## ABSTRACT

A safe system is defined as a system that prevents unsafe states from producing safety failures, where an unsafe state is defined as a state that may lead to safety failure unless some specific action is taken to avert it. The problem that this thesis addresses is how to find places in Ada programs where faults are likely to occur during program execution.

The approach is to build an automated translation tool that translates Ada programs into a software fault tree. [Lev 83] The tool works as follows: 1). The Ada parser and lexical analyzer calls the Automated Code Translation Tool (ACTT) upon recognition of an Ada statement; 2). The ACTT produces a template representing the statement; 3). The templates are linked together as a software fault tree.

The result is a program that takes Ada source code as input and produces a software fault tree as output.

## **ACKNOWLEDGEMENTS**

I would like to take this opportunity to thank a number of people, for without their assistance, guidance, and especially patience, this thesis would not have been completed. First, I would like to thank Professor Shimeall for the endless support he gave me throughout the entire process. His willingness to provide assistance in solving problems and his constant availability throughout were key contributing factors to this thesis completion. Additionally, I would like to thank Professor Erickson for his contributions in making this thesis more understandable. Thanks are also due to Dr. Friedman and Mr. Lombardo for their previous works on automated code translation and fault tree editors, respectively.

Last, but most definitely not least, I would like to especially thank my wife, Gemma. Her loving support, patience, understanding, and encouragement during our stay in Monterey provided me the inspiration to finish this project.

## I. INTRODUCTION

Since the invention of computers, from main frames to the micro systems, the appearance and usage of these devices in today's society has grown at a tremendous pace. Computers today are used in all aspects of everyday life. The range of devices that use computers include the complicated systems of the space shuttle and different weapon systems to the less intricate systems of calculators and small appliances. With the introduction of computer systems, there exists the requirements to ensure that these systems will perform as intended without catastrophic side effects. In essence, the goal is to ensure that the computer systems operate safely. A system is defined by *The American Heritage Dictionary* as a group of interacting, interrelated, or interdependent elements forming a complex whole.

### A. SAFETY

Safety has been defined as a state that is free from conditions that can cause death, injury, occupational illness, or damage to or loss of equipment or property. [Lev 86] Leveson, along with others, have stated that this definition is unrealistic because by this definition any system that presents any element of risk would be labeled unsafe. [Lev 86] Risk is defined as a function of the probability of the hazardous state occurring, the probability of the hazard leading to a mishap, and the perceived severity of the worst potential mishap that could result from the hazard. [Lev 86]

Safety can be used as a relative term depending on the situation. An item may not be safe under all circumstances and conditions, but compared to the alternatives to that item, it may be the safest choice available. For example safety razors and safety matches by their very nature poses some risk; however, they are safer then their alternatives and they provide benefits to the user at a more acceptable level of risk then their alternatives. [Lev 86]

In the development of a system, trying to eliminate all unsafe or hazardous conditions may be impossible. Instead of removing the risk, a displacement of the risk to another area

is frequently the result. In these situations one must use a risk/benefit analysis to determine what is the best solution. For example, nitrate, which is used in foods, have been linked to cancer. However, nitrate is also used to prevent botulism. "Benefits and risks often have trade-offs, such as trading off the benefits of improved medical diagnosis capabilities against the risks of exposure to diagnostic X-rays." [Lev 86] The trade-offs between the benefits and the risks are dependent on the particular situation and are usually defined by political, moral and economical decisions of the users.

Safety depends on the situation in which it is measured. Leveson stated that nothing is completely safe under all conditions. Items that may be relatively safe under most conditions could become hazardous if the right conditions exist. An example of this is drinking too much water, which could in turn, lead to kidney failure. [Lev 86]

To understand safety, one must distinguish safety from reliability. Reliability pertains to the probability that a system will perform its intended function for a specified period of time under a set of specified environmental conditions, thus making a system failure free. [Sal 76] Safety is concerned with the possible errors that may lead to a hazard and reliability looks at all possible errors. Since not all errors cause hazards, safety requirements only look at the subset of the errors that cause the undesired events. [Lev 86]

According to Brown, safety is not reliability, availability or any other attribute or combination of attributes. In some situations, safety and reliability may actually counter each other. If the design is unsafe to start with, no degree of reliability is given to make it safe. Along with this, if a system fails to a safe state, it is not reliable but it is safe. [Bro 88]

Leveson states that safety and reliability can complement each other or can have no direct relationship with each other. A hydraulic system of an aircraft is more safe when it is more reliable. On the other hand, measuring reliability for munitions pertains to detonation at the "desired time and place, while safety is related to inadvertent functioning". For reliability and safety in this example, there is no direct relationship. [Lev 86]

In addition, another aspect of reliability, availability, does not equate to safe. Availability is the probability that a system or component is operational at a specific time, available when needed. [Sal 76] "A system may be safe but not available and may also be available but unsafe (e.g., operating incorrectly)." [Lev 86]

## B. SYSTEM SAFETY

System safety pertains to the safety of the system, both hardware and software. A safe system is defined as a system that prevents unsafe states from producing safety failures, where an unsafe state is defined as a state that may lead to safety failure unless some specific action is taken to avert it. [Lev 86] In the past hardware-oriented system engineers have treated the computer as a black box because of the "newness" of software engineering and the "significant difference between software and hardware". [Lev 86] Software engineers on the other hand "treated" the computer as merely a stimulus response system". [Lev 86] According to Leveson "the greatest cause of problems experienced when computers are used to control complex processes may be a lack of system-level methods and view points". [Lev 86] In order to better resolve problems with systems, these old views must be changed to an outlook that views the system as a whole. Leveson stated, "...that software itself is not 'unsafe'. Only the hardware that it controls can do damage." [Lev 86]

System safety is a subdiscipline of systems engineering that applies scientific management and engineering principles to ensure adequate safety throughout the system life cycle, within the constraints of operational effectiveness, schedule, cost and performance. [Lev 86] The primary goal of system safety is to develop an acceptable safety level into the product before production or operations occur. This goal can be achieved in two steps. First, hazards need to be identified by applying scientific and engineering principles. Along with this, hazards need to be controlled through analysis, design and management procedures. The second step is to eliminate the hazards that pose an

unacceptable risk from the system design. [Lev 86] Even though this is simply stated, the process is very complex.

## C. SOFTWARE SAFETY

In the previous section the overall safety of the system was considered. This section takes a look at specifically the software issue because hardware reliability has improved impressively in the last few years and they are no longer a major cause of system failures. According to Cha, software has become the major "bottleneck" in further improving the system. He also stated that perfectly safe software is impossible and un-necessary and that a more realistic goal is to develop software that is free from hazardous behavior. [Cha 91]

Brown defines software safety as the optimization of system safety in the design, development, use and maintenance of software systems and their integration with safety critical hardware systems in an operational environment. [Bro 88] The intent of software safety is to ensure the software will function in a system context without creating an unacceptable level of risk.

Software safety, however, is difficult to achieve. All methodologies in developing software use humans and humans are fallible. [Lev 83] According to Brown, virtually all errors that occur in software may be attributed to humans. These errors can be grouped into four categories: design, coding and testing, operator, and maintenance. [Bro 88] Additionally, "software...has a large number of discrete states without the repetitive structure found in computer circuitry. Although mathematical logic can be used to deal with functions that are not continuous, the large number of states and lack of regularity in the software results in extremely complex mathematical expressions." [Lev 86]

Along with this, software safety is difficult because it is hard to develop realistic test conditions. Even with the use of simulations, it is difficult to guarantee that the simulation is accurate. "Software faults may not be detectable except under just the right combination of circumstances, and it is difficult, if not impossible, to consider and account for all

environmental factors and all conditions under which the system may be operating." [Lev 86]

Problems with the requirement specifications can also pose a problem to software safety. In a study of computer mishaps by Erickson and Griggs, it was determined that inadequate design foresight and specification errors are the greatest cause of software safety problems. [Eri 81] [Gri 81] In performing tests on software, the test can only consider the specified requirements and can not look at what was intended by the designer.

#### **D. STATEMENT OF PROBLEM**

Although there exists potential problems and several unknowns in the use of computers in systems that control critical devices, the advantages that computers provide including increased versatility and power, improved performance, greater efficiency, and decreased cost, lend merit to their use in these systems. Computer systems consist of two major components, hardware and software. Even though new discoveries in hardware are occurring constantly, there exist techniques that allow engineers to better handle the problems that arise in hardware. Engineers working with hardware are better able to anticipate the possible problems with hardware because the development of hardware follows long-established procedures. Software, on the other hand, is more complex than hardware because of the large number of states present in software. Additionally, software is normally developed for a particular application only using tests in simulations and controlled environments as a basis for reliability. [Lev 86]

Analyzing software with a purely manual technique is expensive because the step to traverse through the code requires an extra-ordinary amount of time. In addition, performing any function manually may introduce errors because humans are fallible. Automating the entire process poses other problems. One problem with automating the entire process is the loss of human insight required to see the intricacies of the system. Additionally, the experience of the analyst is lost when the process is fully automated. To

achieve a proper balance of manual and automated techniques in software safety analysis, both techniques are required.

This research pertains to software safety analysis, specifically increasing automation of the process. Introducing automated methods into software analysis may provide the analyst the opportunity to use his time more efficiently. The removal of the detailed work of code translation allows the analyst to focus on the semantics of the analysis, not the syntax of code. The primary purpose of this research is to assist in automating the process of translating code into usable structures for software fault tree analysis.

Software fault tree analysis is a method of software safety analysis that looks at the logic of the software. In this process, an undesired event caused by the software is identified and is labeled as the top node. The process works by looking at the top node and identifying the preconditions that are required for the top node to occur, given the design of the software. This process continues for each node at each level until the current node can not be further decomposed.

This thesis introduces a prototype tool that will translate Ada statements into pre-defined template structures that are used in software fault tree analysis. This tool performs a static analysis of Ada code using Ayacc, an Ada parser generator; Aflex, an Ada lexical analyzer generator; FTE, a graphical fault tree editor; and self-generated code. After inputting the Ada code into the tool, the tool will basically parse the given Ada input and upon recognition of various Ada structures, build pre-defined templates. Upon completion of the parsing and template generation, an FTE-compatible file will be generated.

One question addressed by this research looks at the ability to automate the software fault tree analysis. Introducing automation to most processes reduces the time required to complete the process since machine is inherently faster than man. If automating software fault tree analysis provides more benefits compared to costs, then it may be of value to implement some automation to the process.

Another question addressed pertains to the cost of automating software fault tree analysis. A purely manual technique is too expensive, but a purely automated process also

has problems. If a tool can be developed that strikes a balance between manual and automated techniques, the cost of automating software fault tree analysis could be reduced.

## E. SUMMARY OF CHAPTERS

Chapter II provides background information that is related to this thesis. Areas covered in this chapter are fault tree analysis, software fault tree analysis, and previous works in this area including fault tree editors, the use of templates to represent statements, and the automation of code translation for software fault tree analysis. Chapter III covers the actual tool developed. Information on Ayacc and Aflex are also provided. Additionally, an extended example is reviewed in this chapter. Chapter IV provides the conclusions including the recommendations and provides a summary of possible future work. Appendix A contains the Ayacc and Aflex specification file input. Appendix B is a listing of the source code excluding the generated code by Ayacc and Aflex. Appendix C provides the templates for individual Ada structures. Appendix D contains the output of the Automated Code Translation Tool when the example procedure FAKE\_OVEN\_CONTROL was inputted into the tool.

