

If a write hit occurs, the Resolved_Signal_Tag showing the word that was found is loaded into SHIFT_REGISTER. WSR_Select is a '0', which selects the SHIFT_REGISTER data and outputs the data onto the Word_Select_Bus. Thus, the CAM array is again setup for a write operation.

If a read hit occurs, SR_Select becomes a '1' and is stored into DFF1. The Q output of DFF1 then selects the shift operation of the SHIFT_REGISTER and on each clock pulse it is shifted upward until the prefetch block size is reached. Q is also input into NOR2 whose output becomes a '0', which goes onto the Bit_Select_Bus. Thus, data are read in a FIFO manner from the CAM array on each clock pulse.

WORD_SELECT_CLOCK. The purpose of this component is to act as the clock inputs for the registers in the WORD_SELECT component. The schematic diagram is shown in Figure 39 and its VHDL code is in Appendix C.

This component has three output ports. One of these outputs, Word_Sel_Reg_Clock, is connected to the SHIFT_REGISTER of the WORD_SELECT component. It clocks this register during the prefetch cycle to load incoming data into the register. The other two output ports, TOS_Clock and TOS_ClockNot, are connected to the TOS_SHIFTER of WORD_SELECT. These two signals are the clock inputs of

Figure 39. Schematic Diagram of the WORD_SELECT_CLOCK Component

TOS_SHIFTER to shift the register prior to the write operation during the Read Miss state.

The output Word_Sel_Reg_Clock is determined by the following boolean equation:

$$\text{Word_Sel_Reg_Clock} = (\text{Search_Complete})(\text{Resolved_Tags})(\text{Write}) + (\text{CP})(\text{Counting}).$$

This means that when a search is complete, a match was found in the CAM array, and a write function was requested, or when the systems clock pulses during a prefetch cycle (i.e., Counting = '1'), Word_Sel_Reg_Clock is asserted.

The output TOS_Clock needs to have a rising and falling edge to act as the clock input for the TOS_SHIFTER. Therefore, a change detector was placed on the component. When the signal Read_Miss changes from '0' to '1' or vice versa, the change detector outputs a '1' for a short period of time. Read_Miss is determined as follows:

$$\text{Read_Miss} = (\text{Read})(\text{Search_Complete})(\text{RTnot}).$$

Thus, when a read is requested, the search is complete, and the search was unsuccessful, Read_Miss becomes a '1'. This signal is ANDed with the output of the change detector to pulse TOS_Clock. Therefore, TOS_Clock pulses only when Read_Miss transitions to '1'. TOS_ClockNot is the complement of TOS_Clock. The buffer, BUF1, is needed to ensure TOS_Clock and TOS_ClockNot transition at the same time.

Putting it All Together

With the four states of the MCC in mind, the logic and control lines were drawn schematically to represent the operations the MCC was to perform. Therefore, a structural gate level design was integrated onto the chip model to control the CAM array. Table 7 shows the necessary inputs into the CAM array to accomplish each operation for the various states. All of the components that make up the MCC were discussed in some detail above. Refer to those sections for further clarification of the signal and component names.

Table 7
CAM Array Inputs for the Main CAM Cache States

	Bit_Select_Bus	Word_Select_Bus
<i>Read</i>		
Search	1	0
Hit		
Read	0	Resolved_Signal_Tag
Miss		
Write	1	TOS_Output
<i>Write</i>		
Search	1	0
Hit		
Write	1	Resolved_Signal_Tag
Miss	N/A	N/A

As stated before, each function begins with the search operation. This operation requires that the Bit_Select_Bus be asserted high and the Word_Select_Bus be asserted low. If, during a read, the search is successful, the MCC goes into the Read Hit state and the read operation is performed. A read requires the Bit_Select_Bus to be asserted low and the word being read must have a '1' asserted on its Word_Select_Bus lines. Alternatively, if the search is unsuccessful, the Read Miss state is entered. This state requires a write operation in which the Bit_Select_Bus must be asserted high and the Word_Select_Bus gets the data from the TOS_SHIFTER of the WORD_SELECT component. The TOS_SHIFTER holds the next stack position for a write.

If the search is successful during a write function, then the Write Hit state is entered and a write operation is performed. During a write operation, the Bit_Select_Bus must be asserted high. The Word_Select_Bus receives the Resolved_Signal_Tag data indicating the word that was found. If the search were unsuccessful, the Write Miss state is entered and no further action is required.

The operation of the entire MCC will now be discussed. Since the Read and Write functions require a search, the search will first be explained. The remainder of this section describes the functionality of the MCC in each of the four states.

The Search. According to Table 7, the Bit_Select_Bus must be asserted high and the Word_Select_Bus must be asserted low to accomplish the search. The Bit_Select_Bus gets its data directly from the Bit_Select port of the controller. This port is '1' as long as the MCC is not prefetching in the Read Hit state. The Word_Select_Bus gets its data indirectly from the SHIFT_REGISTER (see Figure 38). This register uses the D-type flip-flop with Reset. As long as the MCC is not in the prefetch mode, a change either in the Read or Write port will cause the SHIFT_REGISTER to reset. When the Read or Write ports change, the FUNCTION_CHANGE_DETECTOR detects the

transition and clears the register to all zeros. Note that after each function is complete (either the read or write function), the SHIFT_REGISTER is reset. Thus, when new data are to be operated on during a read or write function, Word_Selector will have been reset to zeros and will be ready for another search operation. Also note that SHIFT_REGISTER is reset upon the initialization of the MCC by the Master_Reset signal.

As mentioned above, the Word_Select_Bus gets its data indirectly from SHIFT_REGISTER during a search operation; 2 x 1 multiplexers are located between the two (see Figure 38). The output data of SHIFT_REGISTER are fed into the In0 ports of the 2x1 multiplexers. Consequently, the multiplexers must have a '0' value at the Sel ports before the data are output onto the Word_Select_Bus. This is done by the SELECT_WORD_SELECT component shown in Figure 37 which monitors the change in the Read port of the MCC. When the Read signal transitions from '1' to '0', FUNCTION_CHANGE_DETECTOR outputs a '1' onto signal Function_Change, which is connected to the Reset port of an edge-triggered D-type flip-flop in SELECT_WORD_SELECT. This resets the flip-flop to '0'. Its output, WSR_Select, is connected to the Sel ports of the multiplexers in WORD_SELECT, thereby selecting the data from SHIFT_REGISTER. Upon initialization, the Master_Reset signal also resets this D-type flip-flop. Consequently, the MCC is set up for a search operation after initialization.

The Read Hit. To do a read, the Read port of the MCC must indicate that a read function is requested and the address to read must be available. If the search operation, as explained above, is successful, then the MCC enters the Read Hit state and begins its prefetching cycle. Only one bit of the Resolved_Signal_Tag vector will be '1' on a search hit. This is because an address will never appear more than once in the CAM ar-

ray since during a write function, a search is performed first, and if successful, the new data are written over the old.

The Resolved_Signal_Tag lines are connected to the In_Vector port of SHIFT_REGISTER through the Tags_In port of WORD_SELECT (see Figures 32 and 38). These data are stored into the SHIFT_REGISTER by clocking them in with the CP (the MCC's clock port) ANDed with the Counting signal (see the WORD_SELECT_CLOCK component in Figure 39). They are ANDed to ensure the SHIFT_REGISTER is clocked only when the MCC is prefetching. The SHIFT_REGISTER's outputs are selected by the multiplexers and the data are output into the CAM array.

After SHIFT_REGISTER is loaded, the Sel0 port of SHIFT_REGISTER is changed to a '1'. This is accomplished with the Counting signal. When it changes to a '1', it clocks itself into DFF1, shown in Figure 38. This signal is connected to the Sel0 port of SHIFT_REGISTER. A '1' on this port switches its functionality from loading to shifting. Since its Clockin port is connected to the CP port of the MCC and ANDed with the Counting signal, the register will shift upward the number of times defined in the prefetch block size, allowing data from the CAM array to be read from the MCC in the order in which they were written.

Another requirement for the read operation is that the Bit_Select_Bus be all '0's. This is done by using the output of DFF1 of WORD_SELECT (Figure 38). When it changes to a '1', it clocks itself into DFF2. The output of DFF2 is then NORed with the output of DFF1, which is essentially the Counting signal with a delay. The Counting signal comes from the PREFETCH_COUNTER that is stimulated by the Resolved_Tags, Read, and Search_Complete (a timing signal signifying the completion of a search) signals ANDed together. The result of the AND signifies a read hit has occurred. The

PREFETCH_COUNTER produces a '1' and asserts the signal Counting high as long as the binary counter inside the PREFETCH_COUNTER does not equal the predefined prefetch block size. The binary counter counts up by one on each clock pulse. The counter's output is compared with the prefetch block size. When they are equal, the PREFETCH_COUNTER produces a '0' on the Counting signal, meaning the prefetch cycle is complete.

While Counting is '1', the MCC's clock is able to clock the SHIFT_REGISTER. On each clock pulse, the register is shifted up by one and the contents of that CAM word are read. Thus, the predefined number of words is prefetched, each word being read on the clock pulse.

