ABSTRACT

This thesis documents the development of an interim Small Autonomous Underwater Vehicle (AUV) Navigation System (SANS), a self-contained, externally mountable navigation package. The purpose of SANS is to determine the position of a submerged object of interest located by an AUV. The volume of SANS must not exceed 120 cubic inches and total system accuracy of 10.0 meters rms or better is required. An Inertial Navigation System (INS) is implemented to compute the ascent path during transit from an object of interest to the surface. INS hardware components include miniature spin gyroscopes, a compass and a depth transducer interfaced through an analog to digital converter. Global Positioning System (GPS) is used to determine the AUV's location after reaching the surface. The reciprocal of the ascent vector is applied to the AUV's GPS position to accurately determine the location of the target of interest. A primarily object-oriented software architecture is implemented here with extensive software testing to verify the proper operation of key modules.

The objective of this thesis is to quantify the adequacy of the selected components in meeting these requirements and to develop a breadboard design demonstrating the basic functions of the interim SANS. This research concludes that the components selected for the interim SANS meet the accuracy requirements provided the AUV maintains a climb angle which is equal to or steeper than 12 degrees from a typical mission depth of 20 meters.

ACKNOWLEDGMENTS

The author wishes to express his admiration and appreciation to Dr. Se-Hung Kwak who served as primary advisor in this research. His broad base of experience contributed immeasurably to the learning process. Dr. Kwak helped me to "understand" more about computer hardware during the design of the gyroscope driver described in the text than I have "learned" in hundreds of hours of instruction. Most of all, his contagious enthusiasm and eternally cheerful smile spurred me on in the darkest of hours.

A debt of gratitude is certainly owed to Dr. James Clynch, who served as second reader. His careful guidance and wisdom broadened the author's appreciation for the concepts involved in systems engineering and scientific research. His willingness to spend long hours in assisting the author, often at short notice, contributed immeasurably to the quality of the finished product while greatly relieving the stress involved.

Dr. Robert McGhee has been a great pleasure to work with and to know. His steady guidance as principal investigator has and will most certainly continue to make valuable learning experiences such as this available to many students.

Mr. Russ Whalen provided the technical knowledge which made this entire research practical. Above all else, his friendship provided a sanity check when needed most.

Last, but certainly not least, the author wishes to thank his wife, Cathy, and his three wonderful children, Laura, Greg, and Alyssa. They have selflessly given the understanding and support which made the successful completion of this work possible.

I. INTRODUCTION

A. BACKGROUND

Many of the missions proposed for Autonomous Underwater Vehicles (AUV's) require a high degree accuracy in navigation. The Global Positioning System (GPS) provides perhaps the most accurate navigation information currently available. The feasibility of incorporating GPS into a Small AUV Navigation System (SANS) was evaluated by the thesis of James Bernard McKeon with a favorable assessment. Some major concerns addressed by McKeon were accuracy, acquisition time (to limit the probability of counter-detection) and power consumption. [Ref. 1]

B. PURPOSE

There are two distinct phases embodied in the eventual employment of a SANS. The first of these is the transit phase involving navigation of the AUV from a launch position to an area where an underwater mapping mission is to be conducted. After the mapping mission is complete, the AUV will transit back to a recovery position. This mission may involve waypoint steering and artificial intelligence applications such as obstacle avoidance. The second distinct phase called the mission phase involves execution of the mapping mission. The objective here is to determine the locations of underwater objects identified by the AUV in the area of interest.

The purpose of this thesis is to document the development of an interim system meeting the mission execution (mapping phase) objectives of the SANS. Specifically,

this interim system will occupy less than 120 cubic inches and will demonstrate the feasibility of determining the position of a submerged object located by an AUV to within 10 meters. The term AUV should include any small underwater vehicle which could easily carry such a compact device.

C. PRINCIPLES OF OPERATION

The interim system seeks to incorporate GPS position fixing into the SANS. In order to resolve the location of a submerged object, two problems must be solved. First, the path travelled from the submerged object to the surface must be determined since GPS signals cannot penetrate water. Secondly, the AUV's position on the surface must be accurately determined so that the location of a submerged object may be resolved by applying the reciprocal of the ascent path.

Commercially available inertial navigation systems will soon exist which exceed the accuracy requirements and are compatible with the volume requirements of SANS. This would permit identification of multiple targets with only occasional GPS updates for navigation accuracy. This capability will be explored in future research. In the interim SANS, a pop-up mode is employed in order to locate each underwater object. The AUV's ascent path is calculated trigonometrically by measuring the depth change, pitch angle and compass heading throughout the ascent. On the surface, data from the GPS receiver is recorded to resolve the location of the target through post-processing.

D. SCOPE OF THESIS

This thesis reports the findings of the second year of research in an ongoing research project. The objectives of this thesis are limited to defining the hardware and software architecture required to conduct the mapping phase of the mission. These objectives are described by McGhee et al. and include [Ref. 2] :

- a. Low Power Consumption. Operation from an external battery pack for 24 hours is desirable.
- b. GPS antenna exposure time in survey area should be minimized. Up to 30 seconds exposure allowed but intervals between such exposures should be as long as possible, exceeding several minutes at a minimum.
- c. The GPS antenna should present a very small cross section when exposed and should not extend more than a few inches above the surface.
- d. For the mapping phase of the mission, system positioning accuracy of 10 meters rms or better is required with post-processing, submerged as well as surfaced.
- e. Total volume not to exceed 120 inches. Elongated, streamlined packaging is preferred.

The feasibility of meeting the objectives of the mapping phase is demonstrated initially by a "breadboard" system design. The performance of individual components is assessed through analysis of data collected from the "breadboard" system operating onboard an instrumented golf-cart traversing a surveyed test track. Eventually, a "wet design" prototype is planned which will be carried externally aboard the Naval Postgraduate School AUV-2 as part of a technology demonstration. The transit and

return phases characterized by more relaxed navigation accuracy requirements will be addressed in future research.

E. THESIS ORGANIZATION

This thesis explores hardware components required to implement the interim SANS and the software architecture to support this mission execution. While the technical expertise of the author lies more in the realm of the software design, both topics are covered in sufficient detail to ensure that the overall system performance satisfies the design objectives.

Chapter II reviews previous and ongoing work, especially that which relates to the incorporation of GPS and inertial navigation into AUV navigation.

In Chapter III, a detailed problem statement is presented. The requirements for the GPS serial line interface and translation of the binary format is examined. Problems related to the computation of the distance travelled from datum are discussed.

Possible solutions involving gyros or accelerometers to determine the climb angle are examined.

Chapter IV details the design of the SANS. Those characteristics of the individual hardware components which are significant to the design of the SANS are presented. The software design methodology and philosophy is presented in this chapter.

Chapter V delineates the process and results of software testing. Various approaches to testing are considered and a testing philosophy and strategy are developed. Reliability of key modules are examined.

In Chapter VI, the experimental data gathered during system validation is presented along with detailed analysis. The accuracy and adequacy of individual components is described with comparison to advertised technical specifications. The performance of the complete system is also assessed.

Chapter VII concludes with a summary of the results of this research. Future research topics are also described.

II. SURVEY OF PREVIOUS WORK

A. AUV NAVIGATION

As stated by McKeon [ref. 1]:

Approaches to navigating of AUV's fall into two different categories: sensor based navigation and external signal based navigation. Sensor based navigation refers to an AUV navigational system that is self contained.

For AUV missions of extended duration (in excess of 100 hours), current sensor based navigation systems alone are considered incapable of providing the accuracy necessary to perform precise mapping operations. Most external signal navigation systems require continuous exposure of some sort of signal receiver. This is a serious restriction which negates many of the advantages of an AUV. McKeon proposes a navigation system combining the strengths of sensor based and external signal based navigation systems for AUV navigation. [Ref. 1]

Previously, the most widely available forms of external signal navigation systems were Loran and Omega. Both of these are considered unsuitable for AUV navigation due to limited coverage, relative inaccuracy and the requirement for uninterrupted signal reception in Loran.

B. INCORPORATION OF GPS INTO AN AUV

With the Initial Operational Capability (IOC) of the GPS satellite network in 1993, continuous worldwide GPS coverage will be available [Ref. 3]. This combined with the accuracy of GPS shown in Table 2.1 makes it an ideal candidate for use as an

**TABLE 2.1 : GPS POSITIONING ACCURACY
(IN METERS)**

	PPS	SPS
NON-DIFFERENTIAL	16	100
DIFFERENTIAL	2-4	2-4

external signal navigation source in AUV's. McKeon provides a detailed analysis of the expected accuracy of an AUV based GPS receiver with consideration for the requirement to minimize antenna exposure. A navigation solution was achieved in 30 seconds or less with a 57% success rate (86 of 150 cases). The position errors fell within the expected range with a standard deviation of horizontal error of 29 meters. [Ref. 1]

Dr. SeHung Kwak developed an assembly language serial line interface for a GPS receiver during implementation of a Suitcase Navigation Data Logger (SNDL) [Ref. 4]. This interface is used extensively in the implementation of the GPS and AUV communications here because of its compatibility with Ada, the development language for SANS.

C. INERTIAL NAVIGATION IN AUV'S

In Reference 2, McGhee et al. examine the incorporation of available inertial navigation systems into an AUV. These systems include fiber optic gyros, ring laser gyros and vibratory rate sensors. Analysis shows that systems exceeding the accuracy

requirements within the size and power consumption restrictions outlined in Chapter 1 are feasible and should be available in 1994. These findings are supported by the work of Hutchinson et al. in Reference 5.

The utilization of GPS to correct inertial measurements for navigation of an AUV is addressed by Brown [Ref. 6] and Nagengast [Ref. 7]. A model based on a medium grade INS using ring laser gyro's (RLG's) and combinations of high and low accuracy GPS was used to simulate actual conditions. The results from computer simulations matched expectations with one nautical mile per hour drift in the INS. Nagengast's estimate of GPS error is 43 meters (one standard deviation of horizontal error). This is larger than McKeon's result but still within the expected range.

In Reference 8, Miller develops an extended Kalman filter adapted for an AUV which seeks to optimize the INS navigation solution.

D. KALMAN FILTERING TECHNIQUES

A major objective in the incorporation of GPS into an AUV, especially in a tactical environment, is the requirement to minimize the probability of detection. The SANS must optimize the accuracy of the GPS position while minimizing the duration of antenna exposure. No previous work has been identified which addresses the incorporation of a Kalman filtering technique to update a navigation solution for an AUV using GPS data. This is due to the narrow scope of the problem in AUV navigation where antenna exposure must be minimized and time between exposures

may be large. Most commercial GPS receivers already incorporate some filtering technique internally to produce position fixes.

III. DETAILED PROBLEM STATEMENT

A. GPS NAVIGATION

"The GPS has two levels of accuracy, the Standard Positioning Service (SPS), and the Precise Positioning Service (PPS)." [Ref. 3] In SPS, an intentional inaccuracy is introduced into the satellite broadcast signals to degrade the accuracy of non-PPS receivers through a process called Selective Availability (SA). This limits the accuracy of the GPS solution of non-PPS receivers in real-time to 100 meters (two standard deviations horizontal error) unless differential processing is used. PPS processing requires the use of cryptographic keys to decode and remove the error in broadcast signals and yields an accuracy of 16 meters as shown in Table 2.1. [Ref. 10]

The use of cryptographic keys aboard an AUV is undesirable. Even with relatively tamper-proof secure devices, the potential for loss causes concern. As seen in Table 2.1, real-time differential processing or differential post-processing can improve GPS accuracy to 2-4 meters (SA on or off) negating any advantage of processing with SA off. This also alleviates the concern of placing cryptographic keys aboard an unmanned vehicle.

A commercial GPS receiver manufactured by Motorola is being used to conduct research in the development of the interim SANS system. In order to achieve the objectives for accuracy during the mapping phase established in Section I.D.d, differential processing is required. To permit differential post-processing, the GPS

receiver transmits satellite range format messages containing "raw" (unprocessed) satellite range data. These messages are transmitted through a serial connection to the host computer where they are stored in non-volatile memory. A second receiver operating concurrently at a known location is used to determine and record the total error degrading GPS accuracy. This error includes inaccuracy due to atmospheric conditions and SA. The error in the range data recorded by the SANS is corrected during post-processing to yield the accuracy described in Table 2.1.

Position format messages, which are another message format transmitted by the GPS receiver, permit navigation updates during mission execution or during transit. Both position format and satellite range format messages are transmitted in Motorola proprietary binary format in RS-232 compatible serial stream. In position format messages, the latitude and longitude are 32-bit two's complement encoded in 4 bytes each. This binary format necessitates the development of a module capable of receiving, storing, and processing variable length binary data streams.

In order to conserve power, the GPS receiver must be unpowered when not in operation. Since this receiver cannot output position and satellite range format messages at the same time, initialization must provide for transmission of the appropriate message format depending on the current mission phase. During transit phase, the receiver must be initialized to transmit position format messages for position updates. During mapping phase, satellite range format message transmission must be initialized to provide satellite range data for post-processing.

B. SUBMERGED NAVIGATION

In order to calculate the distance from a submerged object to the surface where an accurate GPS fix can be obtained, the depth change, climb angle and direction of travel (heading) must be known. Heading is measured by a compass and depth change is measured by a depth transducer. The compass and depth transducer selected for use in SANS both produce an analog output which is converted to digital data by an Analog to Digital (A to D) converter. The specifications and interface for these are covered in the section IV.A (system hardware) and Appendix A (technical specifications).