## II. BACKGROUND INFORMATION

### A. FAULT TREE ANALYSIS

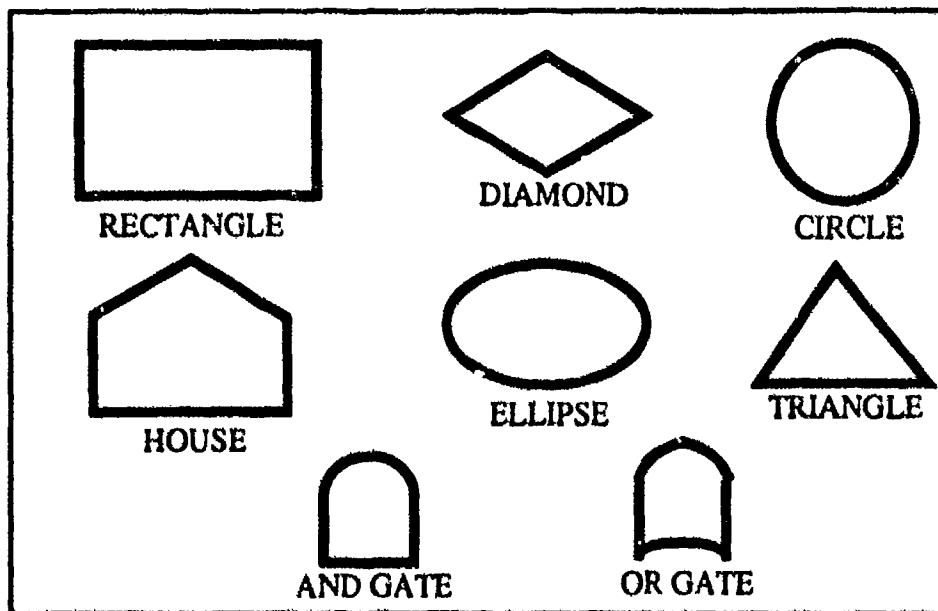

Fault tree analysis (FTA) is a method of deductive safety analysis where a fault tree depicts the logical interrelations of basic events that lead to a particular event of interest. [Lev 91] FTA originated initially in 1961 at Bell Laboratories to aid in the analysis of the Minuteman missile. Boeing further developed FTA in the mid 1960's. [Sal 76] A fault tree consists of a fault event, a failure situation resulting from the logical interaction of primary failures or failures of interest; a branch, the connection between two fault events or fault tree gates; and a fault tree gate, the boolean logic symbol that relates the input to its output event. [Fus 73] The fundamental concept of FTA is to decompose a physical system into a fault tree, also known as a logic diagram, where certain specified causes lead to one specified event of interest. This specified event of interest is also known as the "Top" event. [Sal 76]

To develop a fault tree, the initial step is to define the top event that will be analyzed. After the top event is defined, the next step is to locate the event(s) that by themselves, or in combination with others lead to the top event. This analysis looks for a plausible sequence of events that can lead to the event of interest in the context of the system's environment. [Mcg 89] If one or more event(s) is/are required to produce the event of interest, an And Gate is used to connect the event(s) to the event of interest. If one or more event(s) can lead to the event of interest, the event(s) is/are connected to the event of interest with an Or Gate. This process will continue until all events in the tree are defined or are not decomposable. [Sal 76] The results of the fault tree either depict the method of how the top event could occur or show that the top event can not occur. [Mcg 89] For a more detailed discussion on fault trees see the papers by Salem and Fussell. [Sal 76] [Fus 73]

## B. SOFTWARE FAULT TREE ANALYSIS

McIntee coined a phrase "Soft Tree" in 1983 for a process which looked at software analysis using FTA techniques. This technique required a schematic of the system and a flow diagram of the software. His work basically started by identifying a top event and worked backward through the schematic and flow diagram. The result of this process provided a detailed path for how the process worked from the top to the bottom and through the hardware and software. [Mc 83]

Taylor in 1982 [Tay 82] and Leveson and Harvey in 1983 [Lev 83] provided initial information on software fault tree analysis (SFTA). SFTA is a technique to analyze the safety of a software design that is similar to Soft Tree which uses methods similar to FTA. SFTA looks at the logic contained in the software. The primary purpose of SFTA is to ensure that the logic of the software does not produce system safety failures. Additionally, SFTA determines environmental conditions that could cause the software to create a safety failure. [Lev 83]

**Figure 1 Common Software Fault Tree Symbols**

SFTA, like FTA, is designed to work from the identified hazard backwards to the initial command to execute the system. In addition, SFTA uses a subset of the symbols used

for FTA. (See Figure 1) The “rectangle” represents an event that will be further analyzed. The “diamond” is used for nonprimal events, which are not developed further for lack of information or insufficient consequences. The “circle” indicates an elementary event or primary failure of a component where no further development is required. The “house” is used for events that normally occur in the system. It represents the continued operation of the component. The “ellipse” is used to indicate a state of the system that permits a fault sequence to occur. This system state may be normal or a result of failures. The “triangle” represents another sub-tree for the node which is not depicted on the current tree. The “and gate” serves to indicate that all input events are required in order to cause the output event. The “or gate” indicates that any of the input events may produce the gated event. [Rol 86]

This common use of symbols allows for the interfacing of SFTA and FTA, thus providing a means for systems analysis of the hardware and software. The process of SFTA is similar to FTA, the difference is that SFTA pertains to software events and that SFTA does not employ the probabilistic approach of FTA, but instead deals with logic. “The basic procedure is to assume that the software has performed in a manner, which has been determined by the hazard analysis will lead to a catastrophe, and then to work backward to determine the set of possible causes.” [Lev 91] After determining the catastrophe that occurred, the process works backward to the next level to determine the necessary preconditions for the catastrophic event to occur. Each child of each node will encounter the same process until the child can not be analyzed for some reason. The result of this process is a tree diagramming how an undesired event could occur or proof that an event could not occur. [Lev 91]

SFTA provides many advantages to software analysis. The advantages include the following:

- Provides the focus needed to give priority to catastrophic events and to determine the environmental conditions under which a correct state becomes unsafe.
- Provides a convenient structure to store the information gathered during the analysis which can be used later for redesign.

- The technique is familiar to hardware designers.
- Provides a single structure for specifying software, hardware, human actions and interfaces with the system.
- Allows the examination of the effects of underlying machine failures or environmental changes versus verification techniques which assume system operates correctly. [Lev 83]

## C. PREVIOUS WORK

### 1. FAULT TREE EDITORS

Editors to graphically display fault trees have been developed to facilitate the drawing of fault trees by the analyst. These tools allow the user to interactively modify the graphic representation of a fault tree using an automated graphic editor. The use of automated editors reduces the time required to draw the trees by removing the manual tasks necessary. Additionally, some of the errors that may have been caused by the manual drawing can be eliminated with an automated graphic editor. Two tools reviewed during the research of this thesis are the Software Fault Tree Analysis Tool [Rol 86], developed at the University of California, Irvine and Fault Tree Editor (FTE), developed at the Naval Postgraduate School. This thesis used FTE because it was readily available and operational at the time this thesis was initiated.

The Fault Tree Editor is an interactive fault tree design tool. FTE was written by Charles P. Lombardo, a computer systems programmer at the Computer Science Department at the Naval Postgraduate School in Monterey California. FTE was developed using the C programming language and XView, an OPEN LOOK toolkit for the X11 Windowing system.

Once FTE is running, the user can load a file to display a fault tree. The file can either be a file created by the tool or a file that meets the specifications of FTE. The specification of an FTE file consists of four lines for each node on the tree. The first line is a string of characters that represent the label of the node. This value is the label displayed on the node within the tree. The second line is another string of characters that represent the description of the fault. The third line is also a string of characters. This string of characters

is the file name of the code associated with the node. The fourth line contains seven integer fields that are separated by any white space except a new line. These values represent the starting and ending line numbers of the code associated with the node, the X and Y coordinates where the node is located in the FTE graphical drawing field, the type of node, the type of gate attaching the node to its children, and the number of children of the node. The file is arranged with the four lines of each node grouped together and each node ordered in a pre-order fashion according to its relationship to the root node. (See Figure 2)

## 2. SOFTWARE FAULT TREE TEMPLATES

Taylor discussed the building of fault trees and software fault trees in his paper in 1982. Using techniques from FTA and SFTA discussed above, Taylor used finite state models of plant components in the development of the fault tree. Taylor's process used the

plant components, also known as “mini-templates”, in building the fault trees. At each level, the event being analyzed would be matched to the mini-template to determine the events required to cause the undesired event. The process terminated when a spontaneous or normal event was encountered.

Leveson, Cha, and Shimeall wrote several papers on SFTA in 1987, 1989, and 1991. Their work provided a manual means to perform SFTA for Ada code. Their work used predefined templates as the failure semantic of the Ada programming language statements. These templates were based on Ada statement structures, showing that if a particular Ada structure caused a fault, where could that structure have caused the fault. By linking the templates according to the code, the software fault tree generated would provide a tree depicting where faults, if they occurred, could occur. [Lev 91] Modified versions of the templates are in Appendix C.

### **3. AUTOMATED SOFTWARE FAULT TREE ANALYSIS**

Friedman automated SFTA for certain code structures of Pascal in 1993. His procedure consisted of four steps. Initially, a lexical analysis of the input would remove the blanks, tabs, and carriage returns and breakdown the code into distinguishable items called tokens. The second step involved the parsing of the tokens. This parsing step would generate a list structure that described the syntactic structure of the program. Upon completion of the parsing step, the list would be traversed creating the software fault tree using pre-defined templates and rules. This step would produce an ASCII file that would be compatible to a proprietary editor tool so that the tree could be drawn. The final step is the actual drawing of the tree using the generated ASCII code and the editor tool. Friedman's tool used a commercial software product called Tree-Master that allowed the analyst to edit, display, and print the tree. [Fri 93]

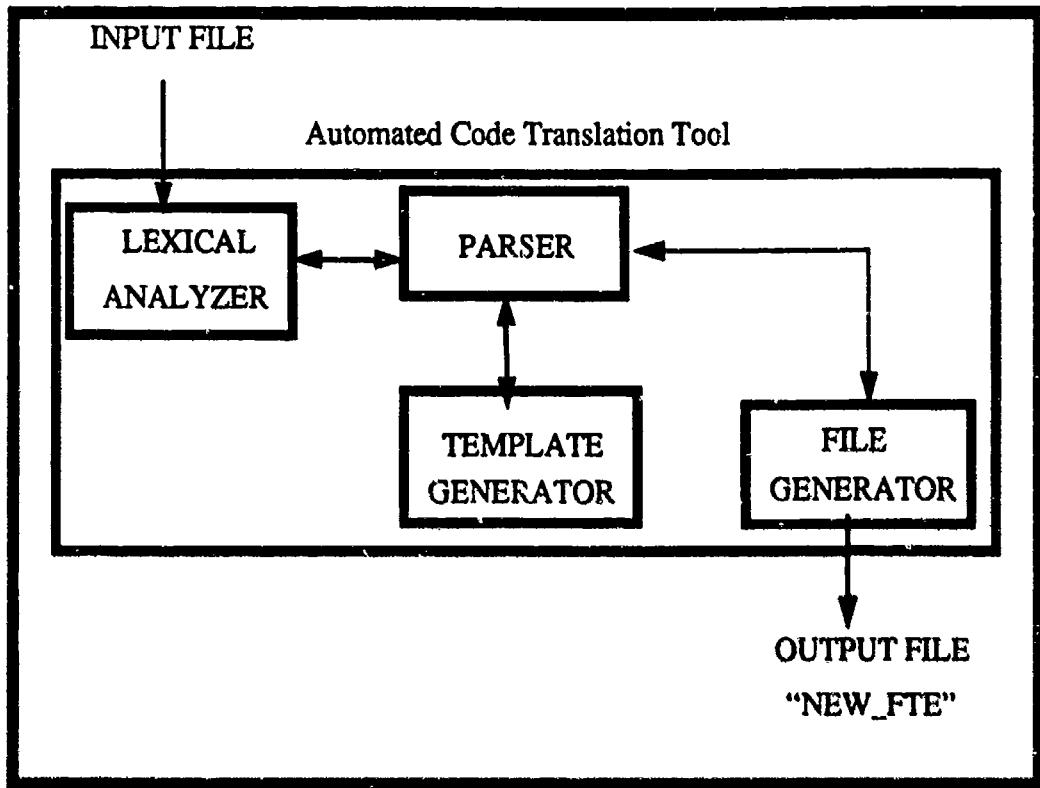

Friedman's research provides an introduction of automation to the software fault tree analysis methodology of software analysis. His tool, however, only looks at a limited number of code structures of Pascal, namely the assignment-statement, the if-statement,

and the while-statement. This research looks at the use of automation in the code translation of Ada code since Ada code is used in control systems more than Pascal and Ada code contains unique structures, such as exceptions and tasking.

### **III. AUTOMATED CODE TRANSLATION TOOL PROTOTYPE**

In the past, the code translation for SFTA has normally been performed using manual techniques. The use of manual techniques is a timely proposition. In addition, the use of manual techniques can lead to the introduction of errors because humans are fallible. This thesis introduces a prototype for an automated code translation tool to minimize the amount of manual code translation needed for SFTA. This tool is intended to reduce the amount of time necessary and reduce the number of errors in translating code by limiting the amount of human involvement. This chapter will discuss the tool, detailing the items used in the development of the tool and the methodology used in building the tool.

The Automated Code Translation Tool, as its name suggests, is a tool that will translate Ada statements into template structures to be used in SFTA. The tool consists of basically four components. The first component is a lexical analyzer. The lexical analyzer will determine if the given input consists of valid tokens. The next component is a parser. This part of the tool will check the given input to ensure that valid Ada constructs are used. The third component is a template generator that will transform valid statements into templates representing possible events associated with the statement in a format suitable for SFTA. The final component of the tool is a file generator that will create a file that meets the specifications of an FTE file type. Each component will be discussed in the following sections. (See Figure 3)

**Figure 3 Automated Code Translation Tool Structure**

#### A. THE LEXICAL ANALYZER AND PARSER

A lexical analyzer is a part of a system that breaks up the inputted code into meaningful units called tokens. Tokens can be names, constants, reserved words, or operators, among other things that are defined by the programming language. The lexical analyzer will also remove white space including blank spaces, empty lines, and carriage returns. The primary purpose of the lexical analyzer is to determine if the given input consists of valid tokens for the programming language. [Ill 90] The lexical analyzer for the Automated Code Translation Tool was built using an Ada based lexical analyzer generator called Aflex. For more information on Aflex, see the Aflex user manual. [Ngu 88]

The specification file for Aflex used to develop the lexical analyzer in the Automated Code Translation Tool was developed by Herman Fischer of Litton Data Systems in March 1984. The lexical input information in this file represents the grammar for ANSI Ada. No

modifications to the file were required in the development of the tool. The Aflex specification file for the Automated Code Translation Tool is located in Appendix A.