The Read Miss. If a miss occurs on a read, then the address and its corresponding data need to be written into the CAM. The CAM is written to in a FIFO manner. Therefore, the TOS_SHIFTER will be used to select the word to be written. The only purpose of this shift register is to keep track of the top of the stack. In the MCC, this register is shifted just before the write to the CAM. This is done by merely clocking the register. The clock input is the AND result of the Read, Search_Complete, and Resolved_Tags' signals (see Figure 39). Those signals ANDed together signify a read miss. Since a complete clock cycle ('0' to '1', then '1' to '0') is needed to shift the TOS_SHIFTER, a CHANGE_DETECTOR was used to detect the transition of the AND result. The CHANGE_DETECTOR produces a '1' for a short period of time then returns to '0', therefore completing its own clock cycle.

The Sel port of the multiplexers in the WORD_SELECT component (Figure 38) is determined by the SELECT_WORD_SELECT component. The AND result of the Read, Search_Complete, Resolved_Tags', and Data_Avail_MEM signals is connected to the input of the D-type flip-flop of the SELECT_WORD_SELECT and (after going

through an OR gate) is also connected to the flip-flop's clock port. Thus, the AND result clocks itself into the D-type flip-flop. The output of the flip-flop is connected to the Sel port of the multiplexers, thus selecting the TOS_SHIFTER. The Bit_Select_Bus is already set to '1's, so the write occurs as soon as the data are present on the Address_In and Data_In ports.

After this read function is complete, the Read signal is asserted low and the FUNCTION_CHANGE_DETECTOR detects this change and outputs a '1'. This '1' then goes through the Clear2 port of WORD_SELECT and resets the SHIFT_REGISTER. This sets the MCC up for the next search operation. Now, let's take a look at the write function.

The Write Hit. The write function, as mentioned before, also starts with the search operation. In this case, the Write signal is asserted high and the address and data are available on the Address_In and Data_In ports, respectively.

The search is performed and, if successful, the Write Hit state is entered. In this state, the word that matched the input address will have its data replaced by the new data. The word is selected by the Resolved_Signal_Tag vector (this vector signifies which word is matched) being loaded into the SHIFT_REGISTER of WORD_SELECT. The Resolved_Signal_Tag vector is connected to the In_Vector port of this register (see Figure 38). The AND result of the Write, Search_Complete, and Resolved_Tags signals is used to clock the inputs into the SHIFT_REGISTER (see the WORD_SELECT_CLOCK in Figure 39). This AND result signifies a search hit on a write function. The output of SHIFT_REGISTER is input into the CAM array on the Word_Select_Bus through the multiplexers. Since the Bit_Select_Bus is already set up to do a write (i.e., the Bit_Select_Bus lines are all '1's), the write operation is performed on the selected word and the old data are replaced with the new.

The Write Miss. If, on a write function, the search is unsuccessful, the Write Miss state is entered. In this state, the MCC simply asserts the Write_Miss port high for a short period of time and then waits until called upon again.

Summary

This chapter detailed the design of the MCC from its functionality through the final integration of the CAM array and the controller. The VHDL model of the chip was designed and built from the bottom up. The CAM cell design was taken from DeCegama (3:87) and implemented in VHDL. The CAM cell was then used to build the CAM array, and the logic associated with the CAM array was integrated onto the chip model. Basic components such as flip-flops and shift registers were needed in order to put the rest of the model together. Once these basic components were built and tested, larger components were assembled. These larger components were pieced together to form the controller and the controller was integrated onto the chip model. A VHDL description of the main CAM cache used to exploit structural locality was the final product.

IV. Testing and Analysis

Overview

In Chapter 3, the inner workings of the MCC were discussed in detail. Let's now take an overview at the MCC and analyze its behavior. This chapter contains a look at the behavior of the MCC and the testing of the chip model to verify its functionality. The context of how the MCC fits into a memory subsystem will be discussed. The performance of the MCC as to the timing of the operations in each of the four states is described. A detailed analysis is then presented including critical-path calculations as well as a critical view on how to improve the MCC's performance and space utilization. Finally, some issues that need to be considered during the fabrication of the chip conclude the chapter.

Behavior of the MCC

As described in Chapter 3, the MCC takes on one of four distinct states: the Read Hit, Read Miss, Write Hit, and Write Miss states. Depending on the function requested (read or write) and the data available, the MCC will enter one of these states. This is shown in the VHDL behavioral description of the MCC located in Appendix D. Figure 40 shows a diagram of the states and how the states are entered.

Figure 40. State Diagram of Main CAM Cache

Figure 41 shows the flowchart of how the chip model works. Regardless of whether a read or a write function is requested of the MCC, a search is performed first. After the search is performed, one of the four states shown in Figure 40 will be entered.

When the CPU requests a read and provides the address, either the Read Hit or Read Miss state will be entered. If the address is found in the CAM array, the Read Hit state is entered. This is the only state that works synchronously. When a read hit occurs, the MCC begins to prefetch memory locations in the order in which they were written into the cache. On each clock pulse, the SHIFT_REGISTER is shifted upward resulting in the next array position in the CAM to be read. As each new address and associated data become available on the MCC's output ports, a signal called Data_Out_Available is asserted high, signifying that the data are available.

If the address is not present in the CAM array, the MCC asserts high the Read_Miss port signifying that a read miss has occurred. The MCC then goes into a wait state until main memory has placed the requested data on the data bus. The MCC must be notified, through the Data_Avail_MEM port, that the data are available on the bus from main memory. The data are then written onto the TOS of the CAM array.

When the CPU requests a write, the address and data are also provided. If the address is present in the CAM array, the Write Hit state is entered. During this state, the Write_Hit port is asserted high and its current data are replaced with the new data. If the address is not stored in the MCC, the Write Miss state is entered and the MCC simply asserts its Write_Miss port signifying that a write miss occurred and waits for the next function.

Testing

Each component of the VHDL model was thoroughly tested to ensure that its functionality corresponded to the expected behavior. Throughout the initial testing of

Figure 41. Flowchart of MCC

each component and the MCC itself, the word length was set at 6 bits, composed of 3 bits for the address and 3 bits for the data. The CAM depth was also initialized at 3. This was sufficiently large enough to ensure the model was working correctly, but small enough to allow the simulations to run very fast.

Appendix F contains the code used to exercise the MCC model as well as a simulation run including inputs and outputs. The appendix has the file used to stimulate the MCC, the test bench, and the configuration file. The simulation run contains a simulation of each of the four states. This data is part of the data used to analyze the performance and find the critical paths through the MCC.

A small memory system is shown in Figure 42 and the VHDL code is in Appendix G. This system consists of the MCC connected to a CPU and main memory (MEM) by buses and control lines. The only purpose of the CPU model is to produce addresses and request the memories to read or write the address. The sole purpose of MEM is to produce data corresponding to the address from the CPU and to produce data during the Read Miss state of the MCC. This system was built around the MCC to test the MCC only. It is not how an actual memory system works. The word length used in these tests was 64 bits; 32 for the address portion and 32 for the data portion. The CAM depth was set at 10 words during one test and 15 during another.

Figure 42 shows how the simple memory system is configured. The CPU generates an address and a memory request every 100 ns. If the request is a write, MEM automatically produces data onto the data bus (Data_Sig in the figure and in the code). This makes it appear to the MCC that the CPU produced both the address and the data.

Let's look at how the system works. When the CPU issues a read request, it also places an address on the address bus (Address_Sig). The MCC then searches for the address and if a hit occurs, the Read Hit state is entered and the prefetch cycle is

Figure 42. Simple Memory System Used to Test MCC

accomplished. During the prefetch cycle, the MCC's Valid_Out port is asserted high notifying the CPU that no more requests should be generated. This essentially blocks the CPU. If the address is not in the MCC, then the Read Miss state is entered. The Read_Miss port goes high signaling the MEM that it needs to supply data to the data bus. After MEM_Delay, the MEM supplies the data and asserts the Data_Avail signal. The MCC then takes the data off the bus and writes it into the CAM array.

When the CPU requests a write, the signal Write_Sig notifies the MEM to supply data to the data port. The MCC then searches its CAM array for the address. If found,

the Write Hit state is entered and the write is performed. Otherwise, the Write Miss state is entered and the system waits for the next memory request.

Context

The primary purpose of the MCC is to prefetch memory references in the order the CPU previously used them so structural locality can be captured by the SLC chip. Figure 43 shows the context of the MCC in the memory hierarchy and the data flow between the CPU, the SLC, the MCC, and main memory.

Figure 43. Context of the MCC in the Memory Hierarchy

During a read cycle, the CPU will send a signal signifying that a read is requested, as well as the address of the data to be read. The SLC will accept these data and search its memory for the address. If the address is stored in the SLC, then it, the fastest memory of the hierarchy, will provide the requested data to the CPU. This is the ideal

case and the one that this memory hierarchy is designed for. Since the SLC has captured structural locality, the chances are high that the next reference used by the CPU will also be stored in the SLC.