Figure 3.1 and equation 3.1 illustrate the trigonometry involved in computation of horizontal distance. Figure 3.2 and equations 3.2 and 3.3 illustrate how heading and horizontal distance travelled are resolved into latitude and longitude components. Rather than computing a single vector travelled at the surface, SANS sums a series of vectors calculated for small increments of time during the ascent. This should improve accuracy due to frequent heading and climb angle changes through the ascent. A differential error analysis is conducted using this approach in section VI.D.2. In computing the horizontal distance travelled in equation 3.1, as the climb angle approaches zero, the horizontal distance travelled will approach infinity (the AUV will never reach the surface since the climb angle is zero). Therefore, the minimum climb angle consistent with system accuracy objectives for the interim SANS system must be quantified.

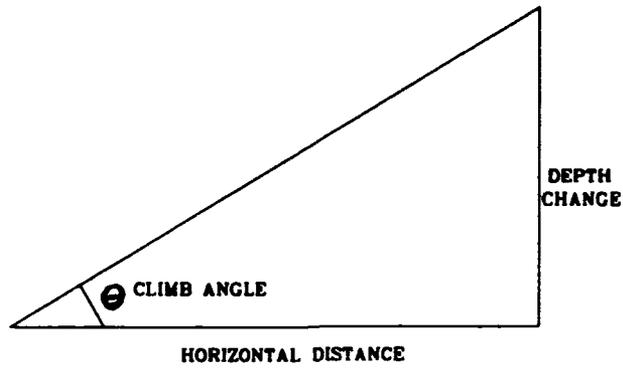

Figure 3.1 : Computation of Horizontal Distance Travelled

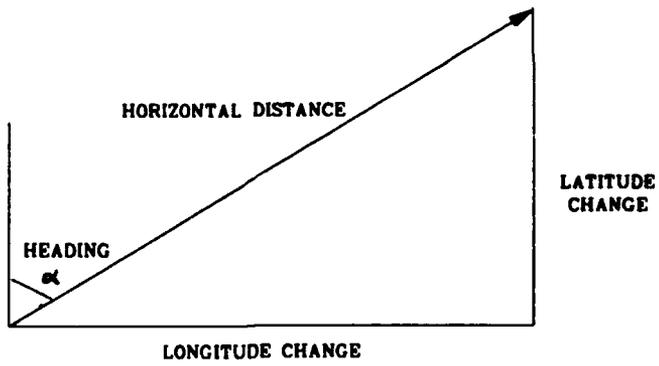

Figure 3.2 : Computation of Latitude/Longitude Change

$$s_H = \frac{DEPTHCHANGE}{TAN\theta} \quad (3.1)$$

$$\delta\phi = s_H * COS\alpha \quad (3.2)$$

$$\delta\lambda = s_H * SIN\alpha \quad (3.3)$$

Where θ is the climb angle.

ϕ is the latitude

lambda is the longitude

The measurement of the climb angle presents the greatest challenge within the space requirements of the SANS. Two approaches are developed here using a miniature gyroscope (gyro) and a single axis accelerometer.

1. Gyroscope

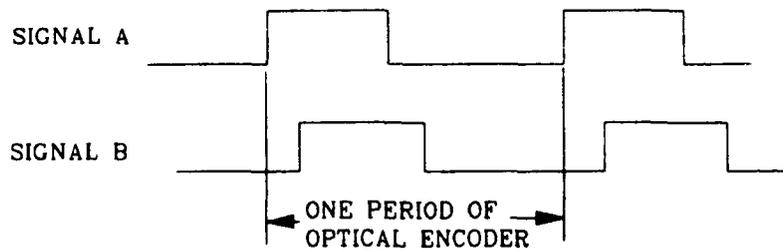

A miniature spin gyro manufactured by Gyration Inc. is small enough for use in SANS and has a very low power requirement (0.1 watts). While the drift rate of the gyro is high, it should be acceptable for the short period of time required to travel from a submerged object to the surface. The error rate of the gyro is evaluated and

impact on system accuracy are assessed in section VI.D along with other system hardware.

The gyro's rotational positional information is encoded in two phase and quadrature digital data signals as illustrated in Figure 3.3. These signals encode the output of an optical encoder. The direction of gyro rotation can be determined by observing which signal rises first and the amount of rotation can be determined by counting the number of pulses. One period of rotation in the optical encoder begins at the rising edge of a pulse in either output signal. The period includes both pulses in the pulse pair and ends at the beginning of the next rising edge in either output signal. One period represents 0.8 degrees of rotation in a low-resolution gyro (0.4 degrees in high-resolution). Only relative position is available from the gyro. The solution in SANS assumes a near level attitude for the AUV at the time an object of interest is located on the bottom. Climb angles during the ascent are relative to this assumed horizontal attitude.

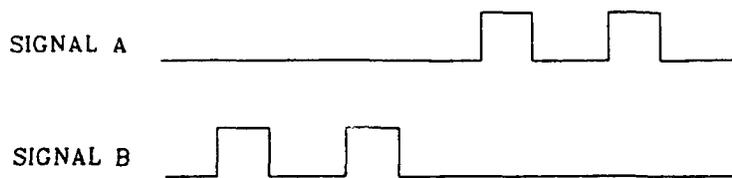

The manufacturer provides a development test box which converts this output into a serial data stream. This test box is too bulky for inclusion in SANS so use of gyro information necessitates development of a module to track gyro rotation. This rotation can be applied to the last known climb angle at regular intervals during the ascent to determine the gyro's new relative position.

A significant problem encountered by Gyration Inc. is high frequency noise in the output signal while the gyro is stationary as shown in Figure 3.4. This noise is

•NOTE : Overlapping pulses indicates valid gyro rotation

Figure 3.3 : Phase and Quadrature Signal Output

Note : Non-overlapping pulses indicate presence of noise only
(no valid gyro rotation is present)

Figure 3.4 : Noise in Phase and Quadrature Signal Output

random and can occur in one or both channels. The software solution developed to track gyro movement must filter out this noise. This can be accomplished by taking advantage of the fact that signals describing valid rotation must follow certain state transition patterns. These patterns will be used in the next chapter to develop a state transition algorithm to count valid state transitions while rejecting invalid state transitions as noise. The pulse count can then be incremented or decremented by the algorithm accordingly.

2. Accelerometer

A second approach which may be developed to determine climb angle in the SANS is inertial measurement based on an accelerometer. McGhee develops a finite approximation of climb angle using the output of a single-axis accelerometer. This is accomplished by sensing the component of gravity along the axis measured by the accelerometer. The longitudinal acceleration of the AUV is assumed to be negligible (constant velocity). This allows the x-axis (vertical) acceleration to be used to determine the climb angle. [Ref. 9]

McGhee points out that a measurement of rotation based on accelerometers will yield best results during low frequency rotation since the precession error in the gyro is predominant. The reverse is true during high frequency pitch attitude excursions where gyros are preferred since the effect of precession error is minimized. A hybrid solution using both accelerometers and gyros would optimize the strengths of each approach. [Ref. 9]

Similar logic applies in measuring heading change. The compass is preferred under stable conditions due to the predominance of precession error in the gyro. During a high rate of rotation, however, the directional gyro yields a better result since the effect of precession error is minimized. Again, a hybrid solution using the gyro to smooth compass heading changes during turns is preferred.

IV. SYSTEM DESIGN

A. HARDWARE DESCRIPTION

A brief description of each hardware device is provided here to summarize some of the significant characteristics essential to the design of the interim SANS. Appendix A provides a more detailed summary of each device's technical specifications. Figure 4.1 illustrates the hardware interface.

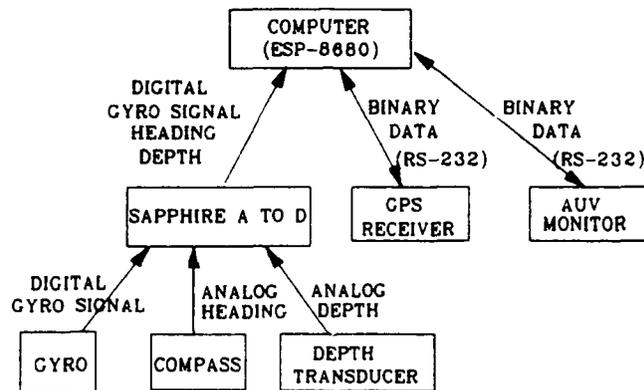

Figure 4.1 : SANS Hardware Devices Interface

1. Sapphire Converter

The Diamond Systems Sapphire card provides a variety of features. The key features utilized in the development of SANS are the Analog to Digital (A to D) conversion and the Digital to Digital (D to D) Input/Output (I/O) capability.

The Sapphire D to D interface provides a 7-bit digital I/O port through a DB-37 connector (37-pin). These include 3 input and 4 output pins. The DB-37 also provides a single external trigger input channel. A 24-bit general purpose I/O port is also provided through the 82C55 programmable interface. Each group of 12 pins may be programmed in sets of 4 pins and 8 pins as inputs or outputs. This permits definition of three 8-bit ports (A through C). Port C can be divided into 2 4-bit ports under mode control. Each of these 4-bit ports can be combined with an 8-bit port to provide 12-bit input/output if desired.

The analog interface provides 8 analog input channels through the software controlled input channel multiplexer. While there are 3 selectable voltage ranges (+/- 5 volts, 0-10 volts and +/- 10 volts), the multiplexer can actually tolerate voltages of up to +/- 32 volts. 8-bit output resolution (1 part in 256) or 12-bit output resolution (1 part in 4096) with a 20 micro-second A to D conversion time is software selectable for each analog input channel. [Ref. 10]

One serious limitation imposed by the Sapphire converter is the availability of only a single interrupt input channel. This restricts the current software architecture to tracking a single gyro at any given time. The interface chosen for the target machine should have at least two interrupt channels so that the directional gyro may be used to aid in heading updates. This is especially important during high rates of turn as discussed in Section III.B.2.

2. Core Module

The Dover Electronics ESP 8680 (Extra Small Package) core module provides an 8086 equivalent central processor. One megabyte Dynamic Random Access Memory (DRAM) is provided as well as two serial ports (RS-232). This module was chosen for its compactness (1.7 inches by 5.2 inches by 1/3 inch) and for its power conservation features. Several modes of operation are provided including full speed operation at 14 megahertz and a low power consumption "drowsy mode" operating at 1 megahertz. Typical power consumption is 0.2 watts at 8 megahertz [Ref. 11]. Two megabyte EPROM (Eraseable Programmable Read-Only Memory) non-volatile memory modules are currently available. 20 megabyte memory modules are expected to be available shortly. Additionally, the manufacturer is currently developing a miniaturized A to D converter with capabilities equivalent to the Sapphire A to D converter.

3. GPS Receiver

The Motorola PVT6 is a lightweight miniature GPS receiver capable of tracking six satellites simultaneously. The receiver is capable of real-time differential processing and can be upgraded to support PPS. Acquisition time is 24 seconds typical time to first fix with an accuracy of 100 meters with SA on without differential processing. With differential processing, 1 - 5 meters accuracy is probable.

When power is applied, the receiver is initialized in the mode that existed when power was last removed. The most recent valid coordinates are stored by the receiver

through reinitialization. This is accomplished by transmitting a formatted binary command (message) through the serial communication line.

Serial stream output is provided through an RS-232 standard interface in a variety of formats. These include National Marine Electronics Association (NMEA) standard format, Motorola Proprietary Binary format and LORAN input/output format. Although the NMEA standard format would be very attractive from the standpoint of compatibility between various receivers, the Motorola Proprietary Binary format was selected since it provides both satellite range information for differential post-processing and position format messages (although not concurrently).

4. Gyroscopes

The Gyration GyroEngine is an optically sensed miniature spin gyroscope (gyro). There are two varieties of gyro available from Gyration, vertical and directional. Both are used in this interim system. The vertical gyro inner gimbals encoder measures the pitch attitude of the AUV during ascent from the object of interest. Roll attitude measured by the outer gimbals is not of interest in this system. The directional gyro's outer gimbals reports yaw information and may be used to smooth the compass heading data during high turn rates.

The GyroEngine generates two phase and quadrature digital data signals from each gimbals encoder. A test box provided by Gyration, Inc. translates this signal into serial stream data interfaced through an RS-232 serial port connection. The test box is useful for evaluating the performance characteristics of the GyroEngine, but is too

bulky to be used in the SANS. A software solution has been developed to permit the GyroEngine to interface directly with the ESP-8680 through Sapphire A to D via Digital Input/Output (DIO). This solution is developed in Section IV.B.2.f and Appendix D.

5. Compass

The KVH C100 Multi-Purpose Digital Compass provides digital output in a 4 digit Binary Coded Decimal (BCD) serial stream format. Analog output is provided in the form of linear or sine/cosine voltage signal. Since the serial stream digital output would require an additional serial port connection in the ESP-8680, the compass analog output is interfaced through the Sapphire A to D converter. A linear voltage is produced proportional to heading in the range from 0.1 volts (000 degrees) through 1.9 volts (360 degrees). This voltage is converted to digital data by software triggered A to D conversion mode through the Sapphire A to D converter. The analog signal from the compass is connected to the Sapphire through one of 8 multiplexed input channels. This input channel is selectable in the parameters file A_TO_D.DAT at run-time.

6. Depth Transducer

The Omega Inc. PX176-100S5V Depth Transducer has an operating range of 0 to 100 pounds per square inch static pressure (PSIS). This equates to 6.7 standard atmospheres or 217 feet (67 meters) depth of sea water. Analog output is 1 to 6 volts direct current (DC). A to D conversion is performed by repetitive software triggered

single A to D conversions in the same manner as the compass signal with the analog input channel similarly selectable.

B. SOFTWARE ARCHITECTURE

The software design for the SANS, can be described at the highest level by three major operations. These are:

- Monitoring the AUV for a position fix request,
- Navigation data-logging for dead reckoning (DR) navigation (post-processed to determine ascent vector), and
- GPS data-logging for post-processed positional information.