A parser is the programming module that performs parsing operations on a computer language. Parsing is the process of deciding whether a string of input symbols is a sentence of a given language, and if so, determining the syntactic structure of the string as defined by a grammar for the language. The primary purpose of the parser is to validate the string as a correct statement for a given language. [Ill 90] The parser for the Automated Code Translation Tool was built using an Ada based parser-generator called Ayacc. For more information on Ayacc, see the Ayacc user manual. [Tab 88]

The Ayacc specification file used to develop the parser in the Automated Code Translation Tool was a modified version of the David Taback and Deepak Tolani specification file. The Taback and Tolani version was an adaptation of the Herman Fischer file used in Yacc. The grammar for the file is organized in the same order as the ANSI Ada Reference Manual.

The modifications to the Taback and Tolani file for the tool consisted of added actions to be performed when particular code structures were recognized. These actions are related to functions and procedures located in separate packages and are components of the template generator which will be discussed in the next section. The packages are FAULT\_TREE\_GENERATOR and TRAVERSE\_PKG and are located in Appendix B. The specification file for Ayacc used in the development of the parser for the Automated Code Translation Tool is located in Appendix A.

## B. THE TEMPLATE GENERATOR

Basically the templates represent the idea "If this statement caused a fault, where could that fault have been introduced within the statement". These templates were developed using the previous work of Leveson, Cha, and Shimeall. [Lev 91] The templates were slightly modified to accommodate the parsing of the Ada grammar. The templates for the

implemented code structures are located in Appendix C. The symbols used in the templates are similar to the symbols used in software fault trees. (See Figure 1)

The template generator consists of functions and procedures that are called when various Ada structures are recognized. The template generator works in concert with the parser. As the parser identifies various structures, the template generator will be called to build the template for the particular structure. This process is exemplified with an if-statement example. (See Figure 4) The following is a description of how the if-statement is parsed using the Ada grammar and how the template is built with the tool.

```
IF temperature < 15.0 THEN
    rad_set:= rad_set + 5.0;
ELSIF temperature < 18.0 THEN
    rad_set:= rad_set + 1.0;
ELSE
    rad_set:= rad_set - 1.0;
END IF;
```

**Figure 4 If-Statement Example**

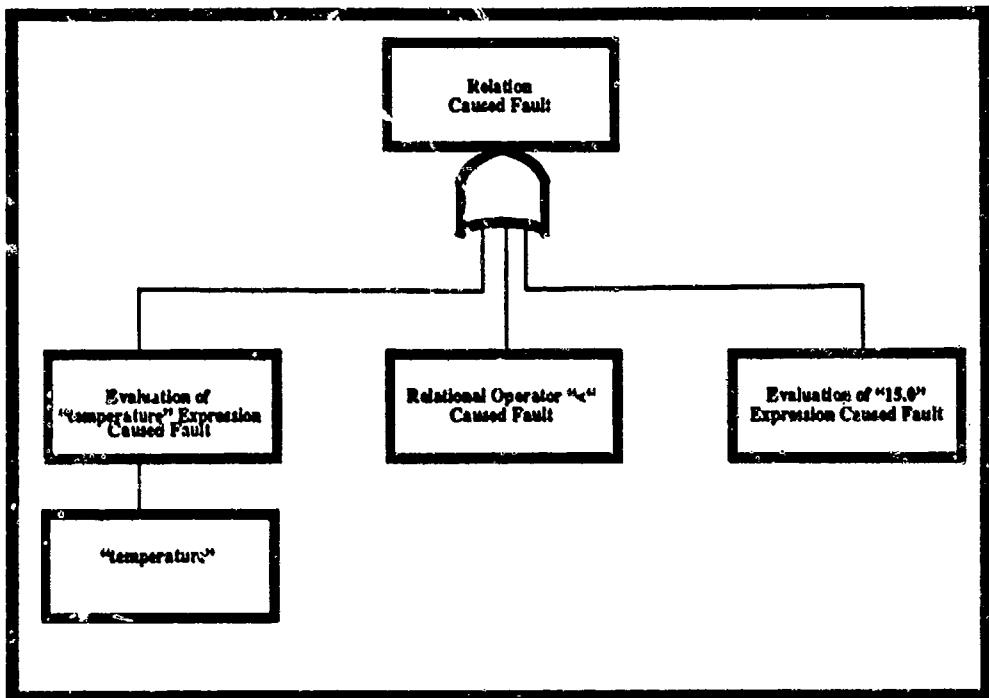

When the parsing of Ada source code begins, it initially starts at the starting non-terminal "compilation". Eventually it proceeds to the sequence of statements non-terminal and then to the statement non-terminal. Using the current token "if", the if-statement grammar rule is selected and the process to build the template for the if-statement begins. The if-statement grammar rule consists of seven grammar symbols. (See Figure 5) Before the if-statement template is built, the parser must identify and parse the individual grammar symbols. This discussion looks at only the parsing of the non-terminals because terminal symbols are recognized by lexical analysis. (When looking at the grammar rules, the capital words identify non-terminals in the rule.)

```
IF_STMT: if_token COND then_token  
        SEQ_OF_STMTS  
        ..ELSIF_COND_THEN_SEQ_OF_STMTS..  
        .ELSE_SEQ_OF_STMTS.  
        end_token if_token ';' ;
```

**Figure 5 Production Rule for If-Statement**

The first non-terminal of the if-statement rule is the condition non-terminal. The condition represents a boolean expression for the if-statement. In parsing the condition non-terminal, the expression non-terminal will be called. From the expression non-terminal, the relation non-terminal with one or more relations and zero or more logic operators, depending on the actual input, will be executed. At the relation level, a template containing possible events related to the actual condition will be built by the template generator and returned to the expression non-terminal level. This template will be passed backward to the condition non-terminal level and in turn passed back to the if-statement non-terminal level for use in the building of the if-statement template.

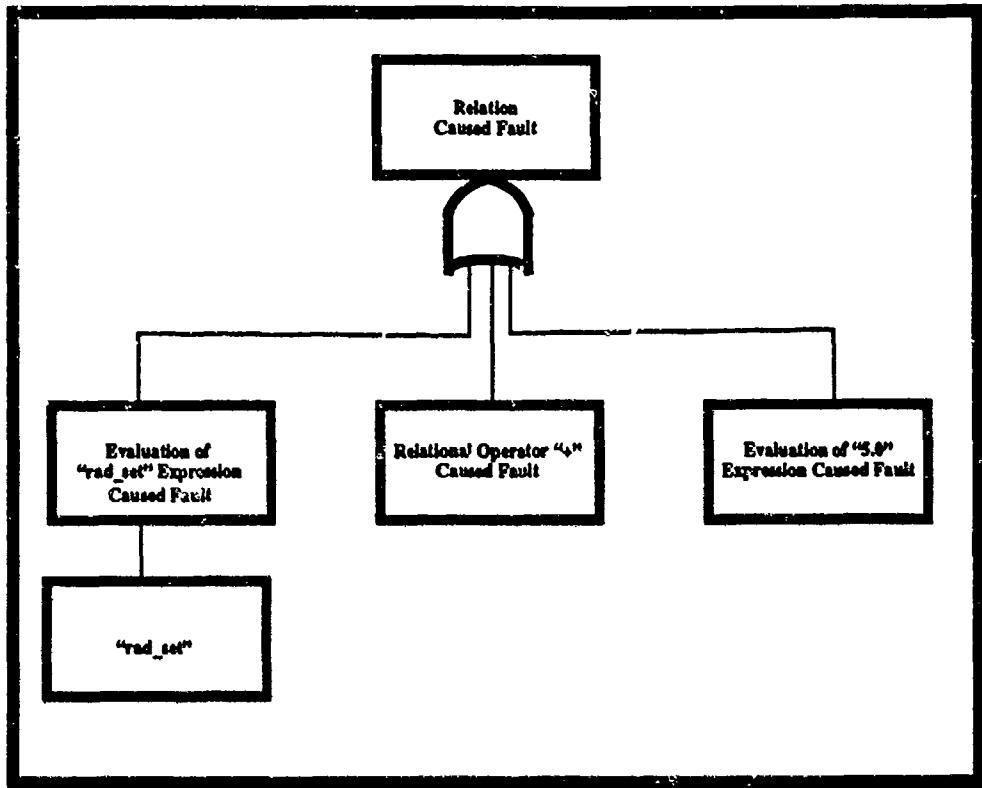

In the example, the condition is a simple relation, "temperature < 15.0". For this condition the template generator will build the simple relation template. (See Figure 6) This template would be passed back from the relation non-terminal back to the if-statement non-terminal through both the expression and condition non-terminals.

**Figure 6 Relation Template for IF Condition**

Following the condition non-terminal, the sequence of statements non-terminal of the if-statement production rule would be parsed. This sequence of statements represents the action that would be performed if the condition evaluated to true. In the example, the parsing would again start at the sequence of statements non-terminal and recognize that the next non-terminal was a single statement. This statement would be identified as a simple statement, followed by recognition as an assignment-statement. At the assignment-statement production rule, the parser would parse the individual components of the rule. The rule consists of two non-terminals, name and expression. For the name non-terminal, the parser would recognize that "rad\_set" is a simple name and at the simple name non-terminal the name template for "rad\_set" would be generated by the template generator.

The next non-terminal of the assignment-statement is the relation, "rad\_set + 5.0". This example is another simple relation. The relation template would be built for this expression by the template generator and passed back to the assignment-statement. (See Figure 7)

**Figure 7 Relation Template for Assignment-Statement**

When the parser returns to the assignment-statement non-terminal, the template generator will create the assignment-statement template with the simple name template and the relation template for the assignment-statement as components to the template. The two previously generated templates would be placed as children to the "Operand Evaluation Caused Fault" node. (See Figure 8) The assignment template will be incorporated into the template for the sequence of statements to represent the sequence of statements for the if condition. (See Figure 9) Since there is only one statement in the sequence of statements, the nodes pertaining to the previous statements will not be necessary. The sequence of statements template would be returned to the if-statement non-terminal level to be used in the creation of the if-statement template.