The MCC also accepts the address from the CPU and does a search in its memory. If the data are found, the prefetch cycle begins and the data are read out of the CAM array in a FIFO manner, one data element per clock cycle. The SLC then stores the data into its memory. One thing to consider is the possibility of a read hit on both the SLC and the MCC. If this occurs, the SLC will be reading data from its memory and providing it to the CPU. Concurrently, the MCC will be in its prefetch mode supplying the SLC with a block of memory references. More research will need to be done to determine what to do if this situation occurs.

One possible solution is simply to ignore the prefetched memory references. This goes along with the assumption that if the SLC contains one reference, then the following references are already contained as structural locality in the SLC. But that will not always be the case. If these references are ignored, then the MCC may be prefetching while another CPU request is generated. If this happens, the MCC may miss a chance to prefetch useful data to the SLC. It may also miss the opportunity to write data to the TOS, thus potentially destroying structural locality. Data may also need to be written into the MCC's CAM array during the prefetch cycle, thus creating cache incoherency in the memory hierarchy. For these reasons, this scheme is not a feasible solution.

Another alternative would be to block the CPU so no other operation can take place on the data buses, except between the MCC and SLC where the prefetching is occurring. If this is done, the CPU will be idle for the number of clock cycles needed to prefetch the entire block of data to the SLC.

The most feasible way to handle this potential problem is to shut down the MCC's prefetch cycle. This can be done by a signal sent from the SLC to the MCC signifying that the SLC contains the data needed by the CPU. This signal can be ORed with the Master_Reset signal in the MCC to selectively initialize desired components. One component that must not be initialized in this case is the TOS_SHIFTER in the WORD_SELECT component of THE_CONTROLLER. This register needs to retain the TOS pointer so memory references can be written into the CAM array in the same order that the CPU uses them. Also, it is important that the contents of the CAM array not be altered.

If the SLC and the MCC do not contain the necessary data, the CPU gets the data from main memory. In this case, the SLC and the MCC wait for main memory to provide the data to the data bus. Main memory will send a signal signifying when the data are available. After receiving this signal, the SLC and the MCC take the data from the data bus and write them into their respective CAM arrays.

The memory subsystem, as dictated by the current design of the MCC, uses write-through to ensure cache coherency. Therefore, all levels of the memory hierarchy are updated on a write-request from the CPU. The SLC will first search its contents for the address to write to. If the address is present, then the data are written into the SLC's memory. Otherwise, the SLC remains idle. The MCC operates the same as the SLC in this case. The main memory performs the conventional write operation.

Performance

This section describes the overall timing for the MCC. The time needed to initialize the MCC and the timing for each of the four states is described. The fastest clock speed allowable for the MCC is 34 ns (29.4 Mhz). This is dictated by the Read Hit state when the MCC uses the clock to prefetch data from the CAM array. Specific time-delays

in the VHDL code were used in the simulation of the MCC and the justification for their use will be explained. The critical paths through the MCC are presented in the next section entitled *Analysis*.

Time for Initializing. Figure 44 shows the timing diagram for initializing the MCC. The signal Master_Reset is used to reset the entire chip model. This signal can be '1' for as little as 38 ns and still initialize the entire MCC. After initialization is complete, Master_Reset must return to '0' before the MCC can perform any operations.

Figure 44. MCC Initialization Timing Diagram

Timing for the Read Hit. Figure 45 shows the timing of the MCC during an entire read hit cycle. Figure 46 is a closer look revealing more detail. Notice that the Data_Out signal transitions at regular intervals. This is due to the synchronous behavior of the MCC during this state. The SHIFT_REGISTER in the WORD_SELECT component of THE_CONTROLLER is shifted upward on the clock pulse, thus allowing the CAM array to perform the read operation.

Figure 45. Read Hit Timing Diagram

Figure 46. Read Hit Timing Diagram - A Closer View

The data to perform the search for the read function should be on the Address_In ports no longer than 2 ns before the Read port is asserted high. Otherwise, the MCC will not enter the prefetching cycle. This restriction can be relaxed by adding an

Address_Enable port to the MCC. This port would replace the functionality of the CHANGE_DETECTORS in the SEARCH_STATUS component of the CONTROLLER, allowing the address to be on the bus at any time before or after the Read port is asserted high. It takes 57 ns after the Address_In ports are asserted with the address for the first output to be placed on the Data_Out ports. Subsequent data are output onto the Data_Out ports at intervals equal to the clock period. It takes 28 ns after each clock pulse for the data to be placed on the Data_Out ports.

The Read port needs to be high for only 26 ns. After that, the CPU is free to request another operation, although the MCC will not respond because it is prefetching data. This is demonstrated by Figures 45 and 46. From 150 to 200 ns, the Read port is high, simulating a read request by the CPU. The MCC does not respond to this new request because it is in the prefetching cycle.

The Valid_Out signal is asserted high 3 ns after the first data word is available on the Data_Out ports. For each read, the Data_Available signal goes high 7 ns after the data element is available, then transitions to low 5 ns later. After the last valid data element is prefetched and the Data_Available signal goes low, another read is performed on the CAM array and the next word of the array is placed on the Data_Out ports. This time the signal Data_Available does not go high. Therefore, the data should not be read as valid.

At the end of the prefetch cycle, the Data_Out ports become all '0's and 3 ns later the Valid_Out signal goes low. This signifies that any data on the Data_Out ports is not valid.

The total time required for the Read Hit state depends upon when the clock pulse enters the MCC. The CP signal is ANDed with the Counting signal, which in turn clocks the SHIFT_REGISTER. Thus, the time required for this state can vary by as much as

one-half of a clock cycle. Using a clock speed of 34 ns, the range of time would be 917 ns to 934 ns while prefetching 25 memory references.

Timing for the Read Miss. The timing diagram for the signals involved in a Read Miss state is shown in Figure 47. After the Read_Miss signal is asserted high, the MCC must wait for the Data_Avail_MEM signal from main memory to be asserted high before writing the data into the CAM array.

Figure 47. Read Miss Timing Diagram

The Read_Miss port of the MCC is asserted high 19 ns after the Read port goes high, indicating that the requested data are not stored on the MCC. So that the CPU is slowed as little as possible, the MCC allows the CPU to take the Read signal low as soon as 8 ns after the Data_Avail_MEM port goes high. The Read_Miss port will go low 3 ns after the Read port goes low.

When main memory asserts the Data_Avail_MEM port high along with supplying the data onto the data bus, the MCC performs the write function and adds these data

the TOS of the CAM array. The Data_Avail_MEM port can go high 18 ns after the read is requested. Even though the Read_Miss port is asserted high 19 ns after the read is requested, the MCC is set up to do the write into the CAM array after only 18 ns. This, of course, is not realistic since the memory would be slower than the MCC. The point is, the MCC is set up to do a write into the CAM array with plenty of time to spare. Data_Avail_MEM must be high for at least 8 ns to allow the write to occur. It should not be high any longer than it takes the CPU to request another operation of the MCC. The data should be available for 31 ns after Data_Avail_MEM goes high.

A 5 ns time period must exist after a Read Miss state and the next requested operation. Therefore, the Read Miss state takes a total of 54 ns to complete.

Timing for the Write Hit. Figure 48 displays the timing diagram for the signals involved during the Write Hit state. Here, the CPU supplies the address and data to be written into memory and asserts the Write port high. It takes 31 ns for the Write port transition to reset the SHIFT_REGISTER in the WORD_SELECT component of THE_CONTROLLER. Therefore, this state requires that the CPU take the Write port low at least 28 ns before the address and data are taken off the data buses. The 3 ns difference is accounted for by the AND gates inside each CAM cell that the data must pass through. If the SHIFT_REGISTER is not reset before the address and data are changed, invalid address and data will be written into the CAM array. The Write port can go low as little as 20 ns after transitioning to high.

When a write hit occurs on the MCC, it takes 19 ns for the Write_Hit port to change to '1'. Only 3 ns after the Write port is asserted low will the Write_Hit port transition back to '0'. The Write Miss state requires 48 ns before the next operation can take place.

Figure 48. Write Hit Timing Diagram

Timing for the Write Miss. The timing for the participating signals of the Write Miss state is shown in Figure 49. The CPU supplies the same type of data as in the Write Hit state above; namely the address, the data, and the Write signal. The Write port must be high and the address and data must be available for at least 20 ns after the write is requested. When the search does not find the address in the CAM array, the Write_Miss port is asserted high after 19 ns. When the Write port is changed back to '0', it takes only 3 ns for the Write_Miss port to return to '0'. The MCC then needs 24 ns after the Write port goes low to reset itself before another operation can begin. The Write Miss state requires 44 ns to complete.

For both the Write Hit and the Write Miss states, the entire computer system must wait for main memory to write the data into main memory before any other operation can occur. This is a drawback of using a write-through policy with no buffering.

Figure 49. Write Miss Timing Diagram

Timing Justification. The time delays used by the MCC are shown in Table 8. They are defined in `chip_pkg.vhd` (see Appendix E) and were used as *generics* throughout the entire model. These generic time delays were supplied by Mehlic (14) who says they are figures derived through SPICE simulations and the actual testing of hardware at the Air Force Institute of Technology.