AUV monitoring must be performed continuously in the event of a request by the AUV to determine the location of a submerged object of interest. This permits the GPS to be unpowered while the AUV is submerged and is intended as an energy conservation measure. DR navigation in the interim system consists of measuring the horizontal distance travelled from a submerged object to the surface as described in Figures 3.1 and 3.2. After the AUV reaches the surface, the GPS position is provided through a serial port connection from the Motorola GPS receiver.

The programming language used in the development of SANS is Meridian Ada version 4.1.1. Assembly language is used for low level, high frequency operations to improve efficiency. The object code for these assembly language modules are compiled by Borland's Turbo-Assembler and linked with the Ada object code using Borland's Turbo-Linker.

In order to produce a logical structure, a precise definition of design requirements is essential. "The primary product of this phase is an approved development (functional) software specification." as stated by Booch [Ref 11]. These requirements form the basis for development of the software structure. They also permit formulation of a test plan to evaluate the performance of the overall system and of individual modules.

a. AUV Monitoring.

AUV monitoring shall be performed continuously during the mapping phase so that when an object of interest has been located by the AUV, sufficient data may be recorded to determine the geographic position of the object. Communication with the AUV shall be via RS-232 serial line communication. DR navigation and GPS processing shall remain inactive with GPS unpowered (except for a low voltage applied to preserve static RAM (SRAM volatile memory) until the AUV requests a position fix.

b. GPS.

The GPS shall be initialized with the receiver in the Motorola proprietary binary format when the AUV requests a position fix. The receiver shall be programmed to transmit both position/status and satellite range format messages on a one second interval when initialized. The host computer shall be configured to receive RS-232 serial communications with connection parameters specified from an input data file at run-time. Upon mission termination, the host machine configuration shall

data file at run-time. Upon mission termination, the host machine configuration shall be restored to the state which existed prior to SANS execution. This is primarily to prevent side-effects due to improper configuration in the software development machine during software development.

All information received through the serial connection by the host machine shall be written to non-volatile memory prior to real-time processing. Satellite range messages will be recorded for post-processing only, while position/status information may be processed for navigation updates as necessary. Position format messages shall be processed to determine the current position and PDOP for navigation updates and the checksum to validate the particular message.

c. DR Navigation

DR navigation outputs shall include pitch attitude and heading in degrees and depth in meters. DR processing shall record input values with a precision commensurate with component accuracy and sufficient to satisfy system accuracy requirements specified in section I.D.d.

(1) Pitch Angle. Gyro position shall be monitored continuously by a process transparent to SANS operation. The process shall take a pair of standard phase and quadrature signals as inputs. Valid pulse pairs [Fig. 3.3] shall be counted on a continuous basis with each unit representing +/- 0.4 degrees of rotation depending on the direction of rotation. Invalid pulses from either signal [Fig. 3.4] are considered "noise" and shall be disregarded in the pulse count. The cumulative value of the pulse

count shall be continuously available for interrogation by the main procedure for DR navigation.

(2) A to D Conversions. Sapphire A to D conversions shall be initialized from a data file containing the multiplexed channels to be used for heading and depth inputs. Analog to digital conversion of analog heading and depth output shall provide 12 bit accuracy (one part in 4096). Digitized output shall be converted into meters for depth and degrees for heading.

2. Software Design

The object oriented design methodology described by Booch [Ref. 11] is used in the design of SANS. The object oriented approach was selected because it provides an advantage in the management of complexity of the system at the highest level over other design approaches.

As the system is decomposed hierarchically, some smaller elements are more logically approached using a functional design methodology. The functional design engineered by Dr. Kwak for the serial line interface was retained in SANS for both AUV monitoring and GPS processing. This approach is also well suited for the implementation of the procedure oriented assembly language driver for the gyro.

Booch suggests the following sequence in the object-oriented design approach [Ref. 11]:

- Identify the objects and their attributes

- Identify the operations that affect each object and the operations that each object must initiate
- Establish the visibility of each object in relation to other objects
- Establish the interface of each object
- Implement each object

a. Identify the Objects

The purpose of DR navigation in the interim system is to produce a vector travelled by the AUV from the submerged object to a position on the surface where a GPS fix is obtained. Figure 3.1 illustrates the computation of the horizontal distance travelled from the pitch angle and depth change during the ascent. Figure 3.2 describes the calculation of the change in latitude and longitude from the heading and horizontal distance travelled.

In order to accomplish the objectives of DR navigation, the AUV's heading, pitch angle and depth change must be accessed for each update cycle. This is accomplished repetitively in small increments throughout the ascent. These data items are treated as objects as described in Table 4.1. Every instance of each object type is stored in a file for post-processing. During post-processing, these values are used to calculate a heading and horizontal distance travelled by the AUV from the target located by the AUV to the surface. The reciprocal of this vector can be applied to the GPS position on the surface to determine the target's location. Determination of heading in this implementation is restricted to compass only due to the restriction of a

TABLE 4.1 : OBJECTS AND OPERATIONS ASSOCIATED WITH SANS

	OBJECT	OPERATION(s)
DR Navigation	Pitch Attitude	Current Value
	Depth	Current Value
	Heading	Current Value
	Delta_Lat_Long	DELTA_UPDATE
GPS Navigation	NAV_DATA_TYPE	PROCESS_GPS

single interrupt input channel in the Sapphire Converter. This restricts the ability to support a second driver to track rotation of the directional gyro.

The primary object associated with GPS is the class object NAV_DATA_TYPE. This object is generated by an operation PROCESS_GPS adapted from Dr. Kwak's functional implementation of a serial line interface in SNDL (see section II.D) consisting of latitude, longitude, position dilution of precision (PDOP) and time. Each position format message is processed to determine the position and PDOP to construct an instance of NAV_DATA_TYPE. The lowest level of PROCESS_GPS is the message interpreter MOTOROLA which replaces SNDL interpreters for other receivers. These receivers produce incompatible GPS message formats. Table 4.1 summarizes the objects essential to the operation of SANS at the highest level along with their associated operations.

b. Identify the Operations

The only operation associated with the basic elements of DR navigation is CURRENT_VALUE of that object. For heading and depth, this is accomplished through module A_TO_D. This module outputs a 12-bit digital value which is proportional in the range 0 through 4095 to the analog output of the respective instrument. These values are translated into appropriate units and written to non-volatile memory by CURRENT_HEADING and CURRENT_DEPTH respectively. Pitch attitude is tracked by an interrupt-driven service routine which may be queried for CURRENT_PITCH at any time by the main procedure.

c. Establish the Visibility

MONITOR_AUV interfaces directly with the AUV through a serial line interface to determine when an object of interest has been located by the AUV. It has no visibility of PROCESS_GPS or DR_NAVIGATION but simply relinquishes control to them when an update is requested. CURRENT_PITCH is invisible to all other operations as is PROCESS_GPS. Heading and depth analog to digital conversions both use A_TO_D but have independent routines for conversion to appropriate units.

d. Establish the Interface

The interface of objects is described fully by the specification of each package contained in the source code for SANS in Appendix B. Figure 4.2 illustrates the order of module dependency.

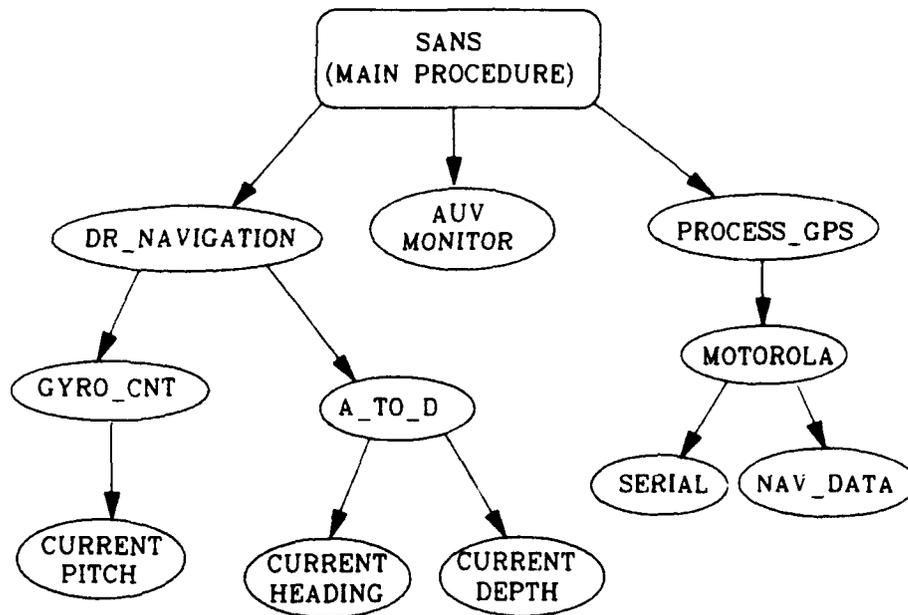

Figure 4.2 : Module Dependency Diagram

e. Implement Each Object (Analog Conversions)

The Sapphire A to D converter accepts control parameters through control registers 1 and 2 which are mapped to the I/O address space of the host CPU. The I/O address space map is shown in Table 4.2. Control registers 1 and 2 are accessed by offsetting the base address (factory preset at 300 Hexadecimal) by 2 and 3 respectively. Meridian Ada package Port provides procedure OUT_BYTE which writes a byte to the specified output port and function IN_BYTE which reads a byte from the specified input port.

TABLE 4.2 : SAPPHIRE I/O ADDRESS SPACE MAP

Offset From Base Address	Write	Read
0	8-bit A to D Trigger	4 LSB's from A to D
1	12-bit A to D Trigger	8 MSB's from A to D
2	Control Register 1	Status Register
3	Control Register 2	No Function
4	Counter 0 Register	Counter 0 Register
5	Counter 1 Register	Counter 1 Register
6	Counter 2 Register	Counter 2 Register
7	Counter Control Register	No Function
8	Port A Output	Port A Input
9	Port B Output	Port B Input
10	Port C Output	Port C Input
11	DIO Control Register	No Function
12-15	No Function	No Function

The sequence of operations in the A to D conversion is [Ref. 10]:

(1) Control register two is used to program the voltage range to be used (0 - 10 volts). The three least significant bits (LSB) in control register one select the multiplexed channel (0 to 7) matching the desired analog input port being utilized.

(2) After specification of the channel and voltage level to be used for the conversion, a switching time (minimum 8.5 micro-second delay) is programmed to

allow the multiplexed channel to stabilize at the analog input level. The conversion is then triggered by writing at the base address with an offset + 1 (301 hexadecimal). The written data can be any value but an ASCII character 1 is used for this specific application.

(3) After the conversion has been triggered, the conversion status register's most significant bit (MSB) indicates status of the conversion (1 indicates complete). This register is located at I/O address 302 hexadecimal (base address + 2). The register's contents are read in a loop using package Port's function IN_BYTE until the MSB indicates conversion complete.

(4) The conversion result is read from the two analog output registers using IN_BYTE. The 4 MSB's from the base address provide the conversion result's 4 LSB's (called the LSBS). The byte from base address + one provides the 8 MSB's (called the MSBS). The digital output value is determined by applying equation 4.1.

$$Value = MSBS * 16 + \frac{LSBS}{16} \quad (4.1)$$

The division by 16 in the LSBS simply removes the 4 LSB's from the register contents. The multiplication by 16 in MSBS shifts this byte 4 bits to the left.

f. Implement Each Object (Digital Phase Counting)

Pitch angle is one object used in the computation of horizontal distance travelled from the datum as shown in Table 4.1. Digital phase counting of gyro phase and quadrature signal outputs is accomplished by initialization of the interrupt service

routine. This requires that the interrupt vector table be modified so that the interrupt level used to interface the gyro input may be handled by the service routine. The service routine implements the state transition algorithm developed below to track valid state transitions. The service routine and algorithm are procedure oriented in nature. Therefore, a functional implementation for this object is appropriate.

Development of the device driver for the gyro was accomplished in three major phases. Initial development concentrated on determining the characteristics of the phase and quadrature output of the gyro through development of a timed polling system. The data collected by the polling system was used to develop and test a state transition model and algorithm to filter out noise and track gyro rotation through valid state transitions. Finally, after development of the state transition algorithm, an assembly language interrupt routine was developed with a service routine adapted from the state transition model.

(1) Polled Sampling System. A polled system sampling both outputs of a particular gimbals on a 1.0 millisecond interval was developed using the Sapphire 82C54 programmable interval timer. The phase and quadrature signals are designated lines A and B by Gyration's documentation. [Ref. 13] As illustrated by Figure 3.3, clockwise rotation of the gyro is indicated by a phase shift to the right (the level of signal A will still be low after signal B has risen). For each pulse, 0.4 degrees of rotation (0.8 degrees in low-resolution gyros) has occurred and the event counter is

incremented to reflect this. Counter-clockwise rotation is indicated by a phase shift to the left (signal A has risen before signal B) and the counter is decremented.

The phase and quadrature output of the gyro is interfaced through the Sapphire card in the Digital I/O (DIO) mode of operation. The inner gimbals output is used for pitch attitude information. Inner Gimbal A (IG-A) is interfaced through IP1 (pin 25 of the DB-37) and Inner Gimbal B (IG-B) is interfaced through IP2 (pin 26).

A 1.0 milli-second polling interval (1,000 Hz) represents a rate which significantly exceeds the gyro's highest rate of 10,000 rpm (167 Hz) at 5.0 volts. The 82C54 (programmable interval timer) in the Sapphire card is used to time the read operations. Mode 3 of the 82C54 provides a square wave through any of the 3 counters in the 82C54. An initial count N is written to the counter control register (base offset + 7) and the counter decrements the loaded value N until this value reaches zero. When this occurs, the counter produces one pulse and reloads the counter with initial count N. This sequence of operations repeated results in a square wave with a period of N clock cycles. Counter 2 is used for this application since its clock input is connected to the host computer's I/O bus clock. Therefore, calibration of the timer is dependent on the host's I/O bus clock speed. The 1.0 milli-second interval on the host machine with a 8.0 mHz I/O clock is achieved by programming an

$$\frac{8,000 \text{ CYCLES}}{8,000,000 \frac{\text{CYCLES}}{\text{SECOND}}} = \frac{1}{1,000} \text{ SECONDS} \quad (4.2)$$

initial count (N) of 8,000 into the counter control register. This produces a square wave with a period of 8000 clock cycles so that the gyro input is polled at a rate of 1,000 Hz at 8.0 mHz as shown in equation 4.2.