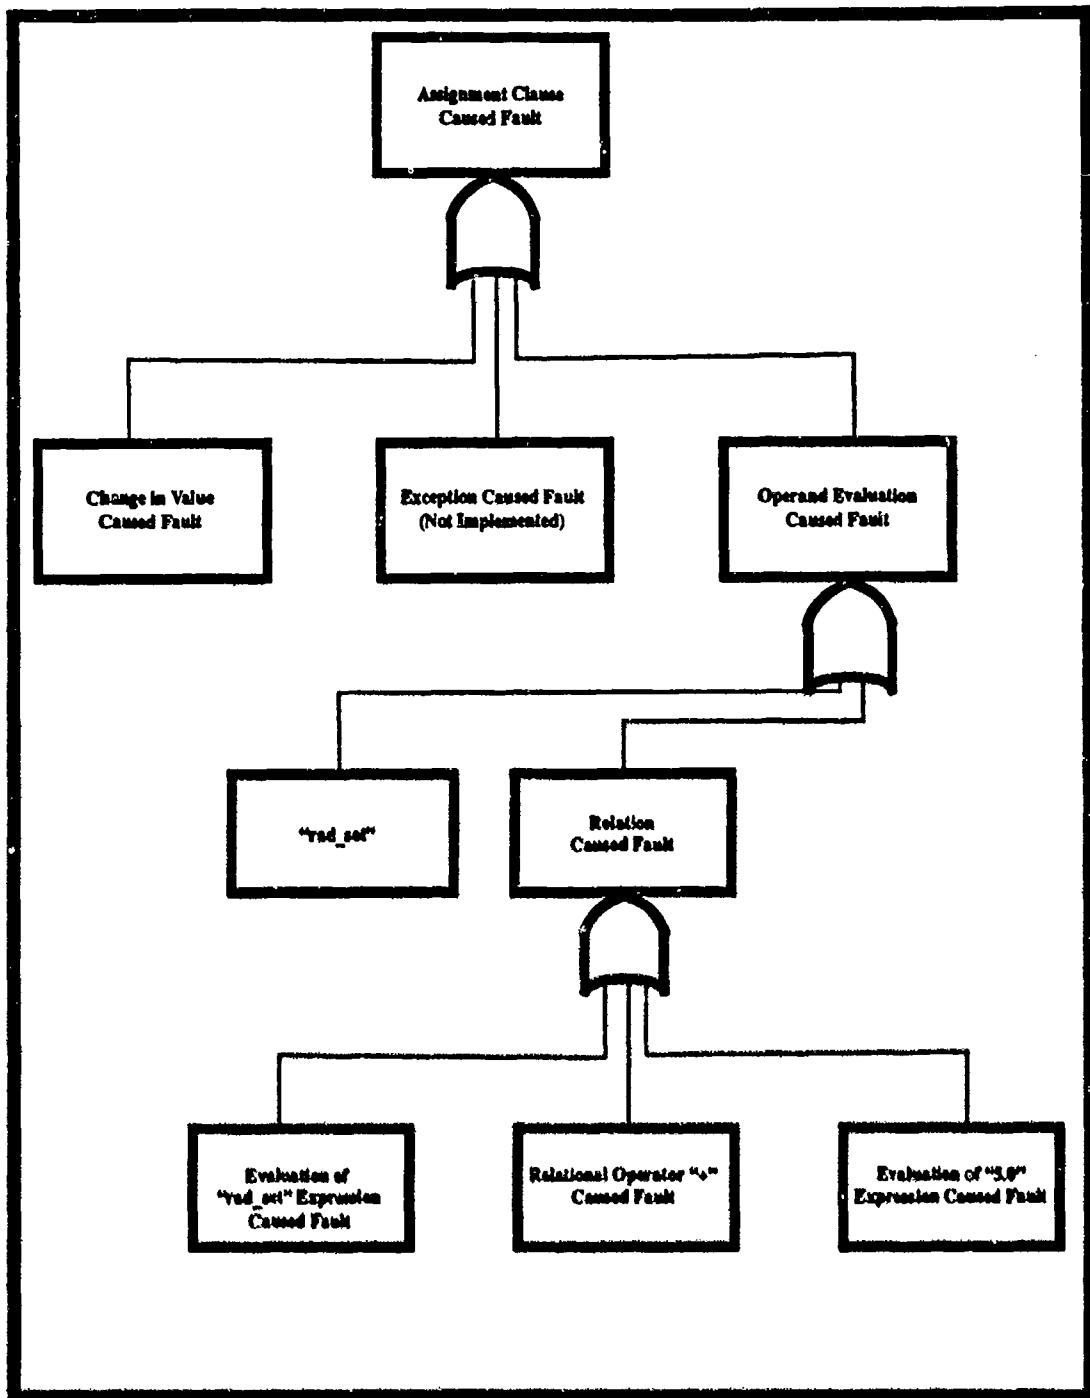

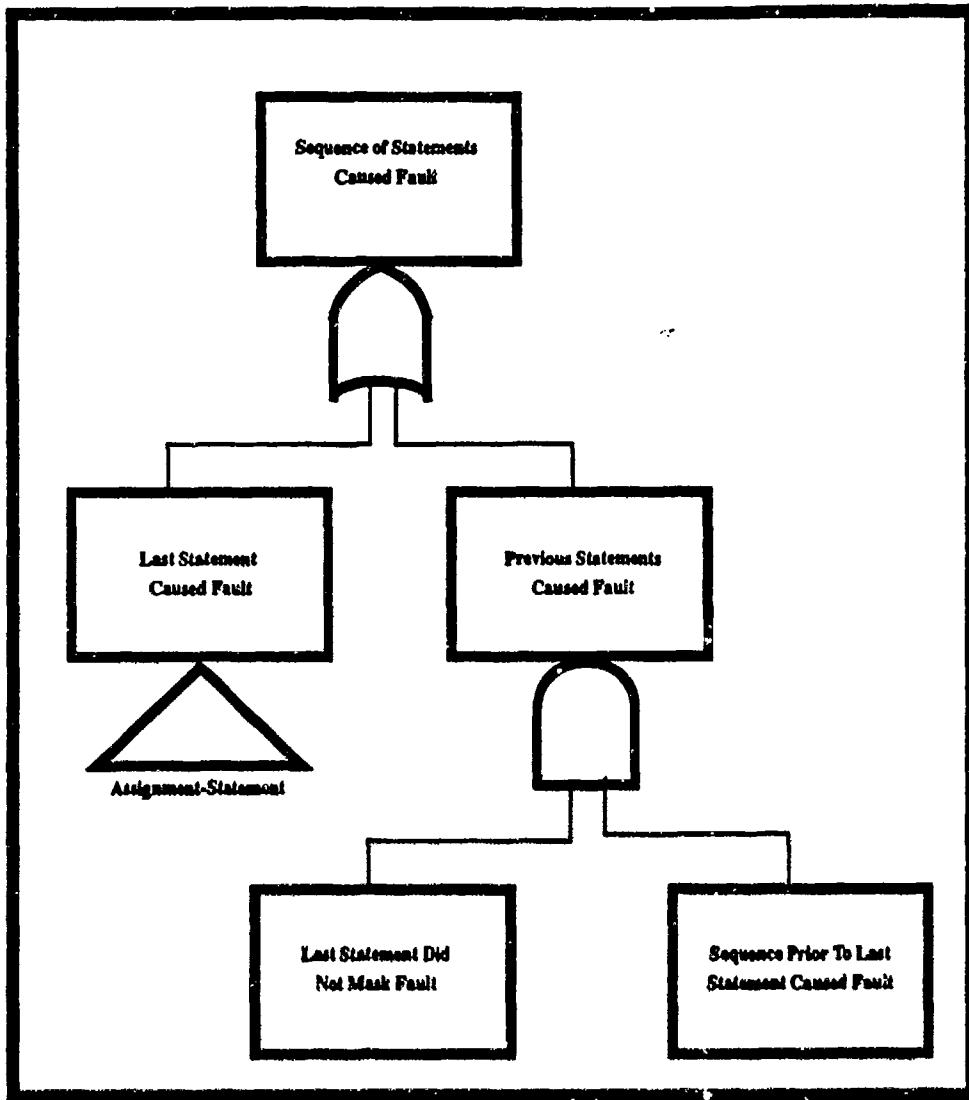

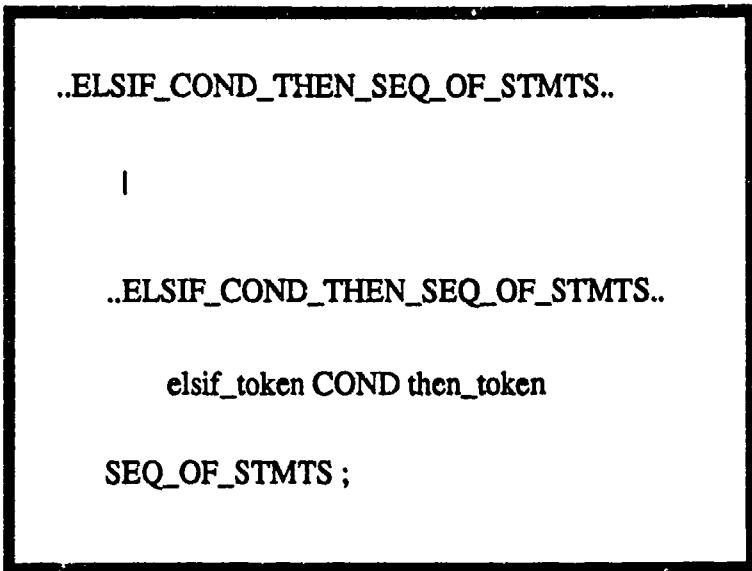

Figure 8 Assignment-Statement Template for If Clause

**Figure 9 Sequence Of Statements Template for If Clause**

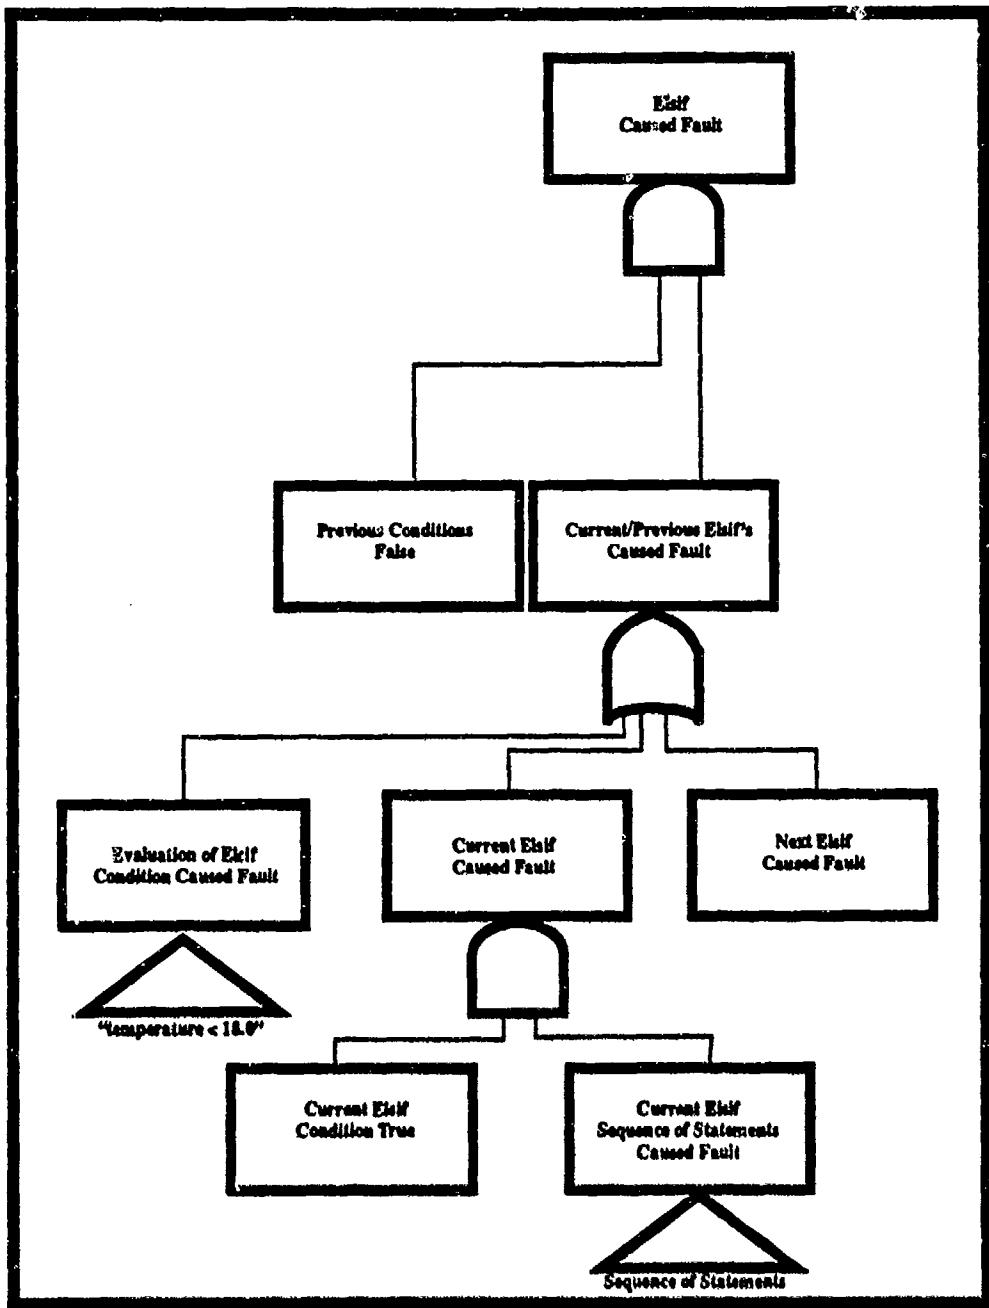

The next non-terminal token to be evaluated from the if-statement production rule would be the token referring to the "elsif" clause. The elsif clause is optional. This non-terminal has three non-terminals in the production rule. These non-terminals are a non-terminal for other elsif's if applicable, a condition non-terminal, and a sequence of statements non-terminal. (See Figure 10) For the example there is only one elsif clause, therefore the other elsif non-terminal will not be executed. The elsif non-terminal is a recursive call to itself and will stop only after all elsif's have been parsed.

**Figure 10 Production Rule for Elsif Clause**

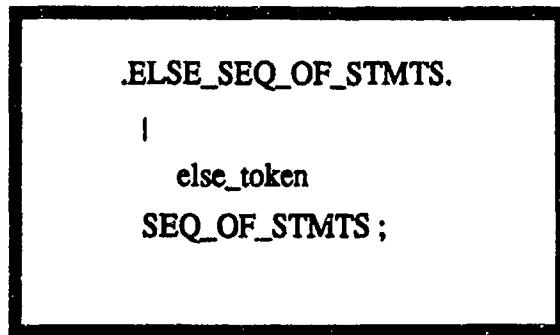

The condition for the `elsif` in the example is “temperature < 18.0”. This condition is another simple relation and would produce a template similar to the condition template for the `if` condition. The sequence of statements following the `elsif` condition is also similar to the previous sequence of statements, another single assignment-statement. The assignment-statement is “`rad_set := rad_set + 1.0;`”. The template generated by the template generator for this statement is identical to the previous sequence of statements except for a change in some of the values to the variables.