Table 8
Generic Time Delays Used in the MCC

Circuit	Time Delay (ns)
AND Gate	3
Buffer	1
D-type flip-flop	6
Inverter	1
Multiplexer	2
NAND Gate	2
NOR Gate	3
OR Gate	4
XNOR Gate	4
XOR Gate	4

These delay values were used for the rise and fall inertial delays for each component. This will not necessarily be the case for a SPICE model nor for the actual hardware implementation of this circuit. For all of the components, the rise inertial delay will probably be different than its fall inertial delay. The actual delays will also more than likely have decimal values. Due to these considerations, the timing of the fabricated chip will be different than the simulation.

Analysis

We now know the time it takes for each of the states to complete its cycle. Let's now investigate why it takes each state the amount of time it does. The critical paths through the chip model determine this time and can be useful for anyone desiring to speed up the MCC.

Read Hit Analysis. The Read Hit is the longest state simply because it prefetches a block of data when activated. The state can be broken into three separate phases. The first phase is the one in which the MCC is setting up for the prefetch cycle. The second phase is the prefetch cycle when the data words are being read on each clock cycle. The third and final phase is when the PREFETCH_COUNTER has completed its counting to the pre-specified prefetch block size and when the MCC is resetting itself for the next operation.

Figure 50 shows the signals of the critical path during the first phase of a Read Hit cycle. This phase, during any read hit, takes 57 ns finish. It is in this phase that the first data word is read from the CAM array.

Figure 50. Critical Path Timing Diagram for Read Hit in First Phase

The times used in Figure 50 are defined as follows.

t_{SC} : This is the time it takes the Search_Complete signal to go high after the Address is available to the MCC. The path for this time is through the SEARCH_STATUS component of THE_CONTROLLER.

t_C : This is the time it takes the PREFETCH_STATUS component to output a '1' onto the Counting_Signal after the Search_Complete signal goes high.

t_{WS} : This is the time it takes the WORD_SELECT component to load the SHIFT_REGISTER and output the correct data onto the Word_Select_Bus so a read can be accomplished. Counting_Signal triggers this action.

t_D : This is the time it takes after the Word_Select_Bus gets its data until the output data from the CAM array is on the MCC's Data_Out ports.

The values of these times are given in Table 9. The total time, therefore, for the first phase of the Read Hit is given by

$$t_{RH1} = t_{SC} + t_C + t_{WS} + t_D$$

which calculates to 57 ns.

Table 9
Signal Times for the First Phase of the Read Hit State

	Time (ns)
t_{SC}	16
t_C	16
t_{WS}	16
t_D	9

The second phase of the Read Hit state consists of the data being read on each clock pulse. Figure 51 shows the critical path through the MCC during this phase. The figure shows only one of the many data words being read. The data are put onto the Data_Out ports at each clock interval.

Figure 51. Critical Path Timing Diagram for Read Hit in Second Phase

The times used in Figure 51 are defined as follows.

t_{CP}: This is the time it takes for the clock pulse to traverse the **WORD_SELECT_CLOCK** component to be input into the **WORD_SELECT** component.

t_{WS}: This is the time it takes for the Word_Select vector to put its data onto the Word_Select_Bus after the Word_Selector_CP signal is input into the **WORD_SELECT** component.

t_D: This is the time it takes for the data to be put onto the Data_Out ports of the MCC after the Word_Select_Bus has received the data specifying the word to perform the read on.

t_{new}: This is the time it takes, after the data are on the Data_Out ports, for the clock to go high again to initiate another data word to be read.

The values of these times are given in Table 10. The total time, therefore, for the second phase of the Read Hit is given by

$$t_{RH2} = t_{CP} + t_{WS} + t_D + t_{new}$$

which calculates to 34 ns.

Table 10
Signal Times for the Second Phase of the Read Hit State

Time (ns)	
t _{CP}	7
t _{WS}	12
t _D	9
t _{new}	6

In the third and final phase of the Read Hit state, the MCC outputs all zeros on the Data_Out ports and produces a '0' on the Valid_Out port. This signifies that the Read Hit state is finished and any data on the Data_Out ports should not be considered valid. Figure 52 shows the critical path of this phase.

Figure 52. Critical Path Timing Diagram for Read Hit in Third Phase

The times used in Figure 52 are defined as follows.

t_{ws} : This is the time it takes for the WORD_SELECT component to use the Counting_Signal to reset the SHIFT_REGISTER and output all zeros onto the Word_Select_Bus.

t_D : This is the time it takes for the CAM array to output non-valid data and for this data to be put onto the Data_Out ports of the MCC.

t_v : This is the time it takes the MCC to output a '0' on the Valid_Out port after Data_Out becomes all zeros at the end of this state.

The values of these times are given in Table 11. The total time, therefore, for the third phase of the Read Hit is given by

$$t_{RH3} = t_{ws} + t_D + t_v$$

which calculates to 44 ns.

Table 11
Signal Times for the Third Phase of the Read Hit State

	Time (ns)
t_{ws}	32
t_D	9
t_v	3

An entire Read Hit cycle can be as short as 917 ns and as long as 934 ns. During the first phase of this state, the first clock pulse occurs, so in order to calculate the total time of the state we need to multiply t_{RH2} by 24 (assuming a prefetch block size of 25). The total time, therefore, for the Read Hit state, assuming the clock pulses at the same time the Counting_Signal goes high, is given by

$$t_{TOT} = t_{RH1} + 24t_{RH2} + t_{RH3}.$$

This equation calculates the total time for a Read Hit cycle to be 917 ns. But suppose the clock does not pulse at the same time Counting_Signal goes high. In this case, half a clock cycle could pass before Word_Selector_CP is effected. Therefore, 17 ns (assuming a clock speed of 34 ns) must be added to t_{TOT} , making the prefetch cycle last 934 ns.

Read Miss Analysis. The Read Miss state takes a total of 54 ns to complete before any other operation can be performed on the MCC. This is the minimum time required

for this state. Figure 53 shows the signals that make up the critical path for this state. The port Data_Avail_MEM is dependent on the speed of main memory. Figure 53 shows the earliest time Data_Avail_MEM can go high. The MCC will wait as long as necessary for this signal and for the data from main memory before writing into the CAM array.

Figure 53. Critical Path Timing Diagram for Read Miss

The signal WSR_Sel is the signal that is input into the multiplexers of the WORD_SELECT component and selects which shift register's outputs will be put onto the Word_Select_Bus. Word_Select is the array of signals that are output from the multiplexers and directly connected to the Word_Select_Bus. The other signals have been discussed earlier. The times used in Figure 53 are described as follows:

t_{SC}: This is the time it takes the Search_Complete signal to go high after the address is available to the MCC. The path for this time is through the SEARCH_STATUS component of THE_CONTROLLER.

t_{DAM}: This is the time between the Search_Complete signal going high and the earliest time the Data_Avail_MEM can be applied.

t_{WSR1}: This is the time it takes the WSR_Sel signal to go high after the Data_Avail_MEM signal goes high. The path for this time is through the SELECT_WORD_SELECT component.

t_{SW}: This is the time it takes for the signals to pass through the multiplexers of the WORD_SELECT component of THE_CONTROLLER.

t_{WSR0}: This is the time between the Word_Select signals changing and the WSR_Sel signal being reset to '0'. WSR_Sel is reset by the Read signal going through the FUNCTION_CHANGE_DETECTOR.

t_{Stab}: This is the time it takes the CAM cells to stabilize after all operations are completed in the Read Miss state.

The values of these times are shown in Table 12. The total time, therefore, for the Read Miss to complete is given by

$$t_{RM} = t_{SC} + t_{DAM} + t_{WSR1} + 2t_{SW} + t_{WSR0} + t_{Stab}$$

which calculates to 54 ns.

Table 12
Signal Times for the Read Miss State

	Time (ns)
t _{SC}	16
t _{DAM}	2
t _{WSR1}	16
t _{SW}	2
t _{WSR0}	11
t _{Stab}	5

Write Hit Analysis. The Write Hit state requires 47 ns to complete. Figure 54 shows the critical paths during this state. Again, this is a minimum time. The Write signal supplied by the CPU is the deciding factor as to how long the MCC remains in this state once it is entered. Figure 54 shows the earliest time allowed for the Write signal to be taken low. It can stay high for as long as needed provided the correct address and data are applied to the MCC.

The signal Word_Selector_CP is the input signal to the clock port of the SHIFT_REGISTER. The other signals in the figure have previously been discussed. The times used in Figure 54 are described as follows:

t_{SC}: This is the time it takes the Search_Complete signal to go high after the Address is available to the MCC. The path for this time is through the SEARCH_STATUS component of THE_CONTROLLER.

t_{CP}: This is the time it takes for the Word_Selector_CP to go high after the search is complete (i.e., Search_Complete = '1'). The path for this time is through the WORD_SELECT_CLOCK of THE_CONTROLLER.

t_{WS}: This is the time it takes for the Word_Select signal vector to put the correct data onto the Word_Select_Bus for the write operation to occur.