The current value of the digital inputs are read through the status register (Sapphire base offset + 2) with bits 5 and 6 representing quadrature input values at the time of the sampling. To extract the values of the 4 MSB's from the 8-bit input, divide by 16 to remove the 4 least significant bits (LSB's).

$$INPUT_BITSS-8 = \frac{INPUT}{16} \quad (4.3)$$

Take the remainder of a division by 4 to extract bits 5 and 6.

$$INPUT_BITSS-6 = REMAINDER \frac{INPUT_BITSS-8}{4} \quad (4.4)$$

Bit 6 is the result of a division by 2 and bit 5 is the remainder of a division by 2.

$$INPUT_BITS = REMAINDER \frac{INPUT_BITSS-6}{2} \quad (4.5)$$

$$INPUT_BIT6 = \frac{INPUT_BITS-6}{2} \quad (4.6)$$

The current phase and quadrature input is read once at the beginning of each 1 milli-second counting cycle. After the current phased quadrature inputs are recorded, the value in counter 2, which is accessed at I/O address 306 hexadecimal (base address + 6), is monitored until the counter cycle ends. Specifically, to read the count, the counter must first be "latched". This records the counter value for the read operation while allowing the counter to continue to decrement. To determine when a cycle has expired, the counter register value is monitored. When the value in the counter data register reaches zero, the counter control register writes back the initial count N (8,000). When this rise in the counter register is detected, the cycle has expired and 1.0 millisecond has elapsed. At this point, the status register is read to determine the current phase and quadrature signal levels and the sequence begins again.

The sequence of operations is the polled state transition counting is:

(a) Write the initial count ($N = 8,000$) to the counter control register to establish a 1.0 millisecond interval on an 8.0 mHz I/O bus clock.

(b) Read the status register of the Sapphire board and extract bits 5 and 6 (equations 7 through 10) to determine the current phased quadrature value of IG-A and IG-B.

(c) Monitor the counter by latching counter 2 and reading the value.

Repeat this process until the counter is incremented back to the initial count (8,000) then return to (a).

(2) State Transition Model Development. After the characteristics of the phase and quadrature output were determined through the timer based polling system, a state transition model was developed to track valid pulse pairs while filtering out "noise". The state represents the most recent value of the gimbals signals A and B where 0 is low (no pulse) and 1 is high. The state transition input similarly represents the new value of the gimbals signals and will always result in a transition to the corresponding state. The output is dependent on the path travelled in the transition, 1 for valid state transitions and 0 for invalid transitions.

If the states of the lines A and B are a and b, then the system state can be denoted ab. There are 4 possible states described by all combinations of a and b. Because the software senses only transitions of either a or b from 0 to 1, the state 0,0 is not visible to the software. Therefore, the software is designed around the three-state transition model in Figure 4.3. Figure 4.4 and Table 4.3 describe the tracking algorithm for the reduced state transition model.