The condition template for the `elsif` and the sequence of statements template for the `elsif` will be passed back to the `elsif` non-terminal. The template generator, after the parser completes the parsing of the non-terminals in the `elsif` example, will use these templates to build the `elsif` template for the `if`-statement. Since there are no other `elsif`’s in this example, the node “Next Elsif Caused Fault”, which pertains to the other `elsif`’s of the statement, will not be required. (See Figure 11)

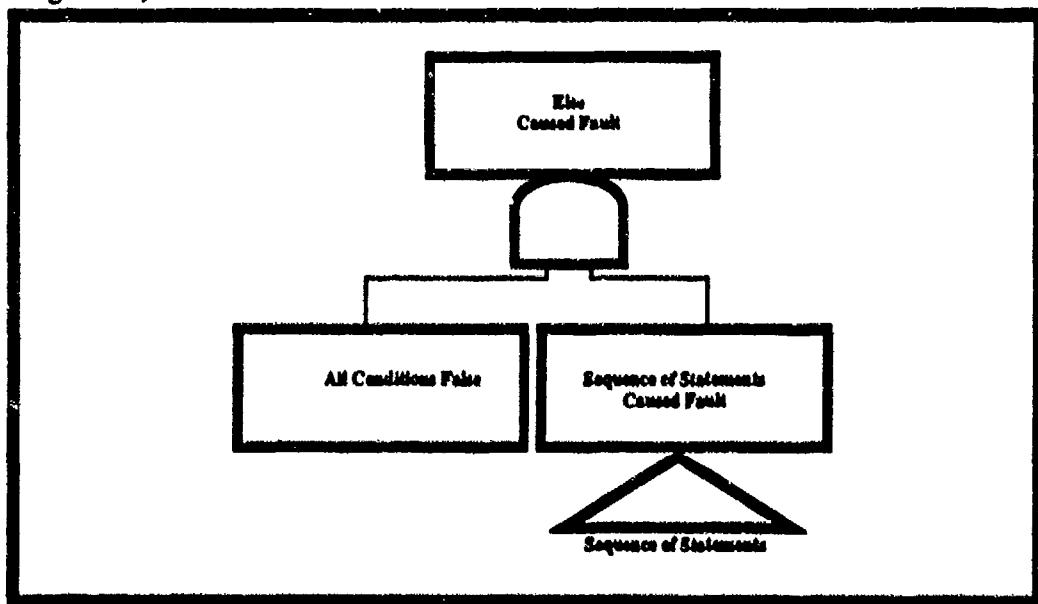

**Figure 11 Elif Template for Example**

The final non-terminal token for the if-statement is the token representing the "else" clause. The else clause is optional and if it exists, it will be executed if there are no previous conditions that evaluated to true. The production rule for the else clause consist of only the sequence of statements non-terminal. (See Figure 12)

**Figure 12 Production Rule for Else Clause**

In parsing the sequence of statements for the example, the parser would again recognize that it consists of only one statement. This statement is the assignment-statement “rad\_set := rad\_set - 1.0;”. Upon recognition of this fact, the template generator would create similar templates as before, excluding the condition template because the condition for the else clause is implicitly defined. The sequence of statements template will be passed back to the else non-terminal where the template generator will build the else template with the sequence of statements as a child of the template. The else template, when built, will be passed back to the if-statement non-terminal to be included in the if-statement template. (See Figure 13)

**Figure 13 Else Template for Example**

Once all the components of the if-statement have been parsed and the appropriate templates have been built, the template generator would be called to build the template for the if-statement. This template would be built using all of the templates that were generated by the non-terminals of the statement. (See Figure 14) Appendix C gives a more detailed version of a generic if-statement template.

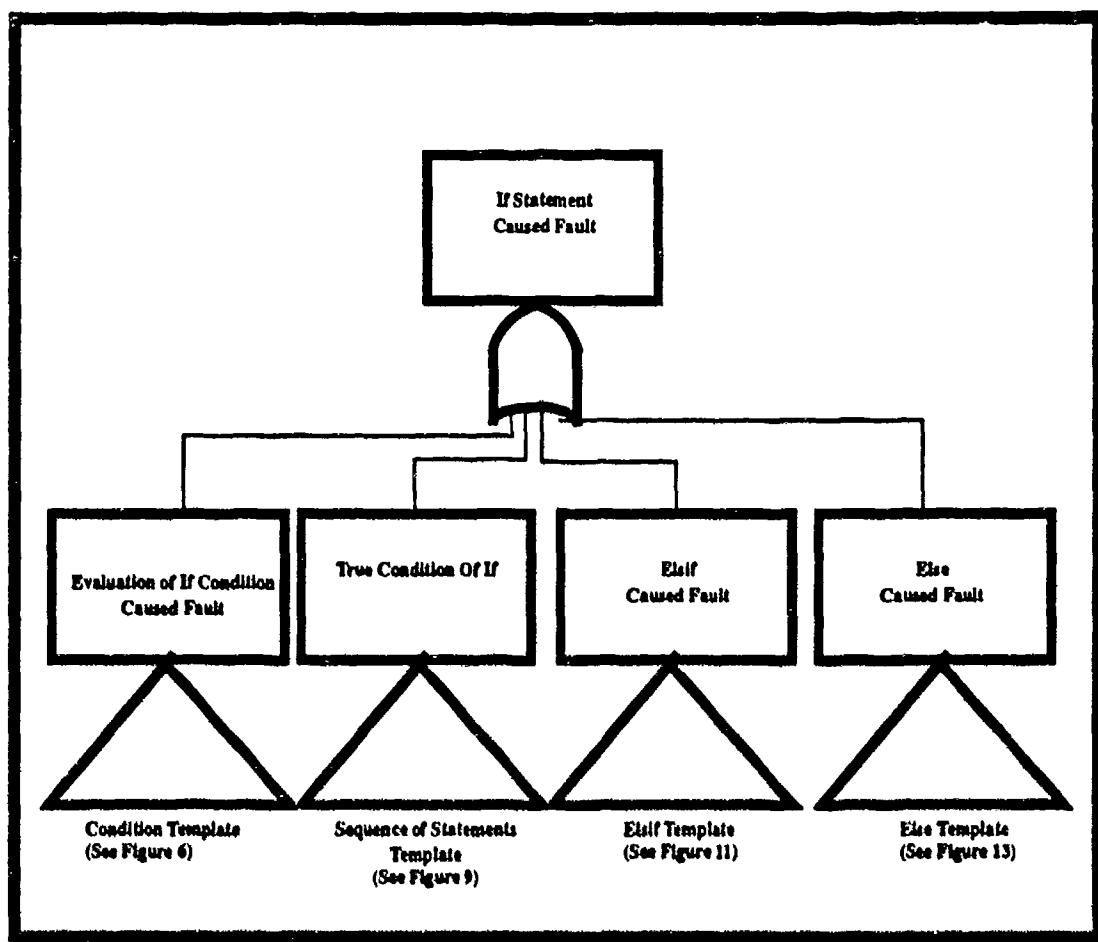

Figure 14 If-Statement Template for Example

## C. THE FILE GENERATOR

The file generator is the part of the Automated Code Translation Tool that produces a FTE type file for the given input. The file generator is composed of Ada procedures that will take the generated templates and convert the data structures into FTE data structures.

Additionally, in accordance to FTE file specifications, the file generator will place the individual nodes in pre-order fashion with respect to their relationship to the root node. The file generator is embedded in the parser as actions and will be invoked when the parsing of the given input is complete. The file generator will produce a file called "NEW\_FTE". This file can be loaded into FTE to display a graphical depiction of the software fault tree for the given input.

## D. THE DATA STRUCTURE

The data structure for the nodes of the software fault tree was constructed using the FTE data structure as a model. This structure was used to facilitate the drawing of the software fault tree upon completion of the parsing and template building. (See Figure 15) The individual fields of the data structure that are similar to the FTE data structure have the same meaning as discussed earlier. The added fields CHILDREN\_NODES and PREV\_ST\_PTR were added to keep track of the family ties because the nodes' relationships as parents and children are maintained by using a linked list. The other added field, OUTPUT\_FLAG was not used in the prototype, but was included to allow the tool to identify structures that provide output in the program. In order to make the data structure compatible, a routine is used to equate the generated file to an FTE compatible file. This routine will remove the additional fields that were added to the data structure to facilitate the parsing. This routine is part of the file generator as discussed in the previous section.

```

type ST_LIST_NODE_PTR is access ST_LIST_NODE;
type ST_LIST_NODE is
record
    * ST_NODE_LABEL: STRING (1..MAX_CHAR_SHORT);
    * ROOT_FAULT: STRING (1..MAX_CHAR_LONG);
    * FILE_NAME: STRING (1..MAX_CHAR_LONG);
    * START_LINE: NATURAL;
    * END_LINE: NATURAL;
    * X_COORDINATE: INTEGER;
    * Y_COORDINATE: INTEGER;
    * TYPE_NODE: NODE_TYPE;
    * TYPE_GATE: GATE_TYPE;
    * NUMBER_OF_CHILDREN: NATURAL;
    PREV_ST_PTR: ST_LIST_NODE_PTR;
    CHILDREN_NODES: ST_LIST_NODE_PTR;
    OUTPUT_FLAG: BOOLEAN;
end record;

```

\*Derived from data fields in the FTE data structure

**Figure 15 Software Fault Tree Node Data Structure**

## E. THE INPUT / OUTPUT

When execution begins, the tool will prompt the user for an Ada file to work with. After the user enters the file name, the tool will process the file. The prototype has limited syntax-error detection, so it is assumed that the file is syntactically correct. The output of the tool will consist of two items. The first item generated by the tool will be an on-screen display of three lists. A listing of the software fault tree will be printed to the screen first. The information provided includes the node's label and fault and the parent's label and gate, if applicable. The next list is a list of the nodes in numeric sequence. This listing was generated to facilitate the reading of the generated FTE software fault tree, which in the prototype, labels nodes by number. The last item displayed on the screen consists of a

listing of the procedures, functions, and exceptions that were located in the input file along with the first node's root fault associated with the procedure, function, or exception.

The second item produced by the tool is an ASCII file called "NEW\_FTE". This file is compatible to FTE and represents the nodes produced in a pre-order listing. To display the software fault tree in FTE, FTE must be started and NEW\_FTE must be in the current directory. Once FTE is started, the generated file can be loaded into FTE using the appropriate FTE commands. This will generate the software fault tree in a graphical form.

## F. EXTENDED EXAMPLE

In order to see the actual code translation for a set of Ada statements performed by this tool, the tool was invoked with the file EXAMPLE.A. This file contained the procedure FAKE\_OVEN\_CONTROL. (See Figure 16) The procedure FAKE\_OVEN\_CONTROL was created to simulate an oven-control system. This procedure is by no means an accurate representation of an oven-control system, but is intended to represent source code where safety could be an important issue

```

procedure FAKE_OVEN_CONTROL(SAMPLING_DURATION : INTEGER;
                            GOAL_TEMP          : INTEGER) is
    OVEN_BUF  is access INTEGER;
    for OVEN_BUF use at 1234567;

    OVEN_TEMP is access INTEGER;
    for OVEN_TEMP use at 2345671;

    LAST_CMD : INTEGER;

begin
    for SAMPLE in 1..SAMPLING_DURATION loop
        if (OVEN_TEMP < GOAL_TEMP - 10 and LAST_CMD /= 1) then
            OVEN_BUF := 1;
            LAST_CMD := 1;
        elsif (OVEN_TEMP < GOAL_TEMP - 10) then
            RAISE OVEN_NOT_RESPONDING;
        elsif (OVEN_TEMP > GOAL_TEMP + 10 and LAST_CMD /= 2) then
            OVEN_BUF := 2;
            LAST_CMD := 2;
        elsif (OVEN_TEMP > GOAL_TEMP + 10) then
            RAISE OVEN_NOT_RESPONDING;
        end if;
        for I in 1..SAMPLING_DURATION loop
            null;
        end loop;
    end loop;
end FAKE_OVEN_CONTROL;

```

**Figure 16 Sample Ada Code Input**

For the procedure FAKE\_OVEN\_CONTROL, the body of the procedure consists of a sequence of statements. A careful review of the procedure FAKE\_OVEN\_CONTROL shows that the sequence of statements consists of a for-loop, which is the main part of the procedure, and two embedded statements within the for-loop. The first statement within the for-loop is an if-statement that contains three elsif clauses. The second statement is another for-loop that contains the null-statement. The following discussion details how the

procedure is transformed from Ada source code to software fault tree structures. Before this discussion starts, it needs to be noted that the tool will translate the source code bottom-up, meaning that the last statement will be translated first and the first statement will be translated last. In this example there is only one statement in the outer level; however, within the outer for-loop there are two statements. The inner for-loop will be translated first and the if-statement will be translated next. The last statement to be translated will be the outer for-loop. A discussion on the translation process of the procedure follows.