Figure 54. Critical Path Timing Diagram for Write Hit

Word_Selector_CP is the signal that clocks the Resolved_Signal_Tag vector into the SHIFT_REGISTER. The path for this signal is through the WORD_SELECT component of THE_CONTROLLER.

t_{FC} : This is the time it takes after the Word_Select vector puts the data onto the Word_Select_Bus for the write, and before the vector is reset to all zeros. Function_Change is triggered by the change in the Write signal.

Function_Change then resets the SHIFT_REGISTER.

The values for these times are given in Table 13. The total time needed for the Write Hit state is given by

$$t_{WH} = t_{SC} + t_{CP} + t_{WS} + t_{FC}$$

which calculates to 47 ns. One nanosecond later the next request can be honored.

Table 13

Signal Times for the Write Hit State

	Time (ns)
t_{SC}	16
t_{CP}	7
t_{WS}	12
t_{FC}	12

Write Miss Analysis. The Write Miss state takes a total of 44 ns to complete. No further action is required of the MCC in this state but it still needs time to perform the search and reset itself for the next operation. Figure 55 shows the critical path through this state. The total time is dependent upon when the CPU takes the Write port low. Shown in Figure 55 is the soonest time the Write port is able to go low without the MCC producing undesired results.

Figure 55. Critical Path Timing Diagram for Write Miss

The times used in Figure 55 are described as follows:

t_{SC}: This is the time it takes the Search_Complete signal to go high after the Address is available to the MCC. The path for this time is through the SEARCH_STATUS component of THE_CONTROLLER.

t_w: This is the time between when the Search_Complete signal goes high and the Write port is able to go low.

t_{wFC}: This is the time it takes the FUNCTION_CHANGE_DETECTOR to output the signal Function_Change after Write goes low.

t_{fS}: This is the time it takes the Function_Change signal to reset the D-type flip-flop in the SEARCH_STATUS component.

The values for these times are given in Table 14. The total time needed for the Write Miss state is given by

$$t_{WM} = t_{SC} + t_w + t_{wFC} + t_{fS}$$

which calculates to 44 ns. At that time the next operation can be performed by the MCC.

Table 14
Signal Times for the Write Hit State

Time (ns)	
t _{SC}	16
t _w	4
t _{wFC}	8
t _{fS}	16

Possible Improvements. One possible improvement for the overall speedup of the memory subsystem is to use a buffered write-through policy. This will allow the CPU to continue its operations without having to wait on main memory to finish a write. This can be accomplished by adding buffer registers to the MCC. Therefore, when the CPU requests a write operation, the MCC will write the data into the buffers. The CPU can then continue working while the MCC waits for the data bus. When the data bus is free, the MCC places the data onto the bus and main memory writes these data into its storage.

A disadvantage to using this policy is the addition of complexity to the MCC. By adding write-through buffers, more control logic will be needed on the chip. This will not only add to the complexity of the chip but it will possibly decrease its storage capacity. The trade-off is speed versus space. If the buffers are used, the CPU can continue its operations without having to wait on main memory. On the other hand, will the decrease in memory storage in the MCC be enough to reduce the amount of structural locality the MCC can hold? Probably not, and since the purpose of this research is to speed up a computer as much as possible, a buffered write-through policy would be advantageous.

The CHANGE_DETECTOR component was used liberally throughout the design to detect a change in a desired signal. The output of the CHANGE_DETECTOR would go high for a short period of time then go low. This period of time was somewhat arbitrarily chosen to be 5 ns. The output needed to be '1' for a short enough period of time not to slow the MCC down too much, yet be longer than the inertial delays of the gates it entered. This period could be shortened to 4 ns since the longest inertial delay of any gate it enters is 4 ns. Table 15 shows the time savings in each of the four states and the component in which the savings could be realized. It is worth noting that the OPERATION_STATUS also contains a CHANGE_DETECTOR but the change would only affect the Data_Out_Available port and not the overall speed of the MCC.

Table 15

CHANGE_DETECTOR Time Savings (ns)

	Read Hit	Read Miss	Write Hit	Write Miss
SEARCH_STATUS	1	1	1	1
WORD_SELECT	3			
FUNCTION_CHANGE_DETECTOR	1	1	1	1
WORD_SELECT_CLOCK		1		
Total Time Savings	5	3	2	2

The main goal of the SEARCH_STATUS component of the CONTROLLER was to allow the CAM array plenty of time to do the initial search before any further operations were performed. By adding an Address_Enable port to the MCC, much of the logic contained in this component can be eliminated. Figure 56 shows a recommended design for the SEARCH_STATUS. The total time savings by implementing this new design is 3 ns during each state of the MCC. Currently, the SEARCH_STATUS component takes 16 ns to complete its operations. In the new design, 13 ns is all the time required: 5 ns through the CHANGE_DETECTOR and 8 ns to accomplish a write into the D-type flip-flop.

The design of the MCC did not consider prefetching data above the current TOS pointer. An obvious way to see the problem this presents is during the initial operations of the MCC in the memory system. If a Read Hit state is entered before the CAM is filled with data, it is possible that bad data above the TOS pointer could be prefetched. If the CAM array is filled with data, a similar situation can occur. Since the TOS pointer is pointing at the top of the stack, any prefetches beyond the pointer retrieve data from the bottom of the stack, thus potentially destroying the prefetch of structural locality. This problem can be fixed by comparing the output of the SHIFT_REGISTER (containing the prefetch pointer) with the output of the TOS_SHIFTER (containing the TOS pointer). When the outputs are the same, the prefetch cycle should be shut down.

Figure 56. New Design of the SEARCH_STATUS Component

Space Savings. Time was a major factor during the designing and building of the MCC in VHDL that prevented the consideration of space savings on the final hardware chip. In this section, the major areas recommended for redesign are discussed. The resulting decrease in the number of transistors will allow the hardware product to be much smaller than it would be if the current design is used.

The CAM cell of Figure 28 is a primary component to consider for redesign. The cell, as it stands, would require 60 transistors to implement. This assumes implementation in CMOS technology without redesign and the number of transistors for each gate shown in Table 16. In contrast, some of the cells described in Chapter 2 of this thesis require only 5 transistors. This is 8.33% the size of the cell in Figure 28. If a 128 x 64 array of these CAM cells were built into the MCC, a savings of 450,560 transistors would be realized.

Table 16
Transistor Requirements for Gates of Figure 28

Inputs	Gate	Transistors
3	AND	8
	Inverter	2
2	NOR	4
3	NOR	6

The CAM cell used in this thesis has two output signals: RX and RY. RX is the complement of the cell content and RY is the actual value of the cell content. These two signals combined are exclusively-ORed to produce the validity bit. This bit is used during the read operation to determine if the data are valid when a multiple read occurs. Since the MCC writes data into the CAM array only when a read miss or a write hit occurs, the situation with multiple words containing the same address will never happen. Therefore, this port, the Valid_Out port, can be eliminated from the MCC. Consequently, a CAM cell with only one output signal is all that is needed.

Another possible place to save chip area is to replace the CAM cells used to store the data portion of the memory word with DRAM. The data portion of the word is never searched during the operation of the MCC. It is merely a storage device to read from and write to. Therefore, a CAM cell with search capabilities is superfluous in this application. A DRAM can store these data with better space efficiency and still be able to access the data quickly. DRAMs consist of only 1 transistor. Therefore, a DRAM is 1.67% the size of the CAM cell used in this thesis and 20% the size of a 5-transistor CAM cell.

Space can also be conserved by redesigning the PREFETCH_COUNTER component (Figure 24). This component uses a binary counter (Figure 19) to count upwards while comparing the result with a predefined value (the prefetch block size). While the values are not equal, the component outputs a '1' from the RS-type flip-flop onto the

Counting port. When the output of the binary counter equals the prefetch block size, the RS-type flip-flop is reset and the Counting port becomes '0'. If the binary counter were replaced with a count-down counter, the register holding the prefetch block size could be removed and the XNOR gates could be eliminated. The AND1 gate could then be replaced by a NOR gate, so when the count-down counter reached all '0's, the NOR gate would output a '1' and reset the RS-type flip-flop. These changes would reduce the complexity of the circuit and possibly increase its speed.

The new design of SEARCH_STATUS shown in Figure 56 has eliminated much of the required logic in that component. It allows the following gates to be deleted from the current design: two AND gates, two OR gates, and one NOR gate. In addition, only one change detector is needed, which eliminates the need for Address_length-1 XOR gates and buffers.

Two AND gates from THE_CONTROLLER can be eliminated. AND2 of the OPERATION_STATUS component has the same inputs as AND1 of the WORD_SELECT_CLOCK component. Also, AND4 of the OPERATION_STATUS component has the same inputs as AND2 of the WORD_SELECT_CLOCK. Therefore, in each of the two cases, one of the gates can be deleted provided the output of the remaining gate is used to satisfy the requirement of the one deleted. In an hierarchical design such as the design in this thesis, it is not surprising to find this type of duplication.