The interrupt driven approach to digital phase counting results in two observable events in one period of the optical encoder's output. The beginning of a period is indicated by a transition to state 1 or state 3 since a pulse has occurred in either signal output. If the other output signal produces a pulse while the first signal is still high, a transition to state 2 will occur. In this case, the pitch count will be incremented or decremented as appropriate. Otherwise, the signal returns to state 1 or state 3 and the event is disregarded in the pitch count. Each unit of pitch count in the

```

Figure 4.6 : Three-State Transition Model Tracking Algorithm

three-state algorithm represents one period of the optical encoder (0.8 degrees of rotation in a low-resolution gyro). Verification of the algorithm is contained in Chapter V (Software Testing) and Appendix D.

(3) Interrupt-Driven Solution. The interrupt routine is modelled loosely after the serial line service routine developed by Dr. Kwak and used for GPS interface in SANS. LPT1 (level 7) is used as the interrupt number to interface interrupt inputs. The interrupt service routine implements the reduced state transition model which compares the current and previous state signals to track gyro rotation. [Ref. 12]

The interface of IG-A and IG-B (inner gimbals lines A and B respectively) is the same as for the polled system with an additional interrupt signal input. IG-A and IG-B are sampled immediately after each interrupt. Sapphire provides one interrupt input channel and the interrupt service routine requires rising edge trigger on either signal (IG-A or IG-B). An integrated circuit was developed by Dr. Kwak [Ref. 14] to generate distinct leading edges for interrupt triggers.

Each gimbals signal is first processed by a dual one-shot (74LS221) integrated circuit (IC). This IC generates a 10.0 microsecond pulse on the leading edge of the input signal pulse. The two signals are combined through a quad OR IC (74LS32) and input through INT.IN (pin 24 of the DB-37). The 10.0 microsecond pulse triggers the interrupt service routine. The service routine reads the value of each gimbals signals. These values are compared with the previous signal values as

illustrated in Figure 4.4 to determine what rotation, if any has occurred. A review of the major operations in the interrupt routine are contained in Appendix C.

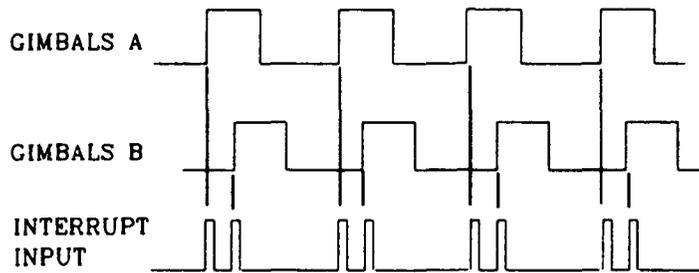

Figure 4.5 : Phase and Quadrature Interrupt Input Signal Generation

The driver developed performs very well as expected with the gyro in motion and at rest. The solution appears practical for the short duration, highly dynamic operations intended for SANS as verified in chapter VI.

3. GPS Update

The Suitcase Navigation Data Logger (SNDL) designed by Dr. Se-Hung Kwak establishes the framework for an RS-232 serial port interface to a GPS receiver. This design was kept largely intact for the GPS interface. The lowest level packages involving the GPS message translation were completely redesigned due to differences in receiver message format. The basic design philosophy for GPS processing in SNDL remains unchanged in SANS.

The AUV may request a GPS update during transit phase for a navigation check or during the mission execution when an object of interest has been located. As with

the gyro driver, the GPS serial line communication is established at each GPS update request and is terminated at completion of that update.

a. Serial Port Communication

When SANS detects an update request from the AUV, the GPS is powered up and INIT_GPS establishes the serial connection with the GPS receiver. The parameters for the connection are specified in the file SETUP.DAT. The initialization routine establishes a buffer where the interrupt service routine writes the bytes received through the connection.

Motorola proprietary binary message format was chosen for data transmission from the receiver. This is the only format which allows transmission of both position information for real-time navigation and satellite range information for post-processing.

PROCESS_GPS permits the main procedure to test for a GPS message by checking the buffer established during initialization through procedure READ_CHAR. The result of this procedure includes a status value which indicates whether the buffer has any new data (messages). When data is in the buffer, all data is processed before exiting to wait for another message. READ_CHAR is an assembly language program linked with the SANS program's Ada object code through pragma interface. Each character read through the serial interface is written to an output file for post-processing before any real-time processing.

b. GPS Message Translation

There are two message formats transmitted by the Motorola receiver.

Position format messages are 68 bytes in length and are distinguished by the 4 byte header @@Ba. The 122 byte satellite range response message is recognized by the 4 byte header @@Bg.

If the first 4 bytes of the message match the position format message, the message is processed to produce an instance of NAV_DATA_TYPE. This is a composite type (record) consisting of latitude and longitude in degrees, minutes and seconds, PDOP and time as described in Section IV.B.2.a. Package Nav provides a procedure for translating milli-arcseconds in long-integer into degrees and fractions of degrees.

Bytes 16 through 19 encode a 32 bit two's complement long-integer. This value represents the latitude in milli-arcseconds in the range +/- 324,000,000 (+/- 90 degrees). Bytes 20 through 23 similarly represent the longitude in the range +/- 648,000,000 (+/- 180 degrees).

To convert the 32-bit two's complement number (4 bytes) to long-integer format, the parity must be determined by comparing the first byte with 127. If the first byte is greater than or equal to 128 (40 hex), then the first bit is one and the value therefore represents a negative number in two's complement form. In this case, all 4 bytes must be converted to a negative equivalent by subtracting 255 from each. A boolean flag is set to trigger the subtraction operation on each succeeding byte.

Each byte is multiplied by the appropriate factor as shown in equation 4.7 to determine the long-integer equivalent.

$$LONG-INTEGER=BYTE1 * 2^{24} + BYTE2 * 2^{16} + BYTE3 * 2^8 + BYTE4 \quad (4.7)$$

The value of PDOP, taken from bytes 36 and 37, provides the relative quality of the position to aid in integration into the update solution. Byte 66 contains a checksum which is the exclusive OR (XOR) of bytes 3 through 65. This value is compared with a checksum produced by the Motorola processor. If the two values do not match, the position is disregarded. Each binary format message is terminated with a carriage return and line feed (ASCII characters 13 and 10). By monitoring for these bytes, the end of the message is recognized so that processing can begin on subsequent messages.

c. GPS Fixing

There are two types of GPS fixes which must be considered in the design of SANS. During transit phase, real-time processing of GPS messages is required to maintain navigation accuracy of 100 meters. The ultimate goal of SANS is to provide GPS information for post-processing and combination with DR submerged navigation ascent vector to allow the location of submerged objects with an accuracy of 10 meters.

The message header distinguishes the message format as described earlier so that only position format messages are processed real-time by SANS for navigation updates to produce instances of NAV_DATA_TYPE. During transit mode, several instances of NAV_DATA_TYPE will be produced while the AUV is surfaced. When the accuracy of the fix is considered adequate by the main procedure, GPS processing will be terminated until the next update request from the AUV. This accuracy assessment will eventually be based on PDOP and relation to previous positions through a Kalman filtering technique.

V. SOFTWARE TESTING

A. INTRODUCTION

In order to provide confidence in the software architecture developed for SANS, a systematic and thorough if not exhaustive testing process is essential. Booch [Ref. 11] states two goals in the design of software tests:

Primary goal : Preventing bugs from entering code by making potential mistakes and misunderstandings visible and by identifying incomplete requirements/design.

Secondary goal : clearly identifying if there is a bug by causing that bug to produce a result that conflicts with a specified or expected result.

SANS is a multi-year project which will progressively incorporate new technology components to achieve improved accuracy. The solution described in this interim SANS design considers primarily the tactical mission execution of underwater mapping. The architecture will expand in the next generation to include the strategic considerations involved in transit to and from the target area and optimization of the mapping phase.

The interim SANS originally utilized Ada tasking to permit concurrent operation of DR Navigation and GPS processing. This concurrency was eventually eliminated since the calculation of the ascent vector and GPS processing occurs consecutively vice concurrently. The resulting structure is much less complicated at the highest level.

While the higher level architecture will probably undergo further radical changes to meet expanding requirements, modules developed in the interim system will be reused to provide a foundation for implementation of the next generation SANS. Due to the nature of development objectives and the elimination of concurrency, the testing approach here concentrates much more heavily on verifying the correct operation of individual modules than of the overall system. A functional (black box) testing approach is consistent with the objectives of ensuring modular correctness.

B. CLASSIFYING REQUIREMENTS

The software system requirements are developed from Section IV.B.1 (Software Architecture : Determining Requirements). Requirements can be classified according to the approach used to verify compliance. The four classification levels are non-testable, inspection (of source code), dynamic analysis (of variable usage, comments, etc.) and execution (of compiled code with selected test data). [Ref. 11]

1. AUV monitoring shall be performed continuously during the mapping phase so that when an object of interest has been located by the AUV, sufficient data may be recorded to determine the geographic position of the object through post-processing. This requirement can be verified by inspection and is satisfied through a loop in the main procedure which "idles" all processes until a position update request is received from the AUV. This loop continuously monitors an RS-232 serial connection with the AUV for an update request message. After the update is complete, the loop is then re-entered until another request is received.

2. DR navigation and GPS processing shall remain inactive with GPS unpowered (except for a low voltage applied to preserve volatile memory) until the AUV requests a position fix. Satisfaction of this requirement with respect to software is verified by inspection of the source code which indicates that DR and GPS processing only occur following an AUV update request. The hardware design must also ensure that power is physically removed from these devices between requests.

3. When an update is requested, AUV_MONITOR shall initiate DR navigation and GPS processing. Inspection verifies that upon receipt of an AUV update request, the AUV monitoring loop is exited so that DR and GPS processing can commence. DR navigation data is collected until the AUV is surfaced where GPS satellite range data is recorded.

4. The GPS shall be initialized with the receiver in the Motorola proprietary binary format with transmissions at a one second interval after the AUV requests a position fix. This requirement can be verified by inspection of source code and through execution of the initialization routine which initializes the receiver in the configuration which existed when power was last removed.

5. The receiver shall be programmed to transmit position/status format messages during transit phase and satellite range format messages during mapping phase when initialized. This requirement has not yet been satisfied but can be verified by inspection. Compliance will occur at implementation of transit phase during future research.

6. The host computer shall be configured to receive RS-232 serial communications with connection parameters specified from an input data file at run-time. This requirement is verified through inspection and execution of the serial communication procedure.

7. Upon mission completion, the host machine configuration shall be restored to the state which existed prior to SANS execution. Inspection shows that the original interrupt masks and vectors are stored at initialization in the data section of the assembly language code for serial connections and gyro driver. These values are restored by CLOSE_SERIAL upon program termination. Prior to program execution, the DOS (disk operating system) program debug.exe is used to verify the current interrupt vector for affected hardware interrupt levels. After termination, DOS debug verifies that the vector table has been restored to its original condition.

8. All information received through the serial connection by the host machine shall be written to non-volatile memory prior to real-time processing. Inspection of package body Motorola shows that this requirement is satisfied since each execution of READ_CHAR is followed by a write to the output file prior to any other processing.

9. Position format messages shall be processed to determine the current position and PDOP for navigation updates and to determine the checksum to validate the particular message. Execution test cases are developed in Appendix F to ensure that position and PDOP are correctly interpreted.

10. DR navigation outputs shall include pitch attitude and heading in degrees and depth in meters. By inspection of the specification of DELTA_UPDATE, the inputs for DR navigation are confirmed. These values are recorded in non-volatile memory along with mission time.

11. DR processing shall record output values with a precision commensurate with component accuracy and sufficient to satisfy system accuracy requirements specified in section I.D.d. Chapter VI examines component and system accuracy to include an assessment of overall system performance.

12. Gyro position shall be monitored continuously by a process transparent to SANS operation. Inspection of the assembly language device driver for tracking gyro rotation shows that interrupts generated from the phased quadrature input are used to trigger an interrupt service routine to count valid pulses. The machine state is saved at each interrupt and restored after the interrupt is handled. Execution of benchmark processes to examine CPU processing limitations for handling interrupts from the gyro driver are detailed in Section V.D.