In the Ada programming language, three types of loops exist, including the "for", "while", and plain loop. The Automated Code Translation Tool will build a similar template for all three loops. The major difference between the three types of loops is the iteration scheme for each loop.

If a loop caused a fault, there are three possible reasons why the loop caused the fault. First, there may exist a situation where the loop was not executed and its non-execution may cause a fault. Another possible reason may involve the evaluation of the loop condition. Finally, there may have been some situation during the Nth iteration that caused the fault. The Automated Code Translation Tool incorporates all three reasons in the loop template when the template is built.

Since the example contains a for-loop, the Automated Code Translation Tool will tailor the generic loop template accordingly. The tool will build the "Parameters Specified Caused Fault" node as a child to the "Iteration Scheme Caused Fault" node, instead of the "Evaluation of Condition Caused Fault" node which is used for a while loop. Along with this, the tool will place the sequence of statements template for the statements in the for-loop in two places. This is done to recognize the fact that the sequence of statements may have caused the fault or that the sequence of statements may have kept the loop condition true when it should have been false. In the embedded for-loop, the only statement in the sequence of statements is the null-statement. In this case, the tree representing the sequence of statements will be null. (See Figure 17)

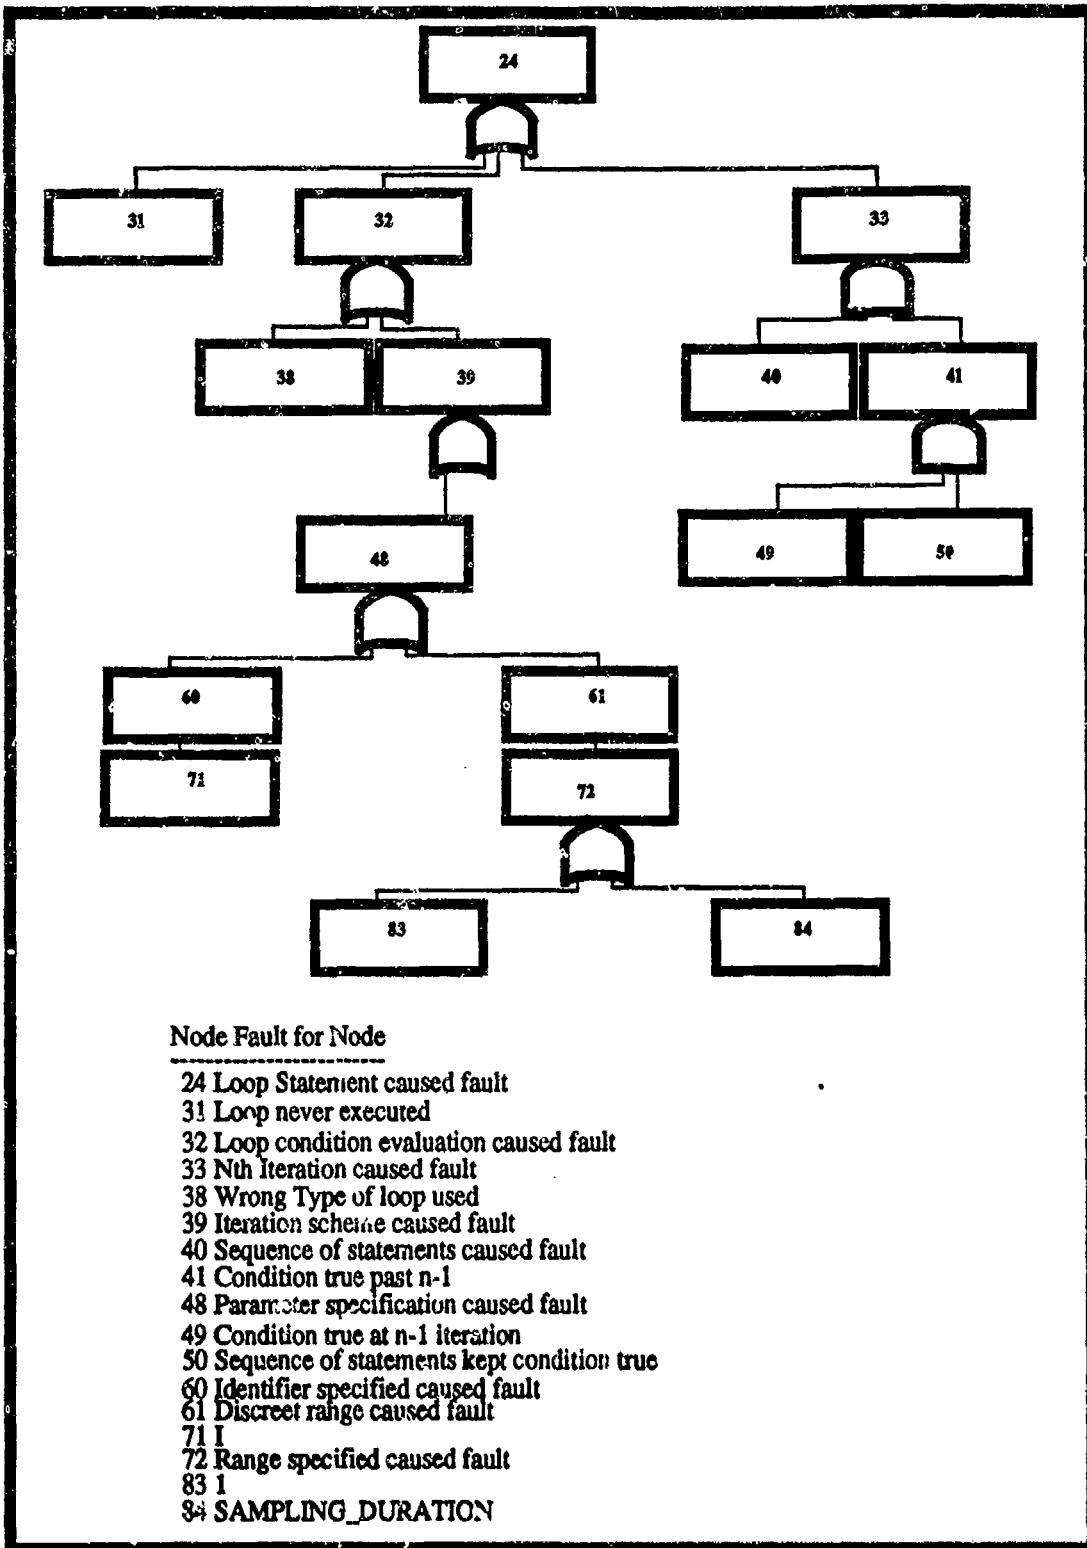

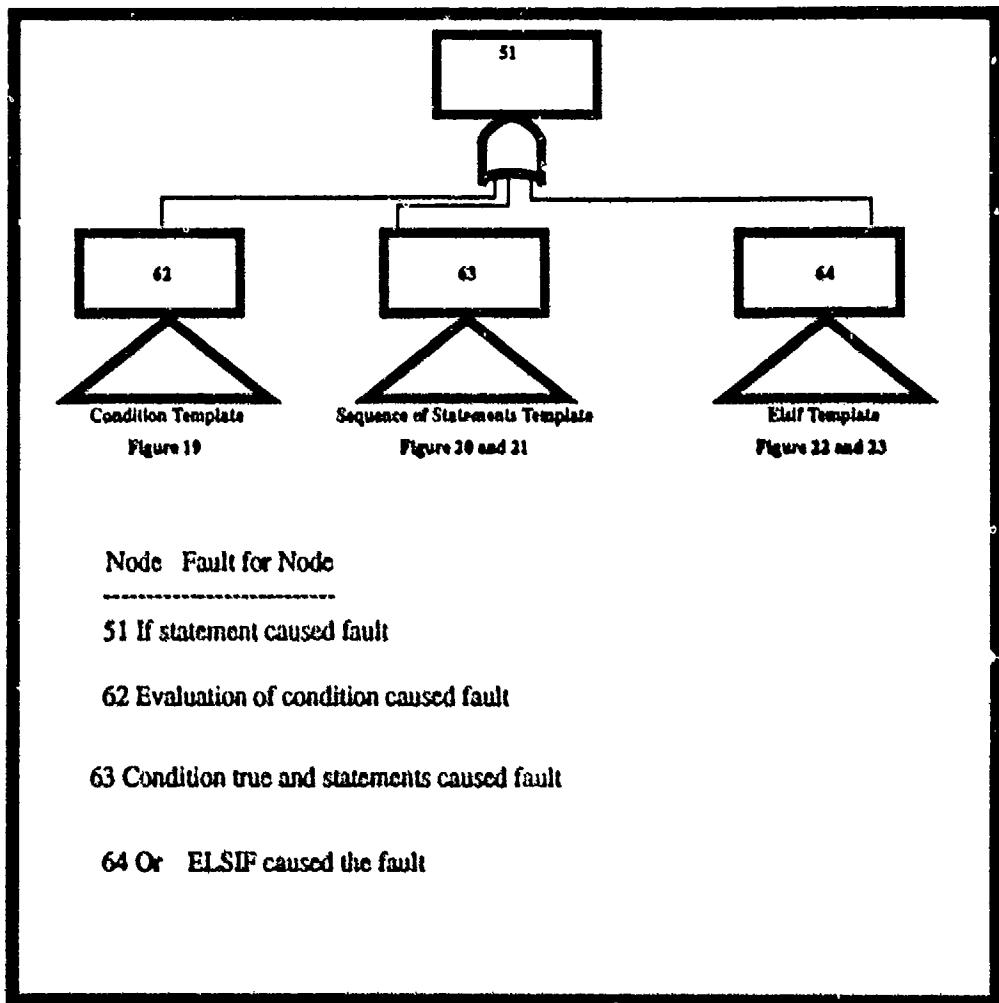

Figure 17 Embedded For-Loop Template for Procedure FAKE\_OVEN\_CONTROL

The if-statement for the procedure FAKE\_OVEN\_CONTROL is similar to the example if-statement discussed earlier in the template generator section. The if-statement for the procedure, however, has three elseif clauses and no else clause. The Automated Code Translation Tool will build the if-statement template using the node “Next Elsif Caused Fault” and its associated nodes several times and not using the node “Else Caused Fault”. Due to the large size of the software fault tree representing the if-statement in the procedure, the software fault tree is depicted in several figures. The figures are shown in the order that they would appear in the software fault tree and not in the order that they were generated.