Hardware Implementation Issues

Some hardware issues could not be considered in this research since only the designing and VHDL implementation of the chip were performed. This section will provide a few areas to investigate before fabrication.

Since the address and data fields are of generic size on the MCC, the total number of pins on the chip is unknown at the writing of this thesis. Aside from the Data_In and

Address_In ports, only 12 other pins are needed. Therefore, a chip made with the data and address being 32 bits wide each, for example, would require 140 pins on the chip (i.e., $(32 + 32) \times 2 + 12 = 140$). These are typical word lengths but if pin-out does present an obstacle, a solution exists to circumvent the problem. A bidirectional buffer to hold the incoming address and data and output the out-going data could be used. This would add to the complexity of the chip but would decrease significantly the number of pins required and would allow for much larger address and data fields.

The number of cells in the CAM array is also not determined in this research. The number of CAM cells a signal can drive before losing its value is finite. Therefore, some form of signal enhancement must be used to allow a signal to propagate to all cells of the CAM array with enough power for each cell to perform the desired operation. The use of buffers is the usual means of performing this task. The location of these buffers must be determined by finding how many cells a signal can drive before losing too much of its value.

During the initialization phase of the MCC, the Master_Reset signal was used to fill the entire CAM array with zeros. This was necessary to avoid operations on Xs (unknowns) that are present in the CAM array upon startup. The problem with this approach is that there is likely an address in main memory made up of all zeros. So, if the CPU requests an operation on that address before the CAM array is filled with valid data, bad data could possibly be sent to the CPU from the MCC. As mentioned previously, a search is the first operation to be performed when the MCC is activated. A search on an X produces Xs on the tag lines, which is not acceptable in the completion of the state operations. A cell that can effectively use an X and output a '0' on the tag line during a search would be ideal. Another solution would be to resolve Xs to '0's on a resolved line. Before implementing this chip in hardware, this issue must be resolved.

Noise was a concern with the AT&T WE-32201 Integrated Memory Management Unit/Data Cache (IMDC). This chip is used to translate virtual addresses to physical addresses. A large noise spike can occur during a normal translation when many cells in the CAM discharge at once. The designers of this chip used very wide power and ground buses and multiple V_{SS} tub ties to keep the noise under 400mV. Therefore, noise should be considered during the implementation phase of the CAM chip described in this thesis. (5:595)

Summary

This chapter provided an in-depth analysis of the MCC. The complete functionality of the MCC was presented as well as the context of the MCC in a memory hierarchy. The performance of the chip model was carefully analyzed and it was determined that the Read Hit state took the longest to complete for an obvious reason: this is the state in which the prefetching of memory references occurs. The Read Hit state takes $57 \text{ ns} + (\text{Prefetch_Block_Size}-1)(\text{Clock_Period}) + 44 \text{ ns}$ to complete. During the testing of the MCC, the Prefetch_Block_Size was set at 25 and the Clock_Period to 34 ns, making the total time to complete the prefetch cycle 917 ns to 934 ns. The remainder of the states, the Read Miss, the Write Hit, and the Write Miss, take 54 ns, 48 ns, and 44 ns, respectively, to complete. The critical paths through these states were determined so the slowest components could be scrutinized for possible speedup. Some suggestions to increase the speed of the MCC were presented as well as potential areas for saving space on the chip. Finally, some hardware considerations were presented for further investigation before the chip is actually fabricated.

V. Conclusions and Recommendations

Introduction

The focus of this thesis has been a proof-of-concept on modeling a cache chip that stores memory references in the order they were used, and prefetching these locations in a FIFO manner so structural locality can be captured by a faster on-chip cache. A content-addressable memory was designed with this in mind. All of the functionalities of the main CAM cache (MCC) were accomplished and a working structural-level VHDL design of the chip was completed.

This thesis is the first iteration of research into the hardware realization of a memory hierarchy that exploits structural locality of memory references. The effort has shown that a main CAM cache that exploits structural locality is a feasible design. The product of this thesis was a VHDL design, starting at the gate level, of a CAM cache that prefetches memory locations in the order they were used by the CPU so an on-chip cache can capture structural locality and provide it to the CPU for fast processing.

Conclusions

The MCC was designed with a bottom-up approach. The functionality of the MCC was first determined; then the logic to implement the functionality was developed. The first operation the MCC performs when activated for any purpose is the search operation. After the search is complete, the MCC enters one of four states: Read Hit, Read Miss, Write Hit, or Write Miss. If the functionality of the MCC were any more complicated than this, then a bottom-up approach would not have been a good one and it may not have been possible to complete the design in one thesis cycle. The approach taken was more intuitive to this researcher. Even if a top-down approach were used, the time it would have taken to incrementally break down a top-level behavioral description into a

structural model would have come close to the time it took to accomplish the bottom-up design.

The functionality concepts of the MCC, i.e., the behavior of the MCC during each of the four states, were successfully implemented in the VHDL model of the MCC. During the Read Hit state, the MCC successfully prefetches the specified prefetch block size of addresses and data allowing another chip, the SLC chip, to write the data into its memory. Thus, structural locality is captured by the SLC. The MCC also writes data into its CAM array in the Read Miss state and writes over old data in the Write Hit state.

Recommendations

The MCC was designed and modeled using the VHDL hardware description language. Before the chip is actually fabricated and placed into a computer memory system, a few areas require further research.

In order for the memory subsystem to be complete, the SLC must be designed. The design will be very similar to that of the MCC. The SLC would have three active states: the Read Hit, Read Miss, and Write Hit states. During the Read Hit state, the SLC would read the requested data from its memory and provide it on its output ports. In the Read Miss state, the SLC would wait on main memory for the data and then write the data into its CAM array using a least-recently-used algorithm. The Write Hit state would act similar to, if not exactly like, that of the MCC. The Write Miss state would be an idle state just as it is in the MCC.

The fabrication of the MCC and the SLC would be the next logical step in building this memory subsystem. The size of the chip now becomes a factor. A CAM cell with as few transistors as possible and with the least power dissipation is recommended. Jones (10) presents some excellent arguments as to the selection of a CAM cell with these

two issues in mind. Once the cell is selected and designed, the size of the CAM array can be determined. From there, the MCC and the SLC can be fabricated.

Once the fabrication of the chips is complete, the computer system utilizing this memory subsystem can be bread-boarded and tested. The communications between the components on the bread-board will be similar to the concept shown in Figure 43. If a specially manufactured CPU with on-chip cache having the capability to communicate with the MCC could be produced, the need for the SLC residing off chip could be eliminated. This would allow for quicker on-chip responses rather than the off-chip communication delays.

Summary

The purpose of this type of research is to make computers run faster than ever. By exploiting structural locality, this goal can be reached. This thesis effort produced a design of a CAM cache that stores memory references in the order they were used by the CPU. The cache then provides these data, in a predetermined block size, to a faster cache (this cache captures the structural locality), which in turn provides the data to the CPU. The CPU can then access these data quickly.

Appendix A: The VHDL Code of the CAM Cell

This appendix contains the VHDL code of the CAM cell. It is the heart of the main CAM cache (MCC) chip. The entity is presented first, then the structure begins on a separate page.

PREFETCH_COUNTER

```
-----
-- Date:   5 September 1991
-- Version: 1.11
--
-- Filename: prefetch_counter.vhd
-- System:  ZYCAD, VLSI net
-- Language: VHDL
--
-- Description: This file contains the entity and structure of the prefetch
--              counter. The binary counter counts upward and is compared
--              using XNOR gates, for equivalence, against the output of the
--              register that holds the number of lines to prefetch. When
--              they are equal, the port "Counting" becomes a '0'. This
--              component allows a line of memory to be prefetched on every
--              clock cycle.
--
-- Associated files:
--   chip_pkg.vhd : This file contains constants, variables, etc. needed
--                  for this file.
--
-- History: Version 1.0 (26 July 1991)
--          Version 1.1 (16 August 1991) - changed inout mode of Counting
--          port to out and added signal Countingout to feed back into
--          the component.
--          Version 1.11 (5 September 1991) - changed prefetch block to
--          subtract 2 instead of 1 from Prefetch_Block_Size. This is
--          because the first read on a prefetch is not counted in the
--          prefetch cycle.

TOS_SHIFTER

```
-----
-- Date:   20 Aug 1991
-- Version: 1.2
--
-- Filename: TOS_shifter.vhd
-- System:   ZYCAD, VLSI net
-- Language: VHDL
--
-- Description: This file contains the entity and structure of a shift
--              register. This register is generic, i.e. you can make it any size you
--              want. The shift register uses edge triggered D flip-flops. It is a
--              circular shift register run by a clock. One unique feature which may
--              be a problem is that it takes 2 ns to stabilize; an inadvertent write
--              is possible. It is used to hold the top of stack pointer for the
--              word select register used to write into the CAM.
--
-- Associated files:
--   chip_pkg.vhd : This file contains constants,
--                  variables, etc. needed for this file.
--
-- History: Version 1.0 (1 Aug 91)
--          Version 1.1 (5 Aug 91) - modified component to clear outputs and
--          load first D FF with a '1' on initial clear.
--          Version 1.2 (20 Aug 91) - modified to handle additional CPnot
--          port of edge_triggered_DFF used to help reset the FF.