13. The process shall take a pair of standard phased quadrature signals as inputs. This requirement is verified through inspection of the assembly language device driver for the gyro as in requirement 12. The signals are interfaced through pins 25 and 26 of the Sapphire DB-37 connector.

14. Valid pulse pairs [Fig. 4.3] shall be counted on a continuous basis with each unit representing +/- 0.4 degrees of rotation depending on the direction of rotation.

This requirement is satisfied through analysis in section V.D.1.a of the 3-state tracking algorithm [Fig. 4.4] contained in section V.E.2.a. Execution test cases contained in Appendix E ensure that the algorithm is correctly implemented.

15. Invalid pulses from either signal (non-overlapping) are considered "noise" [Fig. 4.4] and shall be disregarded in the pulse count. As in requirement 14, analysis verifies the correctness of the algorithm with execution test cases in Appendix E validating the implementation.

16. The cumulative value of the pulse count shall be continuously available for interrogation by the main procedure for DR navigation. Verification of this requirement is accomplished through inspection of the assembly language gyro driver and inspection of the interface between the gyro driver and the main procedure.

17. Sapphire A to D conversions shall be initialized from a data file containing the multiplexed channels to be used for heading and depth inputs. Inspection of the main procedure and package ANALOG shows that the A to D conversion channels are selected from the input data file A_TO_D.dat.

18. Analog to digital conversion of analog heading and depth output shall provide 12 bit accuracy (one part in 4096). Execution of a range of analog inputs from a DC power supply were used to correlate voltage levels with digitized outputs. Inspection of the implementation in package ANALOG shows that 12 bit accuracy is provided.

C. IDENTIFY IMPORTANT CASES AND SELECT TEST DATA

1. Requirements 13 through 16 involve the accurate tracking of gyro rotation and is evaluated in two phases. The state transition tracking algorithm is first verified by informal proof in section V.D.1.a below. Test cases read from an input file are then executed to validate the implementation of the algorithm. Inputs with expected and observed results are contained in Appendix D.

a. There are 4 cases to examine in the 3-state transition tracking algorithm as shown in Figure 4.4. Appendix D contains examples of each state transition case along with results from test executions.

In cases 1 and 3, valid rotation has been indicated by a state transition from state 1 (clockwise rotation) or from state 3 (counter-clockwise rotation) to state 2. This is illustrated in Figures D.1 and D.2 respectively. The results of the test execution demonstrate that the `pitch_count` is correctly computed in each case. Figures D.3 and D.4 demonstrate that the algorithm correctly tracks a reversal in rotation as illustrated by a reversal in the order of rising edges in the gimbals output signals.

In case 2 transitions, the machine is returning to state 1 or 3 from state 2. This is usually an indication that a valid rotation has occurred in the previous sampling and a new pulse has been detected from one signal input. Figures D.1 through D.4 demonstrate that case 2 transitions are correctly discounted by the implementation.

In case 0, no state transition has occurred since the current state is the same as the last state. This is typically the case with noise in a single channel. Figures D.5, D.6 and D.7 demonstrate that no rotation is occurring in case 0 state transitions and also that this case is correctly discounted by the tracking algorithm's implementation.

Case 4 transitions are invalid state transitions between state 1 and state 3. This transition is caused by a pulse from one gimbal then the other where the pulses do not overlap. The likely cause of a case 4 transition is noise in both channels as illustrated in Figure D.8. Figure D.8 also demonstrates that this case is correctly discounted by the tracking algorithm.

2. Requirement 8 calls for the correct interpretation of the latitude, longitude and PDOP from position format messages. This requirement is evaluated through a test implementation of package MOTOROLA which reads a binary input file vice actual receiver messages. In this manner, all paths can be tested and a full range of edge cases can be executed.

The range of latitudes is +/- 324,000,000 degrees in milliseconds. For longitude, the range is +/- 648,000,000 degrees in milliseconds. Test cases include positive and negative two's complement values to exercise hemisphere interpretation and various message formats. Appendix E summarizes test cases with expected and observed results.

D. REAL-TIME PROCESSING VERIFICATION

The elimination of concurrent processing from the main procedure in the interim SANS has greatly simplified the timing requirements at the highest level. In the lowest level assembly language procedures employing interrupts, a statistical analysis is conducted here to evaluate the adequacy of the software development machine to handle the expected interrupts and processing requirements. Growth capability is examined for handling multiple gyros.

The software development machine was benchmarked for 10,000 sine operations to evaluate the effect of the interrupt service routine on central processor unit (CPU) availability. Execution of the sine operations with no other significant load required 306.795 seconds with a standard deviation of 0.085 seconds. After the sine operations were benchmarked, the driver for the gyro was loaded. Both the pitch and roll axis of the vertical gyro were interfaced through the single interrupt input channel to simulate multiple interrupt inputs.

The time to execute the same 10,000 sine operations with both gyro axis highly excited increased by 6.035 seconds with a standard deviation of 0.41 seconds. This is an increase of only 1.97 percent in execution time. The only other time critical processing requirement in SANS is the RS-232 (9600 baud) serial line connection which imposes a similar CPU load. The software development machine should handle such loads with no problems. These conditions should be reassessed when the software and hardware are moved to the ESP-8680 target machine.

VI. HARDWARE CHARACTERISTICS

All accuracy assessments made in earlier research are based on manufacturer's technical specifications. In order to validate these findings, field and laboratory test data are presented here with statistical analysis of those results. This chapter concludes with an assessment of overall system performance based on these findings.

A. MOTOROLA GPS RECEIVER

A major limiting factor in SANS accuracy is the accuracy of the GPS receiver. Extensive GPS data was collected with the Motorola PVT6 receiver to assess the impact on system performance. There are two broad test categories conducted in this research involving GPS. These tests evaluate the receiver for accuracy in a dynamic environment and for acquisition time in a static environment. The major limitation on the test results presented here is the absence of differential processing which has been deferred to future research.

1. GPS DYNAMIC TESTS

GPS dynamic tests were conducted onboard a modified electric golf cart (called the test vehicle). This platform is capable of a top speed of approximately 5 meters/second and provides both 12 volt DC from a deep marine battery and 110 volt alternating current (AC) through a DC to AC converter.

In order to assess the accuracy of field data, the test vehicle is specially instrumented to permit accurate tracking through a surveyed test track. Data is logged

by a general serial I/O handler developed by Dr. James Clynch called GEORGE. This program provides a wide variety of functions including a printer port status (PPS) which logs changes in the condition of the instrumentation devices interfaced through the printer port. [Ref. 15]

Test vehicle instrumentation includes an infrared (IR) sensor which detects reflective IR strips on the surveyed test track. The position of the centroid of the IR strips is known to an accuracy of approximately 1 centimeter. The vehicle is also equipped with a trailing bicycle wheel with magnetic sensors for recording longitudinal distance travelled and a "button" which allows the operator to manually mark some event. Dynamic tests were conducted at Fritzsche Army Air Field (AAF) at Fort Ord, California. The test track was surveyed to an accuracy of approximately 1 centimeter (cm).

The objective in the dynamic GPS data collection is to assess the dynamic accuracy of the Motorola GPS receiver relative to expected SPS accuracy. Fourteen test runs over a one hour period were conducted to gather data. Figure 6.1 illustrates the positional accuracy of the test runs relative to the known course. This is a plot of unprocessed GPS without respect to time.

In order to assess the accuracy of the GPS data, a comparison was made with test track events recorded by GEORGE's operation PPS. This time history will be called "truth data" due to its known relative precision of 1 centimeter. The host computer was corrected to universal coordinated time (UTC) via modem connection to

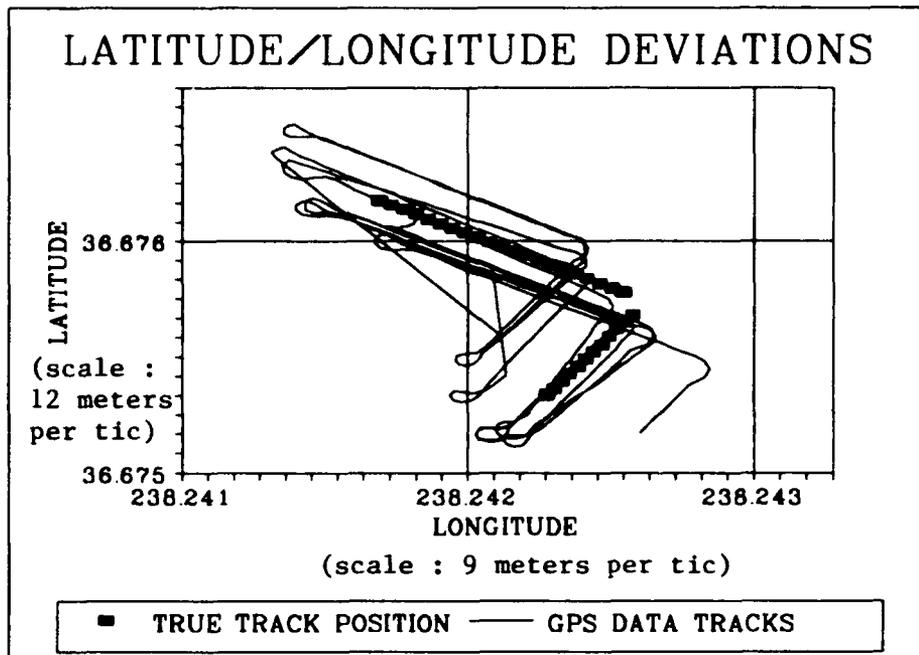

Figure 6.1 : Test Data Results Relative to Known Positions

permit correlation of GEORGE's time reference with GPS time (also recorded in UTC).

The GPS binary data was processed through package Motorola's test procedure to convert data of interest to character format for comparison with GEORGE's "truth data". GEORGE's PPS data was similarly processed to allow for comparison. The raw PPS file was first processed by package BIW (button, IR, Wheel) to identify each event according to its source. The BIW file was then manually processed with reference to the sequence of events recorded at the time of test. The purpose here is to identify the specific location of each IR marker in the "truth data" file for

comparison with GPS positions. The velocity was computed based on wheel revolutions with respect to elapsed time.

Finally, the processed GPS and truth data were correlated using a routine developed by Dr. Clynch called DIFDAT. This procedure compares a specified parameter, in this case time, in each file to interpolate between events occurring asynchronously in the two files. This permits an assessment of the accuracy of the GPS data relative to the known positions in the truth data even though the position times do not correlate exactly. [Ref. 16]

As can be seen in Figures 6.2 and 6.3 the standard deviation of error is 18.7 meters in latitude and 13.2 meters in longitude. This yields a positional error of 22.9 meters one rms which is well within the expected range for SPS accuracy. North and east velocity components were similarly processed from the raw GPS and truth data files. The error is 0.21 meters/second for north velocity components and 0.17 meters/second for east velocity components. This yields a rms velocity error of 0.27 meters/second.

2. GPS STATIC TESTS

Static tests were conducted using the Motorola receiver to assess acquisition time and first fix accuracy. These tests utilize an antenna mounted on the roof of Spanagel Hall at a surveyed location. This site provides a horizon relatively free from obstructions.

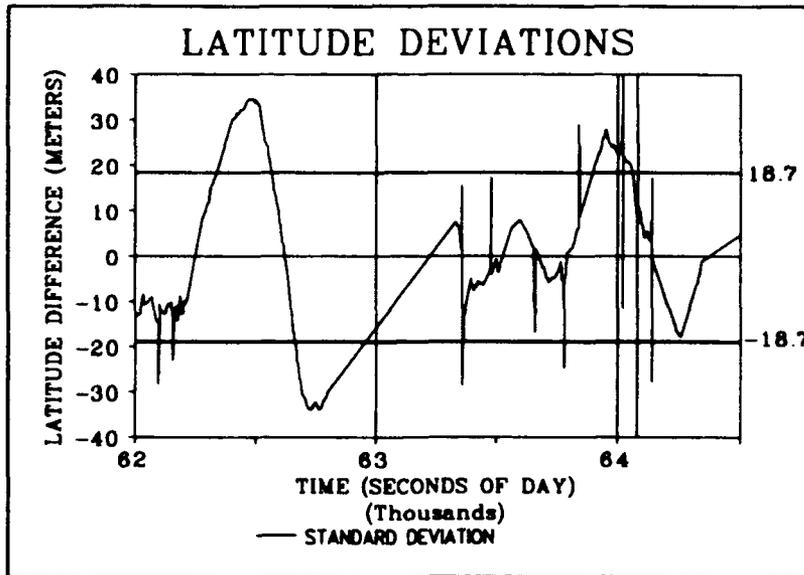

Figure 6.2 : GPS Dynamic Data Latitude Deviations

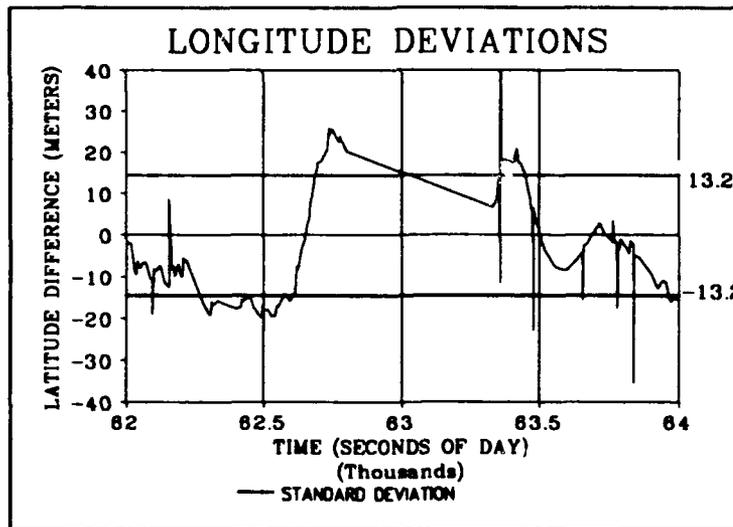

Figure 6.3 : GPS Dynamic Data Longitude Deviations

GEORGE's operation PPS was used to program a relay box which interrupts the 12 volt main power supply to the GPS receiver for a specified duration and interval. However, the 5 volt regulated keep alive power is supplied continuously to preserve the most recent coordinates and constellation in SRAM volatile memory. GPS data is logged using the manufacturer's software to ease processing requirements due to compatibility with commercial spreadsheets.

Appendix F illustrates the results of these tests as a function of the amount of time which the receiver was unpowered. These times range from 90 seconds through 6 hours. The results are summarized in Table 6.1. Although time to first fix (TTTF) is relatively stable through the longest test (6 hours), the accuracy of the first fix degrades considerably beyond 30 minutes off.

TABLE 6.1 : GPS STATIC TEST RESULTS SUMMARY

RECEIVER TIME UNPOWERED	ACQUISITION TIME (rms) SECONDS	FIRST FIX ERROR (rms) METERS	NUMBER of SAMPLES
90 SECONDS OFF	29.1	46.4	45
10 MINUTES OFF	29.6	51.2	30
30 MINUTES OFF	29.2	48.6	39
1 HOUR OFF	28.7	60.9	33
3 HOURS OFF	42.0	75.2	23
6 HOURS OFF	49.4	25.0	15

Analysis of the raw GPS data indicates that the predominant factor in this accuracy degradation is occasional poor geometry in the first set of satellites acquired by the receiver. Inspection of tracked satellites indicates that the geometry improves quickly after tracking the first satellite due to rapid acquisition of additional satellites. However, this process continues to slow as time unpowered increases due to increasing frequency of changes in the currently visible satellites.

The static test results indicate that the TTTF is relatively stable below 30 seconds until the time off exceeds one hour. The first fix accuracy deteriorates steadily as a function of time off with the exception of 6 hours off where the TTTF is excessive. The maximum time between GPS updates should not normally exceed approximately 30 minutes in order to improve first fix accuracy. At this update frequency, antenna exposure can be limited to approximately 30 seconds maximum. Longer intervals between updates are possible but will necessitate longer antenna exposures to obtain a position update of reasonable accuracy.

These test results confirm the manufacturer's specifications in Appendix A and indicate that the objectives for the SANS transit phase are easily attainable. Further testing using differential processing techniques is required to validate feasibility of the accuracy requirements for the mapping phase.

B. GYRATION GYROENGINE

Testing of the gyroscopes was conducted at the AAF test track. The testing was conducted in cooperation with the manufacturer of the gyro and consisted of 10 test