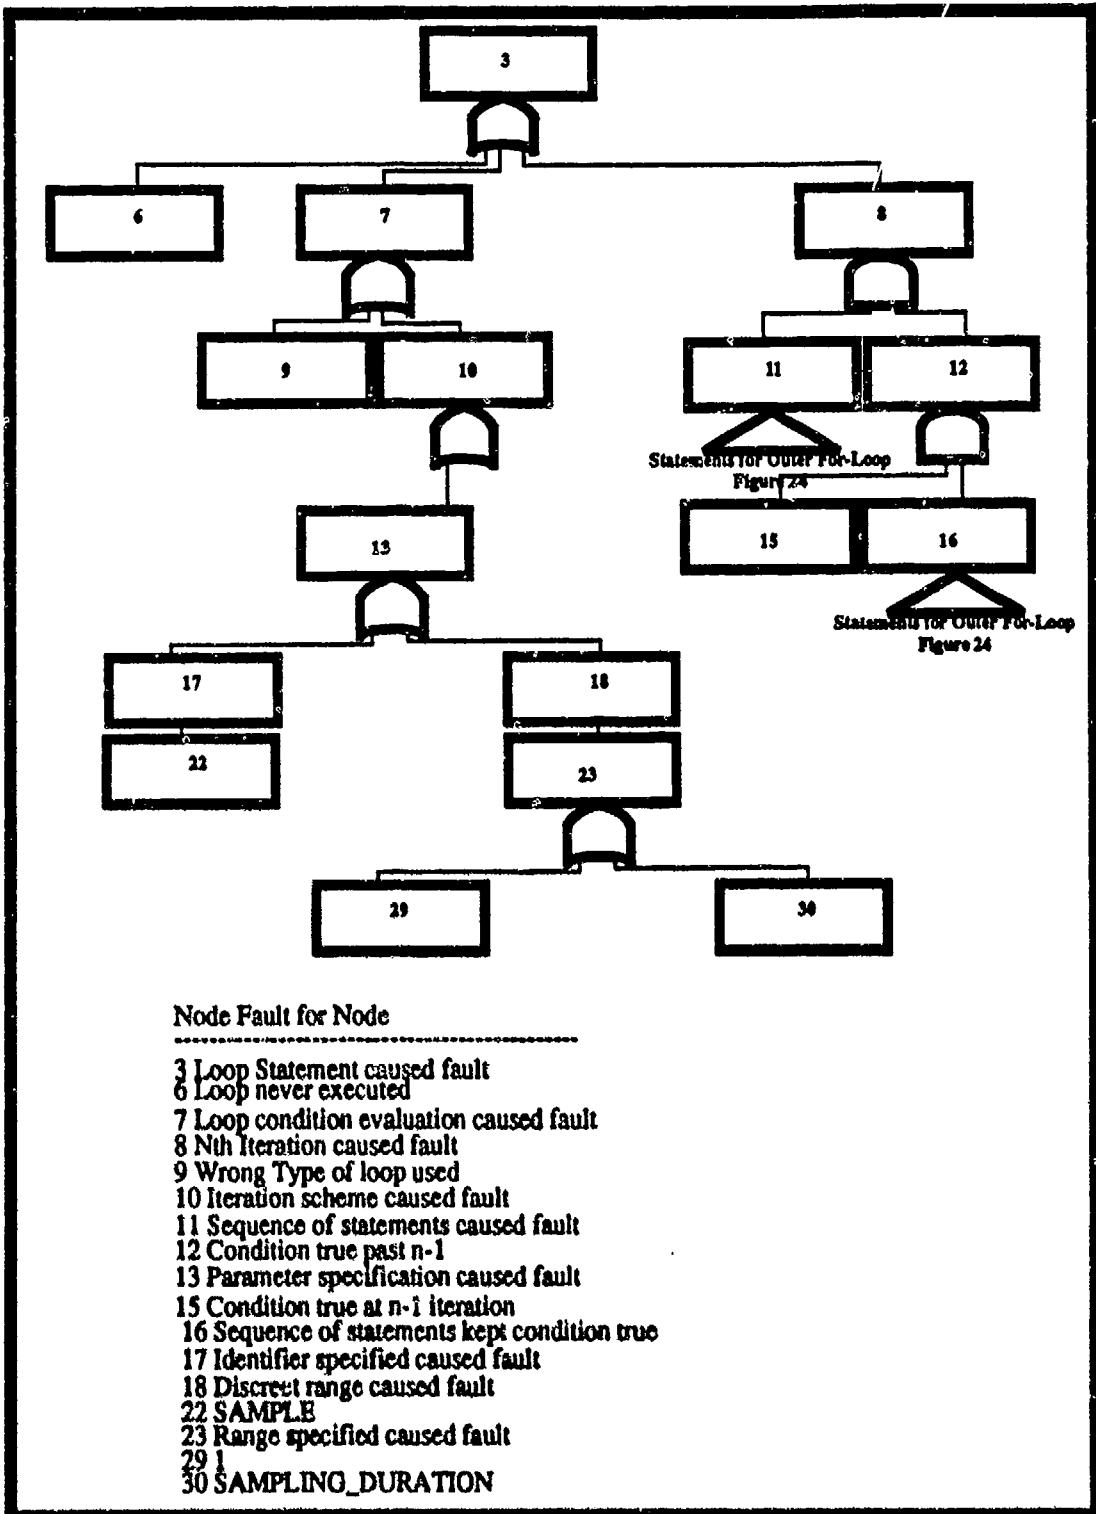

Figure 23 Elsif Template for If-Statement (Continued)

For brevity, the templates representing the other elseif alternatives are not depicted. The templates are identical to the elseif template displayed except for a different sequence of statements for each elseif. Upon completion of the if-statement translation, the Automated Code Translation Tool builds the sequence of statements template for the outer for-loop. This template contains both the embedded for-loop and the if-statement. This template is used in the outer for-loop template representing the statements within the outer for-loop. (See Figure 24)

Basically, the template for the outer for-loop will almost be identical to the embedded for-loop. The only difference is the software fault tree representing the sequence of statements within the for-loop. For the embedded for-loop, the software fault tree was null because the statement within the loop is the null-statement. The outer for-loop contains the two statements discussed above and is represented by the sequence of statements for the outer for-loop.

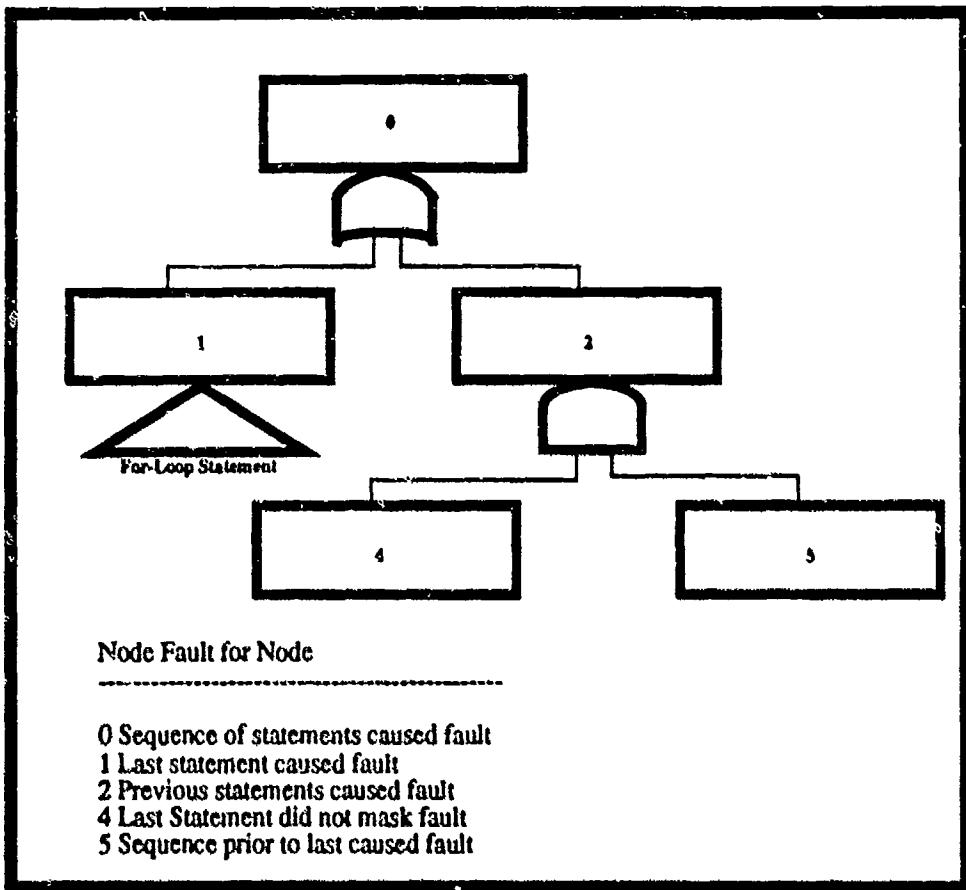

**Figure 24 Sequence of Statements Template for Outer For-Loop**

**Figure 25 Outer For-Loop Template for Procedure FAKE\_OVEN\_CONTROL**

For the procedure FAKE\_OVEN\_CONTROL, the Automated Code Translation Tool will build the sequence of statements template to represent the body of the procedure. The “Last Statement Caused Fault” node will have as its child the software fault tree representing the outer for-loop. Since there is only one statement for this procedure, the “Sequence Prior to Last Caused Fault” node will be null. (See Figure 26) The result from the Automated Code Translation Tool was a software fault tree that consisted over 300 nodes. This software fault tree depicted many possible events that could cause a fault. It is now the analyst’s job to select relevant events and expand the analysis accordingly.

**Figure 26 Sequence of Statement Template for Procedure  
FAKE\_OVEN\_CONTROL**

## G. FINISHING THE EXAMPLE ANALYSIS

To view the generated software fault tree in FTE, the user starts FTE and loads the file by clicking on the “LOAD” icon. FTE will now ask the user for the file to load. By typing

"NEW\_FTE", the software fault tree generated by the Automated Code Translation Tool will now appear in the graphical box. The software fault tree depicted by FTE may not contain all the nodes of the NEW\_FTE file because the drawing field available in FTE is limited. In order to view as many nodes as possible in the FTE drawing field, the algorithm used to generate the X and Y coordinates for the individual nodes was to place nodes on the appropriate level according to their relationship to the root node and to left justify the nodes on each level.

The Automated Code Translation Tool provides a service to the analyst. By automating the code translation, the amount of errors occurring in the translation is reduced to a minimum. Additionally, the time required by the analyst to perform this step is drastically reduced, allowing the analyst to make better use of his time. The tool, however, does not pin-point one specific fault. In order to use the generated software fault tree in SFTA, the analyst must identify a particular fault and modify the generated software fault tree accordingly.

For example in the FAKE\_OVEN\_CONTROL procedure there existed a for-loop that at first glance appeared to have no purpose since the loop body contained only the null-statement. In actuality, this loop was inserted as a delay to provide the control system the required time needed to perform its sensing. If this loop was removed when the code was compiled because of code optimization, the time required to sense the oven temperature would not be sufficient. This would likely cause the exception OVEN\_NOT RESPONDING to be raised. Using the generated software fault tree, the analyst could detect this fault.

Initially, the analyst must select a root fault to analyze. With the selected root fault, the analyst will eliminate the nodes from the output of the Automated Code Translation Tool that do not pertain to the selected root fault. Upon completion of this step, the analyst will need to modify the remaining nodes to ensure that they are relevant to the root fault. The end result of this process would be a software fault tree similar to the one in Figure 27. (See Figure 27)