SEARCH_STATUS

```
-----
-- Date:   5 September 1991
-- Version: 1.3
--
-- Filename: search_status.vhd
-- System:   ZYCAD, VLSI net
-- Language: VHDL
--
-- Description: This file contains the entity and structure of the
--               SEARCH_STATUS component of the CAM chip controller. Its
--               purpose is to determine when the search cycle is complete.
--
-- Associated files:
--   chip_pkg.vhd : This file contains constants, variables, etc.
--                  needed for this file.
--
-- History: Version 1.0 (14 August 1991)
--          Version 1.1 (29 August 1991) - deleted the Search_Delay component.
--          Version 1.2 (3 September 1991) - added a DFF to hold the state
--          that the search has been completed.
--          Version 1.3 (5 September 1991) - added the port Counting to clear
--          the DFF flip-flop when the chip is prefetching. This prevents
--          the prefetch counter from resetting and starting over again.

WORD_SELECT

-- Date: 11 September 1991
-- Version: 2.0
--
-- Filename: word_select.vhd
-- System: ZYCAD, VLSI net
-- Language: VHDL
--
-- Description: This file contains the entity and structure of the
-- WORD_SELECT component of the CAM chip. It
-- contains the shift registers that act as the word select
-- inputs to the CAM array.
--
-- Associated files:
-- chip_pkg.vhd : This file contains constants, variables, etc.
-- needed for this file.
--
-- History: Version 1.0 (12 August 1991)
-- Version 1.1 (20 August 1991) - added port TOS_CPnot to
-- correspond to addition of port to edge-triggered DFF.
-- Version 1.2 (29 August 1991) - added an OR gate to clear the
-- DFF register of the Word_Selector with its output. Its
-- inputs are the Master_Reset and the Function_Change signal.
-- Had to change ports as a result.
-- Version 1.3 (4 September 1991) - added a DFF to hold the Sel0
-- line high during a read hit so the Word_Selector will shift
-- on the prefetch. Also added a CHANGE_DETECTOR to clock the
-- signal in.
-- Version 1.4 (5 September 1991) - added AND gate to feed the Clear
-- port of the Word_Selector. Now it can only be cleared when
-- not prefetching.
-- Version 1.5 (10 September 1991) - added a NOR gate to output to
-- the new Bit_Select port used to connect into the Bit_Select_
-- Bus.
-- Version 2.0 (11 September 1991) - This was a major change due
-- to adding the component controller to the cam_chip. Timing
-- was off and as a consequence data was being written into the
-- CAM array when it shouldn't have.
--

WORD_SELECT_CLOCK

-- Date: 10 September 1991
-- Version: 1.5
--
-- Filename: word_select_clock.vhd
-- System: ZYCAD, VLSI net
-- Language: VHDL
--
-- Description: This file contains the entity and structure of the
-- WORD_SELECT_CLOCK component of the CAM chip.
-- The outputs are fed into the word select registers and act
-- as the clock inputs to those registers.
--
-- Associated files:
-- chip_pkg.vhd : This file contains constants, variables, etc.
-- needed for this file.
--
-- History: Version 1.1 (21 August 1991)
-- Version 1.2 (29 August 1991) - took off the CP input into AND1.
-- Version 1.3 (5 September 1991) - added a buffer to the TOS_Clock
-- port so it will transition at the same time as TOS_ClockNot.
-- Version 1.4 (5 September 1991) - The TOS_Clock and TOS_ClockNot
-- ports go into the TOS_shifter. The values are valid after
-- the falling edge of the clock and the way I had it there was
-- no falling edge. To fix that, I put in CHANGE_DETECTORS to
-- give a rising and falling edge. I wanted this to occur only
-- when a Read was high so I ANDed this signal with the results
-- of the change_detectors. Also, Master_Reset port was used to
-- clock in the Master_Reset signal but the DFFs I'm using don't
-- need a clock to reset.
-- Version 1.5 (10 September 1991) - deleted the Read input into
-- AND3 gate. As long as Counting is '1' then a Read has been
-- requested.
--

end structure;

Appendix D: The VHDL Code for the CAM_chip and THE_CONTROLLER

This appendix contains the VHDL code of the CAM chip and the controller. The CAM chip is the highest hierarchical level of this thesis. The controller is a component on the chip and represents all control logic needed to exercise the CAM array. The entity of the CAM chip is first presented followed by the CAM chip's structural description. Finally, the VHDL of the controller is given.

CAM_Chip Entity

```
-----
-- Date: 9 September 1991
-- Version: 2.0
-- Filename: cam_chip_entity.vhd
-- System: ZYCAD, VLSI net
-- Language: VHDL
-- Description: This file contains the entity of the CAM chip.
-- Associated files: chip_pkg.vhd : This file is where the size of
--                               the CAM array is defined. Other
--                               declarations are also contained
--                               in this file.
--                               chip_pkg_body.vhd : This file contains the sub-
--                               routines Wired_And and Wired_Or
--                               used by the chip.
--                               cam_chip_structure.vhd: This file contains the structure
--                               of the CAM chip. It is formed by
--                               generating copies of the CAM
--                               cell.
-- History: Version 1.0 (3 May 1991)
--          Version 1.1 (12 June 1991) - replaced M, RX, and RY with the actual
--          outputs of the entire chip T, R, and P.
--          Version 1.2 (25 June 1991) - changed name of outputs to correspond
--          with cam_chip_structure wire connections.
--          Version 1.3 (3 July 1991) - added port Load to allow clock into
--          chip as input into registers.
--          Version 1.4 (15 July 1991) - changed ports to correspond to
--          changing input register to Address and Data register.
--          Version 1.5 (8 August 1991) - added ports for Valid_Out bit and
--          Resolved_Tags. These are preliminary changes to get ready to
--          go in and change what I have to what I really need.
--          Version 1.6 (28 August 1991) - deleted the bit select registers
--          and I will use only the MUXs. The MUXs will feed into the
--          Bit_Select_Bus.
```

```
--      Version 1.7 (30 August 1991) - deleted the MUXs and replaced them
--      with inverters since that is all they were acting as. Also
--      deleted registers to hold the Address_In, Data_In, and
--      Data_Out data and replaced them with buffers.
--      Version 2.0 (9 September 1991) - This version contains the
--      controller. As a consequence of adding the controller, a few
--      ports were added and some deleted.

THE_CONTROLLER

```
-----
-- Date:   12 September 1991
-- Version: 1.2
--
-- Filename: the_controller.vhd
-- System:   ZYCAD, VLSI net
-- Language: VHDL
--
-- Description: This file contains the entity and structure of the
--              chip controller. It provides the inputs to the CAM array.
--
-- Associated files:
--   chip_pkg.vhd : This file contains constants, variables, etc. needed
--                  for this file.
--
-- History: Version 1.0 (30 August 1991)
--          Version 1.1 (10 September 1991) - added a port to word_select
--              component (Bit_Select) so port on controller also had to be
--              added.
--          Version 1.2 (12 September 1991) - deleted port Counting since
--              Bit_Select does essentially the same thing.

Appendix E: Chip_pkg and dual_phase_clock

This appendix contains the `chip_pkg.vhd`, `chip_pkg_body.vhd`, and `dual_phase_clock.vhd` files. The file `chip_pkg.vhd` contains declarations for constants, types, and functions. The file `chip_pkg_body.vhd` contains the wired-OR, wired-AND, and conversion functions.

Chip_pkg

```
-----
-- Date:   9 September 1991
-- Version: 1.5
--
-- Filename: chip_pkg.vhd
-- System:  ZYCAD, VLSI net
-- Language: VHDL
--
-- Description: This file contains the package of the CAM chip. This is the
--              file used to define the size of the CAM array. This file
--              also contains other declarations.
-- Associated files: cam_cell_entity.vhd : This file contains the entity
--              description of the CAM cell.
--              cam_cell_structure.vhd : This file contains the gate level
--              design of the CAM cell.
--              chip_pkg_body.vhd : This file contains the sub-
--              routines Wired_And and Wired_Or
--              used by the chip.
--              cam_chip_entity.vhd : This file contains the entity
--              description of the CAM chip.
--              cam_chip_structure.vhd: This file contains the structure
--              of the CAM chip. It is formed by
--              generating copies of the CAM
--              cell.
--              chip_stimulus.vhd : This file exercises the chip and
--              provides inputs to test the chip.
--              chip_test_bench.vhd : This file contains the test bench
--              for the CAM chip.
--              chip_config.vhd : This file contains the
--              configuration of the system.
--              clock.vhd : You guess!
--
-- History: Version 1.0 (6 May 1991)
--          Version 1.1 (12 June 1991) - added Vector_Word_length and
--          Vector_Depth.
```