circuits on the instrumented test track. Only the directional gyro was evaluated due to the two-dimensional orientation of the test track. Gyro data was recorded utilizing the manufacturer's software. GEORGE was again used to record "truth data" from the test vehicle. Processing of the "truth data" was conducted in the same fashion as for the dynamic GPS experiments. This data was then compared manually with the gyro data to determine the cumulative error for each individual run.

The test gyro was powered by 12.0 volts during 8 of 10 test runs. Single test runs were conducted at 5.0 volts and 15.0 volts. During steady state operations at 12.0 volts, the mean drift rate was 2.3 degrees per minute (dpm) with a standard deviation of 2.2 dpm yielding 3.2 dpm rms. This is slightly higher than the product specification for Scorsby drift rates of 1.5 dpm typical and 3.0 dpm maximum [Ref. 13].

During the 9.2 meter radius turn at the corner of the test track with an average speed of 3.0 meters per second, the average acceleration was computed to be 0.16 G's or 1.6 meters per second per second. The observed drift rate was 25.4 dpm with a standard deviation of 15.6 dpm yielding 29.8 dpm rms. The expected drift rate at the advertised specification of 3.0 degrees per second per G for the computed 0.16 G is 30 dpm. These observed and expected results here are consistent and demonstrate that acceleration is the dominant factor in gyro drift rate.

The result of a single test run at 5.0 volts DC is particularly noteworthy. Although steady state drift rate was consistent with other tests, the drift rate in turns was 120

dpm. The high drift rate at this low motor speed is unacceptable for the intended applications in SANS. Since the SANS driver for the gyro was developed for execution at 5.0 volts, future research should concentrate on expanding the envelope of the SANS gyro driver with higher voltages and the resultant higher motor speeds. Further testing is also necessary to validate the performance of the pitch axis of the vertical gyro.

C. DEPTH TRANSDUCER

The Omega Inc., depth transducer was evaluated on a 50 PSI Chandler Engineering dead weight tester. This test bench utilizes a hydraulic cylinder to pressurize the diaphragm of the depth transducer. Pressure is generated in increments of 5 PSI by adding calibrated weights to pressurize the cylinder. The depth transducer's output was measured by a digital voltmeter to 3 decimal points accuracy (milli-volts).

Figure 6.4 illustrates the results of the pressurization schedule. Due to the minimum pressurization of 50 PSI, no measurements are possible between ambient and 50 PSI. The maximum deviation from a linear function in the digital output is observed at the 50 PSI mid-point. The deviation at this point is 16 milli-volts (3.516 volt average over 4 runs with 3.499 volts expected). This deviation correlates to 0.46 percent, which is within the 0.5 percent advertised linearity accuracy. [Ref. 17] For SANS, this translates into 0.335 meter accuracy for full depth excursions.

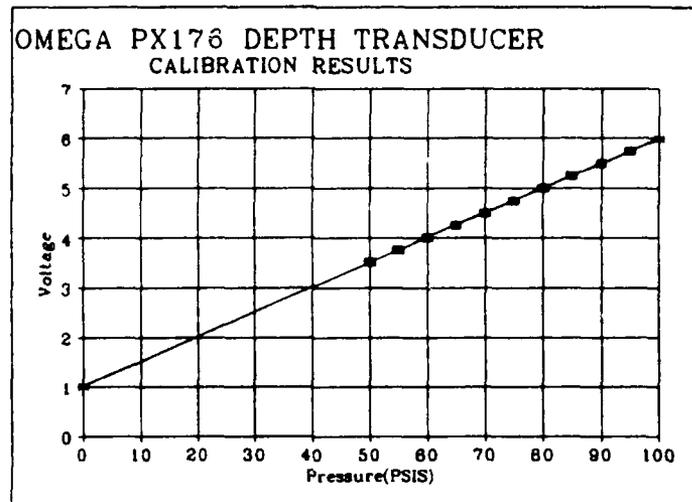

Figure 6.4 : Depth Transducer Calibration Results

D. SYSTEM PERFORMANCE ASSESSMENT

1. GPS Performance

Although not all components of the system have yet been evaluated in their operational mode, some assumptions can be made to assess the overall performance of the interim SANS. The results of the GPS static testing certainly indicate that the target acquisition times and fix accuracy are attainable for update intervals of less than 30 minutes. These results also indicate that differential post-processing should permit GPS positions to be determined to an accuracy of 2 to 4 meters.

2. DR Navigation Performance

The accuracy of the computation of the horizontal distance travelled is affected by the accuracy of the depth transducer and gyro (or accelerometers) during the ascent. The maximum effect of the pitch attitude inaccuracy would occur while SANS is level

(pitch attitude = 0 degrees) since the value of tangent(theta) in the denominator of (Equation 3.2) approaches 0.0 at zero degrees. This would result in an error of infinite magnitude for even small errors in pitch attitude measurement. Similarly, heading measurement inaccuracy affects system accuracy most when the pitch attitude is very shallow since this results in a large horizontal distance travelled and high gyro drift.

The differential approach used here to assess the overall accuracy of SANS was developed by Dr. J. R. Clynch. [Ref. 18] The analysis uses the manufacturer's technical specification in Appendix A except in the case of the gyro drift rate where the slightly higher test results are used. The drift rate for the pitch axis of the vertical gyro is assumed to be the same as that calculated for the directional gyro.

Recall from Figures 3.1 and 3.2 and the text that the climb angle (theta) is measured by the pitch axis of the vertical gyro. Alpha is the AUV heading which will be measured by compass and directional gyro in future development. Let h represent the change in depth measured by the depth transducer and let s_H represent the horizontal distance travelled by the AUV from a submerged object of interest during its ascent to the surface where the GPS position will be determined. Then as in equation 3.2:

$$s_H = \frac{h}{\tan\theta} \quad (6.1)$$

By taking the first derivative:

$$ds_H = dh \frac{\cos(\theta)}{\sin(\theta)} - \frac{h}{\sin^2(\theta)} d\theta \quad (6.2)$$

Because the depth and pitch angle errors are uncorrelated, the sum of the magnitude of the two terms in equation 6.2 can be used to estimate the size of the error in slant range. [Ref. 18] Equation 6.3 yields the position error due to precession in the heading gyro.

$$AOU = s_H * d\alpha * ds_H \quad (6.3)$$

Where AOU is the Area of Uncertainty.

The AOU will be the slant range error times the heading error. The radius of a circle covering the same area will be used as an estimate of the positional error. [Ref. 18] Figure 6.5 illustrates the computation of the positional error.

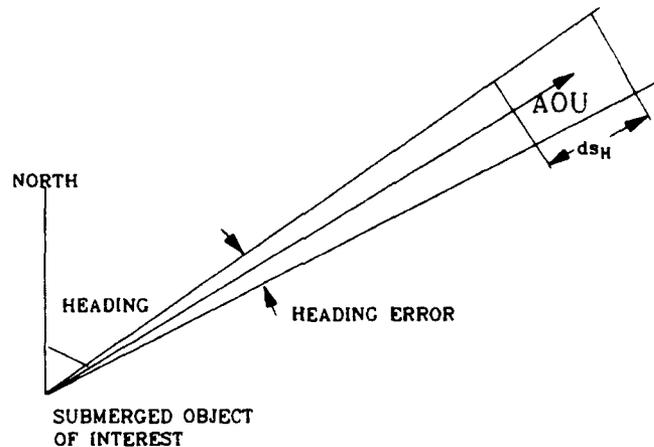

Figure 6.5 : Computation of Inertial Measurement AOU

Table 6.2 tabulates the results of error approximations for varying climb angles. A transit from the depth transducer's maximum depth is assumed with a maximum gyro drift rate of 3.2 dpm as calculated above (assuming no significant accelerations). The GPS error is assumed to be 4.0 meters rms.

TABLE 6.2 : SANS SYSTEM ACCURACY FROM 70 METERS

CLIMB ANGLE	20 degrees	25 degrees	30 Ddegrees
TIME TO CLIMB	39 seconds	32 seconds	27 seconds
GYRO PRECESSION	2.1 degrees 0.036 radians	1.7 degrees 0.03 radians	1.4 degrees 0.025 radians
AREA OF UNCERTAINTY	140.0 meters ²	49.0 meters ²	11.6 meters ²
POP-UP ERROR rms	11.8 meters	7.0 meters	3.4 meters
TOTAL ERROR rms (GPS + POP-UP)	12.5 meters	8.0 meters	5.3 meters

The objective for accuracy during mapping phase of 10 meters rms are achieved by SANS during transits from its maximum depth of 67 meters only when the climb angle is slightly greater than 30 degrees. NPS AUV2 is restricted to much shallower climb angles but also to depths of less than approximately 10 meters. This depth is more typical of the application expected for SANS. As indicated by Table 6.3, climb angles greater than 12 degrees should satisfy the accuracy objectives of SANS.

TABLE 6.3 SANS SYSTEM ACCURACY FROM 20 METERS

CLIMB ANGLE	10 degrees	12 degrees	15 degrees
TIME TO CLIMB	23 seconds	19 seconds	15 seconds
GYRO PRECESSION	1.2 degrees 0.02 radians	1.0 degrees 0.017 radians	0.8 degrees 0.014 radians
AREA OF UNCERTAINTY	101 meters ²	46.3 meters ²	4.4 meters ²
POP-UP ERROR rms	10.0 meters	6.8 meters	2.1 meters
TOTAL ERROR rms (GPS + POP-UP)	10.8 meters	7.9 meters	4.5 meters

VII. CONCLUSIONS

A. SOFTWARE ARCHITECTURE

A primarily object-oriented design approach is used to implement the design of SANS. The major operations performed by SANS are

- Monitoring the AUV for a position fix request
- Navigation data-logging for dead reckoning (DR) navigation (post-processed to determine ascent vector), and
- GPS data-logging for post-processed positional information.

The first and third of these are implemented primarily through a serial communication line routine designed by Dr. Se-Hung Kwak. The GPS processing routine was redesigned at the lowest level to accommodate the proprietary binary format used by Motorola. DR navigation implements a navigation data logger for hardware components of an inertial navigation system. This data includes the results of A to D conversions of compass and depth transducer outputs and D to D counting operations associated with phase and quadrature digital output signals from a miniature spin gyro. D to D operations are implemented in assembly language for higher efficiency due to their high frequency. A to D operations are implemented in Ada.

A major goal in the implementation of SANS has been modularity of code. As new technology is incorporated, this approach facilitates redesign of the entire system

with many modules being reused or replaced. Complexity management in a moderately large software system like SANS is also enhanced. [Ref. 11]

B. SOFTWARE TESTING

Requirements based testing is applied to SANS in order to verify the proper operation of key modules in the implementation. A primarily functional (black box) testing approach is used in keeping with the design goal of modularity to ensure that individual modules may be replaced or reused without side-effects on other modules. Some of the key findings are summarized below.

1. GPS MESSAGE TRANSLATION

a. All paths in package Motorola are reachable through the various test cases represented in Appendix E. All outputs are consistent with expected results.

Validation of checksums are not yet implemented. This requirement will be essential for real-time processing of the position format messages in the implementation of the transit phase of the mission.

b. Values falling outside the ranges of +/- 648,000,000 for longitude and +/- 324,000,000 for latitude are possible if messages are incorrectly translated. Although testing for this situation is not specified as a requirement, correction is advisable and is accomplished by declaring legal ranges for input values.

2. GYRO DRIVER

a. Gyro rotation is correctly tracked through all possible state transitions as demonstrated in Appendix D. This result is consistent with many hours of direct

observation of pre-production gyros under dynamic operating conditions in which only low drift rate precession has been observed.

b. Interrupt handling for the gyro is easily accommodated in the software development machine. Real time processing requirements should be reassessed when the software and hardware are moved to the ESP-8680 target machine.

C. HARDWARE CHARACTERISTICS

All components meet or exceed all critical specifications except for the gyro where the drift rate of 3.2 degrees per minute is slightly higher than the maximum specified (3.0 degrees per minute). The error analysis conducted in section VI.D uses the more conservative results for the gyro rather than manufacturer's technical specifications. Further research is necessary to validate the performance of the pitch axis of the vertical gyro, the compass accuracy and the accuracy of post-processed GPS.

The error analysis indicates that all objectives of the interim SANS are achievable according to research conducted to date. The only major restriction associated with the interim SANS system is the requirement that the AUV must be restricted to a climb angle of slightly greater than 30 degrees from the SANS' maximum depth of 70 meters. During climbs from a more typical depth of 20 meters, a climb angle of approximately 12 degrees will deliver acceptable accuracy. These restrictions are necessary in order to ensure acceptable positional accuracy which is degraded by the increasing degree of gyro precession during the long ascent paths associated with

shallow climb angles. These restrictions will limit a technology demonstration to more shallow depths or to AUV's capable of attaining large climb angles.

D. FUTURE RESEARCH

1. SOFTWARE DEVELOPMENT

All software testing so far has been confined to the software development machine. The next critical phase in the software development is to evaluate the performance in the ESP-8680 target machine. Additional hardware is necessary to support the operation of SANS during this process. The A to D converter selected should have two interrupt input channels so that the yaw axis directional gyro may be tracked to improve heading accuracy during high turn rates. The current implementation of SANS is restricted to the pitch axis of the vertical gyro only.

The primary focus of this research has been the conduct of the mapping phase of the SANS mission. This only requires that satellite range format messages be recorded in order to permit the AUV's location to be determined through post-processing. In order to execute the transit phase of the mission, the Motorola GPS receiver must be reinitialized during the mission to transmit position format messages. This will be accomplished through transmission of preformatted binary messages using package SERIAL's function WRITE_CHAR for writing characters through the serial communication.

2. GYROSCOPES

As stated above, further research is necessary to validate the performance characteristics of the pitch axis of the vertical gyro. This will most likely require laboratory experiments using a servo-driven tilt table. [Ref. 19]

All testing with the device driver for the gyro thus far has been accomplished using pre-production items on loan from Gyration, Inc. During initial operation of the production issue gyros with the software development device driver, some inconsistencies in tracking gyro rotation were observed. Compatibility of the driver with these production items must be assessed. Expansion of the driver's envelope must also be addressed to ensure proper operation at higher input voltages and the corresponding higher motor speeds. Clearly, the field tests indicate that even under moderate acceleration at the low motor speed associated with an input of 5.0 volts, the drift rate is unacceptable for the application intended here. Further research may be necessary to develop a solution incorporating the use of accelerometers to dampen the effect of high frequency pitch excursions.

Finally, an applicability study of a new small but high performance IMU package developed by Systron Donner Corporation is proposed for SANS. This unit is expected to meet the space and power requirements of SANS and easily improve the system accuracy. [Ref. 19]

APPENDIX A
TECHNICAL SPECIFICATIONS

A. SAPPHIRE CONVERTER

Analog Section:

A/D resolution:	12-bits (1/4096)
Linearity error:	1/2 LSB max
Differential linearity error:	12 bits (no missing codes)
Conversion time:	20 μ s max
Maximum conversion rate*:	15kHz with clock timing 30kHz in software burst mode
Input channels:	8, single-ended
Expansion capability:	128 channels, differential
Input ranges:	\pm 5V, \pm 10V, 0-10V
Input range selection:	Software
Input impedance:	2.5M Ω min
Channel-to-channel isolation:	68dB min
Input overvoltage protection:	\pm 32V

Digital Section:

Digital I/O:	31 bits, TTL-compatible
Direction:	4 out, 3 in (J1) Software configurable (J2)

Output voltage levels:

J1:	Low	0.0V min, 0.5V max @ 8mA
	High	5.0V max, 2.7V min @ 400 μ A
J2:	Low	0.0V min, 0.45V max @ 1.5mA (J2)
	High	5.0V max, 2.4V min @ 100 μ A

Input voltage levels:

J1:	Low	0.0V min, 0.8V max
	High	2.0V min, 5.5V max
J2:	Low	-0.5V min, 0.8V max
	High	2.0V min, 5.5V max

Interrupt input: TTL-compatible
rising-edge triggered

Counter/Timer Section:

No. of counters:	3, 16 bits wide each
Type:	Presettable synchronous down counters
Maximum count frequency:	8MHz
Internal clock source:	PC clk+2, PC clk+4 (jumper selectable)

Miscellaneous:

Operating temperature:	0-60°C
Dimensions:	4.2" x 7.0"

*These specifications are derived from tests on a 12MHz 80286-based AT compatible. Maximum speed will vary depending on the speed of the host computer.

B. ESP-8680

Processor	14 MHz 5-volt "8680" (8086 equivalent)
Serial Port	RS-232
Graphics	CGA (Color Graphics Adapter) or LCD (Liquid Crystal Display)
Memory	256K x 8 EPROM or Flash Memory 512K or 1MB DRAM (8-bit or 16-bit wide memory path)
Memory Option	Expansion board adds up to 16MB DRAM
Bus Interface	ISA (Industry Standard Architecture)
Form Factor	1.7" x 5.2" (13.2cm x 4.3cm)
Power Consumption	Draws from 1 mA (sleep mode) to 300 mA (peak load powering back-lit LCD and peripherals)

C. MOTOROLA PVT6

Receiver Architecture	6-channel L1 1575.42 MHz
Tracking Capability	6 simultaneous satellite vehicles
Dynamics	Velocity 1000 Knots (514m/sec) Acceleration 4g
Aquisition Time (Time to First Fix, TTFF)	24 sec. typical TTFF (with current almanac, position, and time) 54 sec. typical TTFF
Accuracy	Less than 25 meters, SEP (without SA)
Operating Temperature	-30°C to +80°C
Physical Dimensions	3.94 x 2.75 x 0.65 inches (100 x 70 x 16.5 mm)
Weight	4.5 ounces (128 grams)
Switched Power	9-16 Vdc or 5 ± 0.25 Vdc
Keep-Alive Power	4.75 - 16 Vdc; 0.3 mA max
Power Consumption	Typical 1.3 W @ 5Vdc input 1.8 W @ 12Vdc input
MTBF	65,000 hours (estimated)

D. GYRATION GYROENGINE

Performance

motor speed: 8,000 revolutions per minute (RPM) to
50,000 RPM selectable by input voltage
Scorsby drift:

Temperature		25,000 RPM	50,000 RPM
-40°C	Typical	6.0°/min.	5.0°/min.
	Maximum	15.0°/min.	12.0°/min.
+25°C	Typical	2.0°/min.	1.5°/min.
	Maximum	5.0°/min.	3.0°/min.
+80°C	Typical	4.0°/min.	3.0°/min.
	Maximum	10.0°/min.	7.0°/min.

Static Drift

-40°C to +80°C; typical 0.5°/min., maximum 1.0°/min.
at 25,000 to 50,000 RPM

Precession

erection system: pendulous inner gimbal
precession period: 135 seconds
precession damping: precession decreases 37% each
precession period
precession angle due to horizontal acceleration:
3°/sec./G, equivalent to 0.14°/1 mile/hour
change in speed

Optical Encoder Output

encoder resolution: 0.1°
encoder linearity: ±1% of full scale maximum
sensor slew rate: 260°/sec.

Power

DC supply voltage: 4V to 12V selects motor speed

maximum DC starting current:

200 mA at 5V

500 mA at 7V

700 mA at 9V

maximum DC running current:

50 mA at 5V corresponds to 10,000 RPM

125 mA at 7V corresponds to 25,000 RPM

350 mA at 9V corresponds to 50,000 RPM

Environmental

operational temperature range: -40°C to $+80^{\circ}\text{C}$

humidity: 80% relative

pressure altitude: -1,000 ft. to 40,000 ft.

shock resistance: 400 G's, 8 ms half sine wave

pulse duration (all axes)

vibration: 2 G's RMS (20 Hz to 2,000 Hz)

Physical

dimensions: 1.3 in. maximum diameter

1.75 in. maximum length

weight: 1.5 oz.

external: molded optical-grade polycarbonate with

butyl rubber expansion seal

internal: gimbal floatation fluid (Brayco 1721

aerospace low-viscosity vacuum oil)

Service Life

40,000 hours

E. KVH C100 DIGITAL COMPASS SENSOR

Accuracy	±0.5° or ±10 mils RMS
Repeatability	±0.2° or ±5 mils
Resolution	0.1° or 5 mils
Dip Angle	±80° Maintains stated accuracy after autocal over ±80° Magnetic Dip Angle
Tilt Angle	±16° Dev.= ±0.3° RMS ±45° Dev.= ±0.5° RMS
Electrical Power	Input Voltage: +8 to +20 VDC or +20 to +30 VDC (user selectable) Current Drain: 20 mA DC; nominal
Size	1.80 x 4.50 x 1.10" (4.6 cm x 11.4 cm x 2.8 cm)
Weight	2.0 ounces (57 grams)
Environmental Performance	Operating Temp.: -22°F to +122°F (-30°C to +50°C) Vibration: 30 minutes random MIL-STD-810 Shock: Handling shock per MIL-STD-810
Digital Interfaces	Standard RS232 Bidirectional Serial Data
Analog Outputs	Sine/Cosine: Sine/Cosine output voltage +2.5V±1.0V OR Linear Voltage: 0 to +3.6VDC into 10K Ohm minimum load

F. OMEGA PX176-100PSIS

PARAMETER	MIN	TYP	MAX	UNITS
Full Scale Output (FSO) @ 25°C	4.90	4.95-5.05	5.10	Vdc
Null Offset @ 25°C	.85	.95-1.05	1.15	Vdc
Linearity (Best Fit)		±.2	±.5	%FSO
Hysteresis		±.25		%FSO
Temperature Error Null 0° to 85°C		±.01	±.02	%FSO/°C
-55° to 0°C +85°C to 105°C		±.02		%FSO/°C
Sensitivity 0° to 85°C		±.01	±.02	%FSO/°C
-55° to 0°C +85°C to 105°C		±.02		%FSO/°C
Stability (1 year)		±1.0		%FSO
Frequency Response		10		KHz
Supply Voltage	9		20	Vdc
Supply Current (Quiescent)		15		mA

--*****
-- File Name : SANS.A
-- Author : Lcdr C. D. Stevens
-- DATE : 12/3/92
-- Adapted from SNDL.a authored by Se-Hung Kwak
-- Comments : SANS consists of 3 major operations
--             AUV_MONITOR is a busy wait
--             while other operations are idle
--             AUV_MONITOR waits for a position update
--             request
--             DR NAVIGATION consists of logging DEPTH, HEADING
--             and PITCH along with the current time in small
--             time increments for post-processing
--             INIT_PROCESS_GPS initializes the Motorola GPS
--             and PROCESS_GPS_DATA logs all Motorola pro-
--             prietary Binary Messages for Post-processing

APPENDIX C

INTERRUPT ROUTINE MAJOR OPERATIONS

The development of the interrupt-driven routine for tracking gyro rotation was outlined in Section IV.B.2.f.(3). This appendix provides specific details outlining the implementation's four basic procedures.

A. INITIALIZE THE INTERRUPT ROUTINE

At the execution of the main procedure, the host machine's interrupt vector table must be adjusted. This permits the Sapphire interrupt input channel to trigger the Gyro's service routine.

1. The initialization routine, `INIT_DIGITAL_COUNTER` disables interrupts and saves the current value of registers to be used during initialization.
2. Interrupt enable is programmed in the Sapphire board through bit 3 (hexadecimal value 8) of control register 1 (base offset + 2). Interrupt enable must be reprogrammed after each interrupt by the interrupt service routine. The value of the pitch count is initialized to 0.
3. The interrupt vector table is set to respond to hardware interrupt level 7 (IRQ7) by transferring control to the interrupt service routine `PITCH_CALC`. The interrupt number and effective address to which control must pass is added to the current vector table.

4. The current hardware level 7 interrupt vector is saved to be restored after termination of SANS. The interrupt level to be replaced (0F hexadecimal corresponds to IRQ7) is loaded into the lower half of the AX register (AL) and the function number (35 hexadecimal for retrieve current vector) is loaded into the upper half of the AX register (AH). AX contains the parameters for Disk Operating System (DOS) function call INT 21. The result of the call is the current code segment address (CS) returned to the ES register and program counter (IP) returned to the BX register (ES:BX). These results are stored in the data segment for later restoration. [Ref. 20]

5. After the current vector for LPT1 has been saved, the new vector is loaded into the interrupt vector table. This vector enables the interrupt service routine to be accessed at each interrupt. The offset operator is used to determine the offset address of the service routine PITCH_CALC. This address is loaded as the new address for the service routine in the interrupt vector table. To program the vector, the offset value is loaded in the DX register and the code segment address (CS register) is loaded in the DS register as parameters for DOS function call INT 21. Interrupt level (IRQ7) is loaded in AL as before, and DOS function number 25 hexadecimal is loaded in AH as additional parameters for INT 21. The result is a new service address for IRQ7 of DS:DX. [Ref. 20]

6. For IBM compatible architecture, the interrupt mask must be set in the 8259 programmable interrupt mask. The current interrupt mask is read from I/O port 21 hexadecimal. The value read from I/O port 21 is AND'ed with 7F hexadecimal (0111

1111 binary), to reset IRQ7 (bit 7). This operation and is performed on the current value and 7F hexadecimal to preserve all current interrupts while enabling the new interrupt. The result is written to port 21 hexadecimal.

7. The contents of the registers are then restored, interrupts re-enabled and control restored to the address in the base pointer.

B. IMPLEMENT THE SERVICE ROUTINE

1. After the interrupt vector table has been set, interrupts are handled by the interrupt service routine. The current state of both inner gimbals input signals are evaluated at each interrupt by reading the contents of the status register from Sapphire base offset + 2.

2. The values of bits 5 and 6 are extracted by operation and with 30 hexadecimal (0011 0000 binary). This makes all bits zero except bits 5 and 6 which retain their value. The result indicates the current state.

3. This state is compared with the previous state recalled from memory to determine if the state transition is valid as described by Figure 4.4. The cumulative rotation since initialization is incremented/decremented as appropriate.

4. The interrupt service routine resets interrupt enable in the Sapphire board through bit 3 of control register 1 for subsequent interrupts.

C. CURRENT_VALUE

The main procedure must be able to access the result of the interrupt service routine's tracking of the gyro rotation. Ada function READ_PITCH interfaces with

the assembly language procedure `READ_PITCH` which loads the current value of the pulse count from the data segment into register `CX`. The contents of `CX` is the function return value.

Whenever the gyro's `CURRENT_VALUE` is required by the main procedure, the pulse count (cumulative rotation since initialization) is determined by a function call to `READ_PITCH`. The difference since the last update is applied as gyro rotation to determine the new pitch angle.

D. RESTORE INTERRUPTS

Before program termination, the interrupt vector table is restored to its initial condition through procedure `RESTORE_INTERRUPTS`. This requires restoring the interrupt mask and vector stored in the data segment at initialization to their initial configuration.

1. *Interrupts are disabled, register contents are saved and the data segment is made visible.*

2. The original interrupt mask is loaded from memory to the `AX` register. This register's contents are written to port 21 to reconfigure the 8259.

3. The original interrupt vector table is restored by loading the original interrupt vector address for `IRQ7` from memory into the `DX:DX` register pair. `IRQ7`, which is 0F hexadecimal, is loaded in `AL` as before and DOS function number 25 hexadecimal is loaded in `AH` as `AX` register parameters for DOS function call `INT 21`. The result of the DOS operation is restoration of the original service address for `LPT1`. [Ref. 20]

APPENDIX D

STATE TRANSITION TRACKING ALGORITHM VERIFICATION

CASE 1 : clockwise rotation (the counter is incrementing).

The result should be 4 units of rotation @ 0.4 degrees/unit.

IG-A	IG-B	PITCH COUNT	STATE	TRANSITION	CASE
0	1	0	1	-	
1	1	1	2	1	
0	1	1	1	2	
1	1	2	2	1	
0	1	2	1	2	
1	1	3	2	1	
0	1	3	1	2	
1	1	4	2	1	

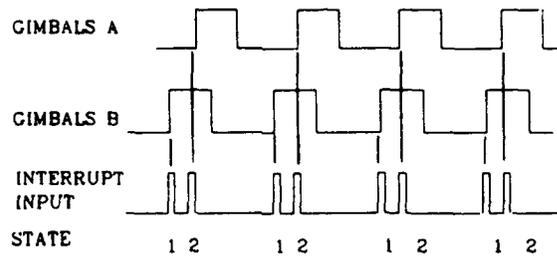

Figure D.1 : Case 1 State Transitions

CASE 3 : counter-clockwise rotation (the counter is decrementing).

The result should be -4 units from initial value.

IG-A	IG-B	PITCH COUNT	STATE	TRANSITION	CASE
1	0	4	3	-	
1	1	3	2	3	
1	0	3	3	2	
1	1	2	2	3	
1	0	2	3	2	
1	1	1	2	3	
1	0	1	3	2	
1	1	0	2	3	

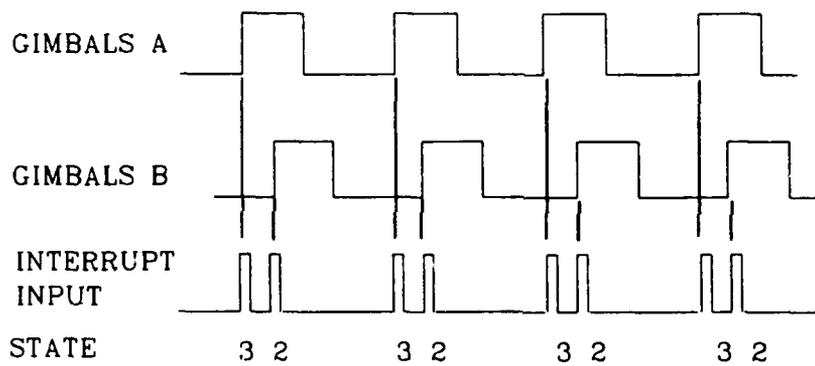

Figure D.2 : Case 3 State Transitions

CASE 1 to CASE 3 : reversal in rotation, clockwise to counter-clockwise.

The result should be 0, increment 2 then decrement 2.

IG-A	IG-B	PITCH COUNT	STATE	TRANSITION	CASE
0	1	0	1	-	
1	1	1	2	1	
0	1	1	1	2	
1	1	2	2	1	
1	0	2	3	2	
1	1	1	2	3	
1	0	1	3	2	
1	1	0	2	3	

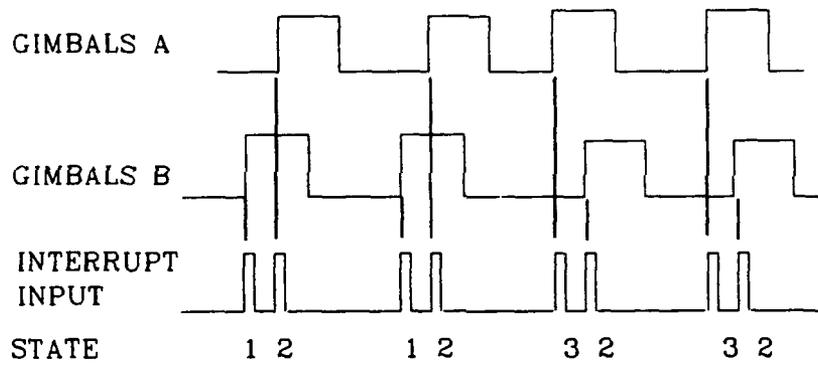

Figure D.3 : Case 1 to Case 3 Rotation Reversal

CASE 3 to CASE 1 : Reversal in rotation, counter-clockwise to clockwise.

The result should be 0, decrement 2 then increment 2.

IG-A	IG-B	PITCH COUNT	STATE	TRANSITION	CASE
1	0	0	3	-	
1	1	-1	2	3	
1	0	-1	3	2	
1	1	-2	2	3	
0	1	-2	1	2	
1	1	-1	2	1	
0	1	-1	1	2	
1	1	0	2	1	

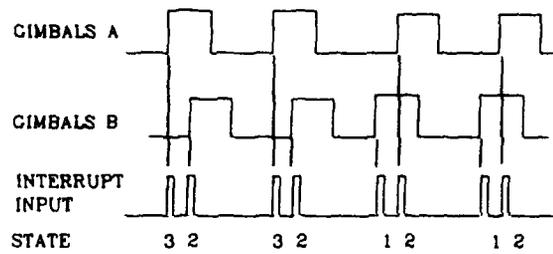

Figure D.4 : Case 3 to Case 1 Rotation Reversal

CASE 0 : Gyro is stationary with noise in IG-A.

The result should be 0 (ignore noise).

IG-A	IG-B	PITCH COUNT	STATE	TRANSITION	CASE
1	0	0	3	-	
1	0	0	3	0	
1	0	0	3	0	
1	0	0	3	0	
1	0	0	3	0	
1	0	0	3	0	
1	0	0	3	0	
1	0	0	3	0	
1	0	0	3	0	

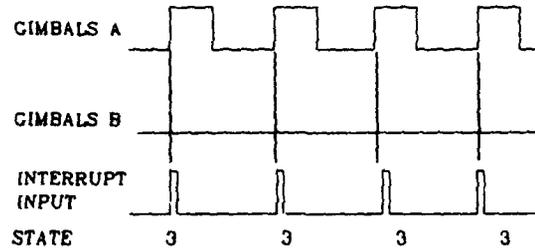

Figure D.5 : Noise in IG-A

CASE 0 : Gyro is stationary with noise in IG-B.

The result should be 0 (ignore noise).

IG-A	IG-B	PITCH COUNT	STATE	TRANSITION	CASE
0	1	0	1	-	
0	1	0	1	0	
0	1	0	1	0	
0	1	0	1	0	
0	1	0	1	0	
0	1	0	1	0	
0	1	0	1	0	
0	1	0	1	0	
0	1	0	1	0	

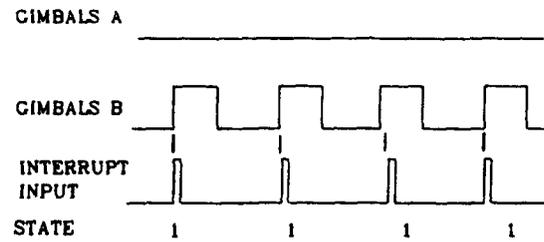

Figure D.6 : Noise in IG-B

CASE 0 : Gyro is stationary with noise in both channels.

The result should be 0 (ignore noise).

IG-A	IG-B	PITCH	COUNT	STATE	TRANSITION	CASE
1	1	0	0	2	-	
1	1	0	0	2	0	
1	1	0	0	2	0	
1	1	0	0	2	0	
1	1	0	0	2	0	
1	1	0	0	2	0	
1	1	0	0	2	0	
1	1	0	0	2	0	
1	1	0	0	2	0	

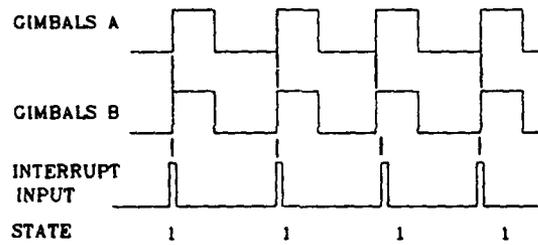

Figure D.7 : Noise in Both Channels

CASE 4 : Gyro is stationary with noise in both channels.

The result should be 0 (ignore noise).

IG-A	IG-B	PITCH COUNT	STATE	TRANSITION CASE
1	0	0	3	-
0	1	0	1	4
1	0	0	3	4
0	1	0	1	4
1	0	0	3	4
0	1	0	1	4
1	0	0	3	4
0	1	0	1	4

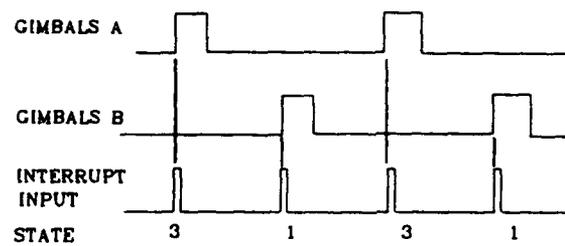

Figure D.8 : Noise in Both Input Channels

TEST CASE III

Only the latitude/longitude conversions are addressed henceforth.

Input:

Latitude (bytes 15-18)

255 218 54 125 (-2,476,329 milliseconds in two's complement)

Longitude (bytes 19-22)

255 217 60 72
(-2,440,472 milliseconds in two's complement)

Output:

South -0.687869 degrees

West -0.677909 degrees

TEST CASE IV

Input:

Latitude

0 0 0 3 (000,000,003 milliseconds)

Longitude

0 0 0 4 (000,000,004 milliseconds)

Output:

North 0.000000 degrees

East 0.000000 degrees