```
-- Version 1.2 (13 June 1991) - added function declarations for
--   Wired_Or and Wired_And as well as the various types used to
--   support them.
-- Version 1.3 (3 July 1991) - added funtion declaratation for
--   Wired_Or_To_MVL7_Vector.
-- Version 1.4 (15 July 1991) - changed Word_length to include
--   Data_length + Address_length.
-- Version 1.5 (9 September 1991) - added function declaration for
--   Wired_And_To_MVL7_Vector.
--

Chip_pkg_body

```
-----
-- Date:   9 September 1991
-- Version: 1.4
--
-- Filename: chip_pkg_body.vhd
-- System:   ZYCAD, VLSI net
-- Language: VHDL
--
-- Description: This file contains the package body that holds the
--               subroutines that can be accessed by any file. It currently
--               contains the Wired_And function to resolve the match bits
--               from each cell of the CAM array and the Wired_Or function
--               to resolve the output data and the validation data from
--               each cell.
-- Associated files: cam_cell_entity.vhd   : This file contains the entity
--                                     description of the CAM cell.
--               cam_cell_structure.vhd   : This file contains the gate level
--                                     design of the CAM cell.
--               chip_pkg.vhd             : This file is where the size of
--                                     the CAM array is defined. Other
--                                     declarations are also contained
--                                     in this file.
--               cam_chip_entity.vhd      : This file contains the entity
--                                     description of the CAM chip.
--               cam_chip_structure.vhd   : This file contains the structure
--                                     of the CAM chip. It is formed by
--                                     generating copies of the CAM
--                                     cell.
--               chip_stimulus.vhd        : This file exercises the chip and
--                                     provides inputs to test the chip.

end process;
end behavioral;
```

Appendix F: Test Code Used to Test the MCC

This appendix contains the VHDL code used to test the MCC. The files contained in this appendix are the stimulus file used to input data into the MCC, the test bench, composed of the MCC and the stimulus, the configuration file for the test bench, and a test run of the MCC using these files. The times in the test run correspond directly to the stimulus file.

The Chip Stimulus

```
-----
-- Date: 9 September 1991
-- Version: 2.0
--
-- Filename: chip_stimulus.vhd
-- System: ZYCAD, VLSI net
-- Language: VHDL
--
-- Description: This file contains the stimulus to test the CAM chip.
-- Associated files: chip_pkg.vhd : This file is where the size of
--                               the CAM array is defined. Other
--                               declarations are also contained
--                               in this file.
--                               chip_pkg_body.vhd : This file contains the sub-
--                               routines Wired_And and Wired_Or
--                               used by the chip.
--                               cam_chip_entity.vhd : This file contains the entity
--                               description of the CAM chip.
--                               cam_chip_structure.vhd : This file contains the structure
--                               of the CAM chip. It is formed by
--                               generating copies of the CAM
--                               cell.
--                               chip_test_bench.vhd : This file contains the test bench
--                               for the CAM chip.
--                               chip_config.vhd : This file contains the
--                               configuration of the system.
--                               clock.vhd : You guess!
-- History: Version 1.0 (10 June 1991)
--          Version 1.1 (12 June 1991) - changed M, RX, and RY to the actual
--          chip output ports T (match tag), R (data output), and
--          P (validation bit of data output).
--          Version 1.2 (25 June 1991) - changed inputs and outputs to vectors
--          (as opposed to matrices) to correspond to the actual inputs
```

```
--      and outputs of the chip. This change corresponds to Version
--      1.2 of cam_chip_entity and _structure.
--      Version 1.3 (3 July 1991) - modified times to correspond to the
--      change that the clock made.
--      Version 1.4 (16 July 1991) - changed data register to two separate
--      registers, one for the address and the other for data.
--      Version 1.5 (8 August 1991) - added ports for valid_out bit and
--      Resolved_Tags. These are preliminary changes to get ready to
--      go in and change what I have to what I really need.
--      Version 1.6 (28 August 1991) - deleted the bit select registers
--      and I will use only the MUXs. The MUXs will feed into the
--      Bit_Select_Bus.
--      Version 1.7 (30 August 1991) - In cam_chip_structure, deleted the
--      MUXs and replaced them with inverters since that is all they
--      were acting as. Also deleted registers to hold the Address_In,
--      Data_In, and Data_Out data and replaced them with buffers.
--      Thus, some of the timing of the stimulus had to be adjusted.
--      Version 2.0 (9 September 1991) - This version contains the
--      controller. As a consequence of adding the controller, a few
--      ports were added and some deleted.

The Test Bench

```
-----
-- Date:   9 September 1991
-- Version: 2.0
--
-- Filename: chip_test_bench.vhd
-- System:  ZYCAD, VLSI net
-- Language: VHDL
--
-- Description: This file is the test bench to test the CAM chip.
-- Associated files: chip_pkg.vhd      : This file is where the size of
--                                     the CAM array is defined. Other
--                                     declarations are also contained
--                                     in this file.
--                                     chip_pkg_body.vhd : This file contains the sub-
--                                     routines Wired_And and Wired_Or
--                                     used by the chip.
--                                     cam_chip_entity.vhd : This file contains the entity
--                                     description of the CAM chip.
--                                     cam_chip_structure.vhd : This file contains the structure
--                                     of the CAM chip. It is formed by
--                                     generating copies of the CAM
--                                     cell.
--                                     chip_stimulus.vhd  : This file exercises the chip and
--                                     provides inputs to test the chip.
--                                     chip_config.vhd    : This file contains the
--                                     configuration of the system.
--                                     clock.vhd          : You guess!
--
-- History: Version 1.0 (10 June 1991)
--          Version 1.1 (12 June 1991) - changed M, RX, and RY to the actual
--          chip output ports T (match tag), R (data output), and
--          P (validation bit of data output).
--          Version 1.2 (25 June 1991) - changed input and output types to
--          correspond to Version 1.2 of cam_chip_entity and _structure.
--          The input and output registers are now those ports described
--          by test_chip below. Changed T to Tag, R to Data_Out, and
--          P to Valid_Out.
--          Version 1.3 (3 July 1991) - added Load port on test chip to allow
--          for a clock input.
--          Version 1.4 (16 July 1991) - changed ports to correspond to
--          Version 1.4 of cam_chip_entity and _structure.
--          Version 1.5 (8 August 1991) - added ports for valid_out bit and
--          Resolved_Tags. These are preliminary changes to get ready to
--          go in and change what I have to what I really need.
--          Version 1.6 (28 August 1991) - deleted the bit select registers
--          and I will use only the MUXs. The MUXs will feed into the
--          Bit_Select_Bus.
```

```
--      Version 1.7 (30 August 1991) - deleted the MUXs and replaced them
--      with inverters since that is all they were acting as. Also
--      deleted registers to hold the Address_In, Data_In, and
--      Data_Out data and replaced them with buffers.
--      Version 2.0 (9 September 1991) - This version contains the
--      controller. As a consequence of adding the controller, a few
--      ports were added and some deleted.
--

Appendix G: The VHDL Code of Simple Memory System

This appendix contains the VHDL code of the simple memory system used to thoroughly test the MCC. It contains the code for a simple behavioral description of the CPU, the main memory, and the structural description of the memory system consisting of the CPU, main memory, and the MCC. The package containing the MEM_Delay constant and a function to convert hexadecimal values to MVL7 vectors is also included.

The CPU

```
-----
-- Date: 28 October 1991
-- Version: 1.0
--
-- Filename: cpu.vhd
-- System: ZYCAD, VLSI net
-- Language: VHDL
--
-- Description: This file contains a simple behavioral model of a CPU. Its
--               main purpose is to generate addresses to the bus with a
--               read or write request.
-- Associated files: chip_pkg.vhd : This file contains declarations
--                               for constants, types, functions,
--                               etc.
--               mem_sys_pkg.vhd : This file contains declarations
--                               for constants, types, functions,
--                               etc. specific to the memory
--                               system.
--               mem_sys_pkg_body.vhd : This file contains the function
--                               to convert hex numbers into
--                               MVL7_Vector.

Main Memory

```
-----
-- Date: 28 October 1991
-- Version: 1.0
--
-- Filename: mem.vhd
-- System: ZYCAD, VLSI net
-- Language: VHDL
--
-- Description: This file contains a simple behavioral model of a memory. Its
--              main purpose is to generate data to the bus when the CPU
--              requests a write or when a read miss occurs on the MCC. I
--              realize this is not the true function of memory, but in order
--              to simplify the testing of the CAM chip, it generates the
--              address on a write request. The MCC doesn't know any better
--              and that's what is being tested anyway.
-- Associated files: chip_pkg.vhd : This file contains declarations
--                               for constants, types, functions,
--                               etc.

-- Date: 24 October 1991
-- Version: 1.0
--
-- Filename: mem_sys_pkg.vhd
-- System: ZYCAD, VLSI net
-- Language: VHDL
--
-- Description: This file contains the function declaration of the function
--               that converts hex values to MVL7_Vector and constants.
-- Associated files: cpu.vhd : This file contains a simple behavioral
--                               description of a CPU. Its main function
--                               is to supply addresses and functions
--                               requests.
--                               mem.vhd : This file contains a simple behavioral
--                               description of main memory. Its main
--                               function is to supply data to the system.