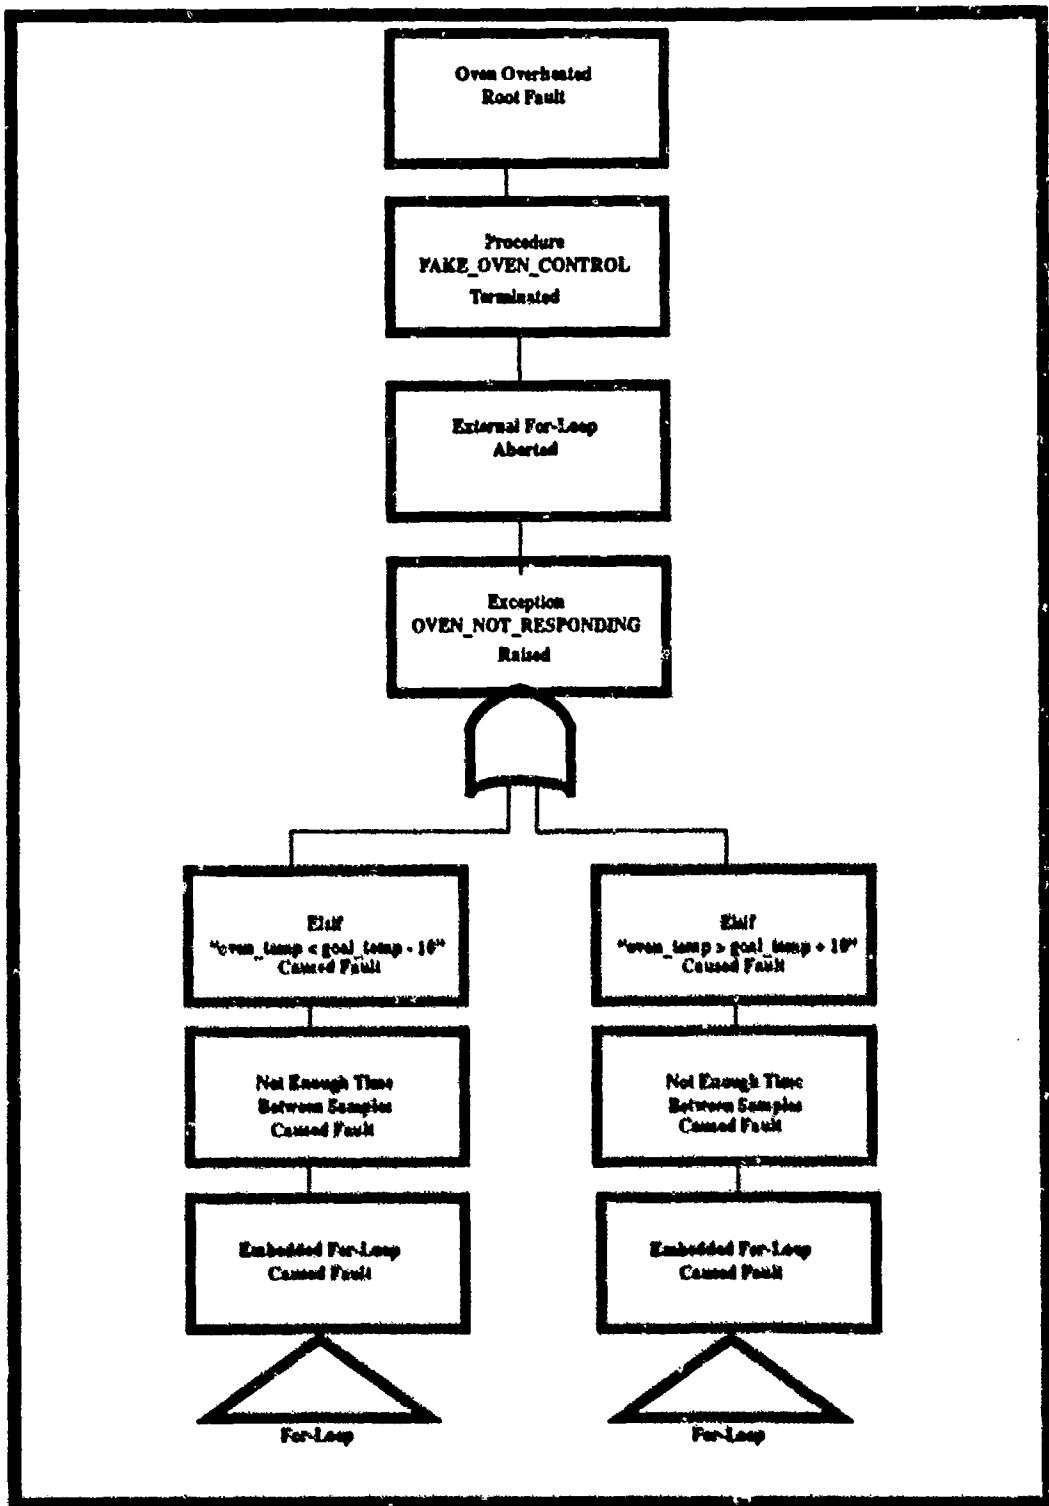

Figure 27 Modified Software Fault Tree for Procedure `FAKE_OVEN_CONTROL`

## **IV. CONCLUSIONS**

### **A. INTRODUCTION**

One question addressed by this research was to look at the possibility of automating the software fault tree analysis. Another question addressed pertained to the cost of automating the process. This chapter provides the answers to the questions. Section B summarizes the significant results of this research. Section C offers recommendations to practitioners in applying techniques of this sort. Section D concludes by giving suggestions for future research.

### **B. RESEARCH SUMMARY**

One result of this research demonstrated that SFTA can be automated to some extent. Analyzing software in a purely manual technique is expensive because of the labor and time intensive step to traverse and translate the code. A purely manual technique may also introduce errors because humans make mistakes. The opposite solution, a totally automated process, has deficiencies because of the loss of human insight and experience of the analyst. Therefore a balance between manual and automated techniques in SFTA should be applied. The SFTA process contains a code translation step that is repetitive and labor intensive. This step is a prime candidate for automation because this step does not require much foresight since the structures of the programming language are constant. With machines inherently faster than man, using machines to perform this task can reduce the amount of time required. This, however, does not replace the need for the analyst in SFTA.

Another outcome of this study demonstrated that the cost to automate a portion of SFTA is significantly lower than the benefits that automation provides. With the existence of several tools, most notably Aflex to produce a lexical analyzer; Ayacc to produce a parser; and FTE to provide a tool to draw software fault trees, the cost to develop a tool to automatically translate code was minimal. This tool provides many benefits. An automated code translation tool provides the analyst the opportunity to use his time more efficiently

by reducing the detailed work of code translation. Additionally, the tool allows the analyst the opportunity to focus on semantics of the analysis and not the syntax of the code. Comparing the costs versus the benefits of automation, the benefits out weigh the associated costs.

## C. RECOMMENDATIONS

The results of this research can help the analyst in providing safe software by facilitating the SFTA process. This thesis uses the concept of SFTA in ensuring that the software for the computer systems is safe. SFTA is not a new idea in software safety, however, the majority of research in SFTA has been performed using manual techniques. Since it has been proven in various research that tasks that require continuous and/or repetitive work is better performed by machines than man, this thesis looked at automating part of the SFTA process, specifically the code translation step. This thesis introduces a tool that removes a large percentage of the human interface. With the introduction of the Automated Code Translation Tool prototype, the tool eliminates the possible errors that could have occurred if the code translation step of SFTA was performed manually.

The Automated Code Translation Tool is a prototype to perform code translation for Ada statements. This tool works on several assumptions. Primarily, this tool is intended to provide an initial translation of the code. This translation is developed with the intention that it will be refined by the analyst. Additionally, this tool looks only at the syntax of the code. Assuming that the code is syntactically correct and that there are no overt logic errors or other errors in the code, this tool will take the input code and translate it into structures that can be used in SFTA.

This tool was developed to look at programs written in the Ada programming language. This tool should be used as a means to translate Ada statements into software fault tree structures representing the statements. The results from this tool should be followed by a thorough review by the analyst to make adjustments where necessary. This tool is a prototype and the result should not be used without an analyst.

## D. FUTURE RESEARCH

There are several avenues of research that can be examined in the future as follow-up studies to this work. As a prototype, this tool looked at only a subset of Ada structures. This work can be expanded to contain the Ada structures that were not included. More specifically, the concept of tasks and exception handling need to be addressed. This tool is a stepping stone in the direction to automate code translation; however, the tool can not be complete until all of the Ada structures are implemented.

Another potential area of research might involve the interface with a graphical editor to display the software fault tree. Even though FTE provides a good graphical editor, the limitation on the drawing field poses a problem. Software fault trees tend to be large by their very nature and a graphical editor is needed to be able to depict the software fault tree in its entirety. Along with this, the algorithm used in the prototype to give the nodes X and Y coordinates was simple. To make the software fault tree more aesthetically pleasing, a more sophisticated algorithm should be developed and implemented.

Translating the output from the Automated Code Translation Tool to a usable software fault tree is another possible area of future research. An automated process to eliminate unrelated parts of the software fault tree and modify the remaining parts to be relevant to the selected root fault would reduce the amount of time necessary for software fault tree analysis and reduce the amount of possible errors caused by the human factor.

Finally, this tool provides a static code translation without any consideration to the actual fault. Future work can examine the possibility of expanding automation in SFTA by looking at the faults more dynamically as the software is working. The process of SFTA is lengthy and costly. With the introduction of automation into the process both the time to perform SFTA and the cost of SFTA can be reduced. This research has established some initial observations and steps towards automation of SFTA, but many more questions are left unanswered.

## APPENDIX A: AYACC AND AFLEX INPUT

### A. AYACC SPECIFICATION FILE:

```
-----  
-- Specification file is a modified version of the Taback and Deepak specification  
-- file. The Taback and Deepak version was an adaptation of the Herman Fischer file  
-- file used for Yacc.

## APPENDIX C: ADA STRUCTURE TEMPLATES

### Sequence of Statements Template

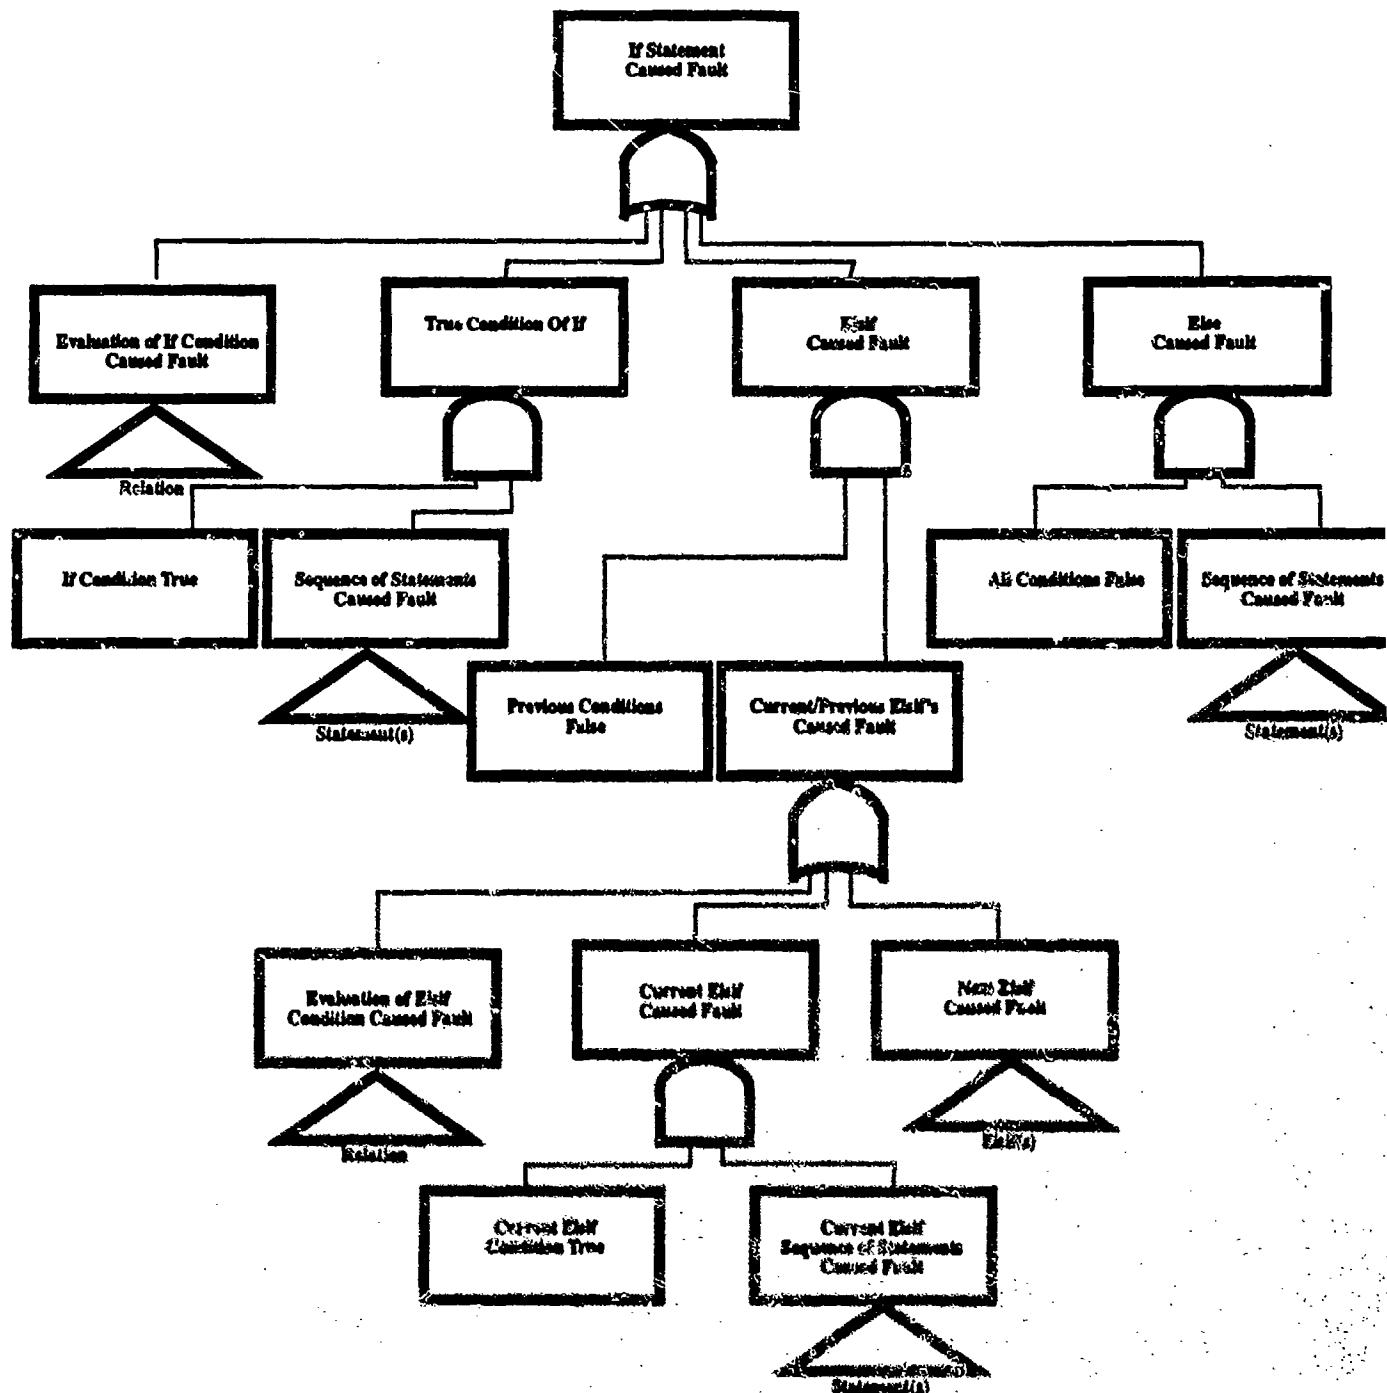

\* Sequence of statements template was not depicted in the works of Leveson, Cha, and Shimeall.

## Assignment Template

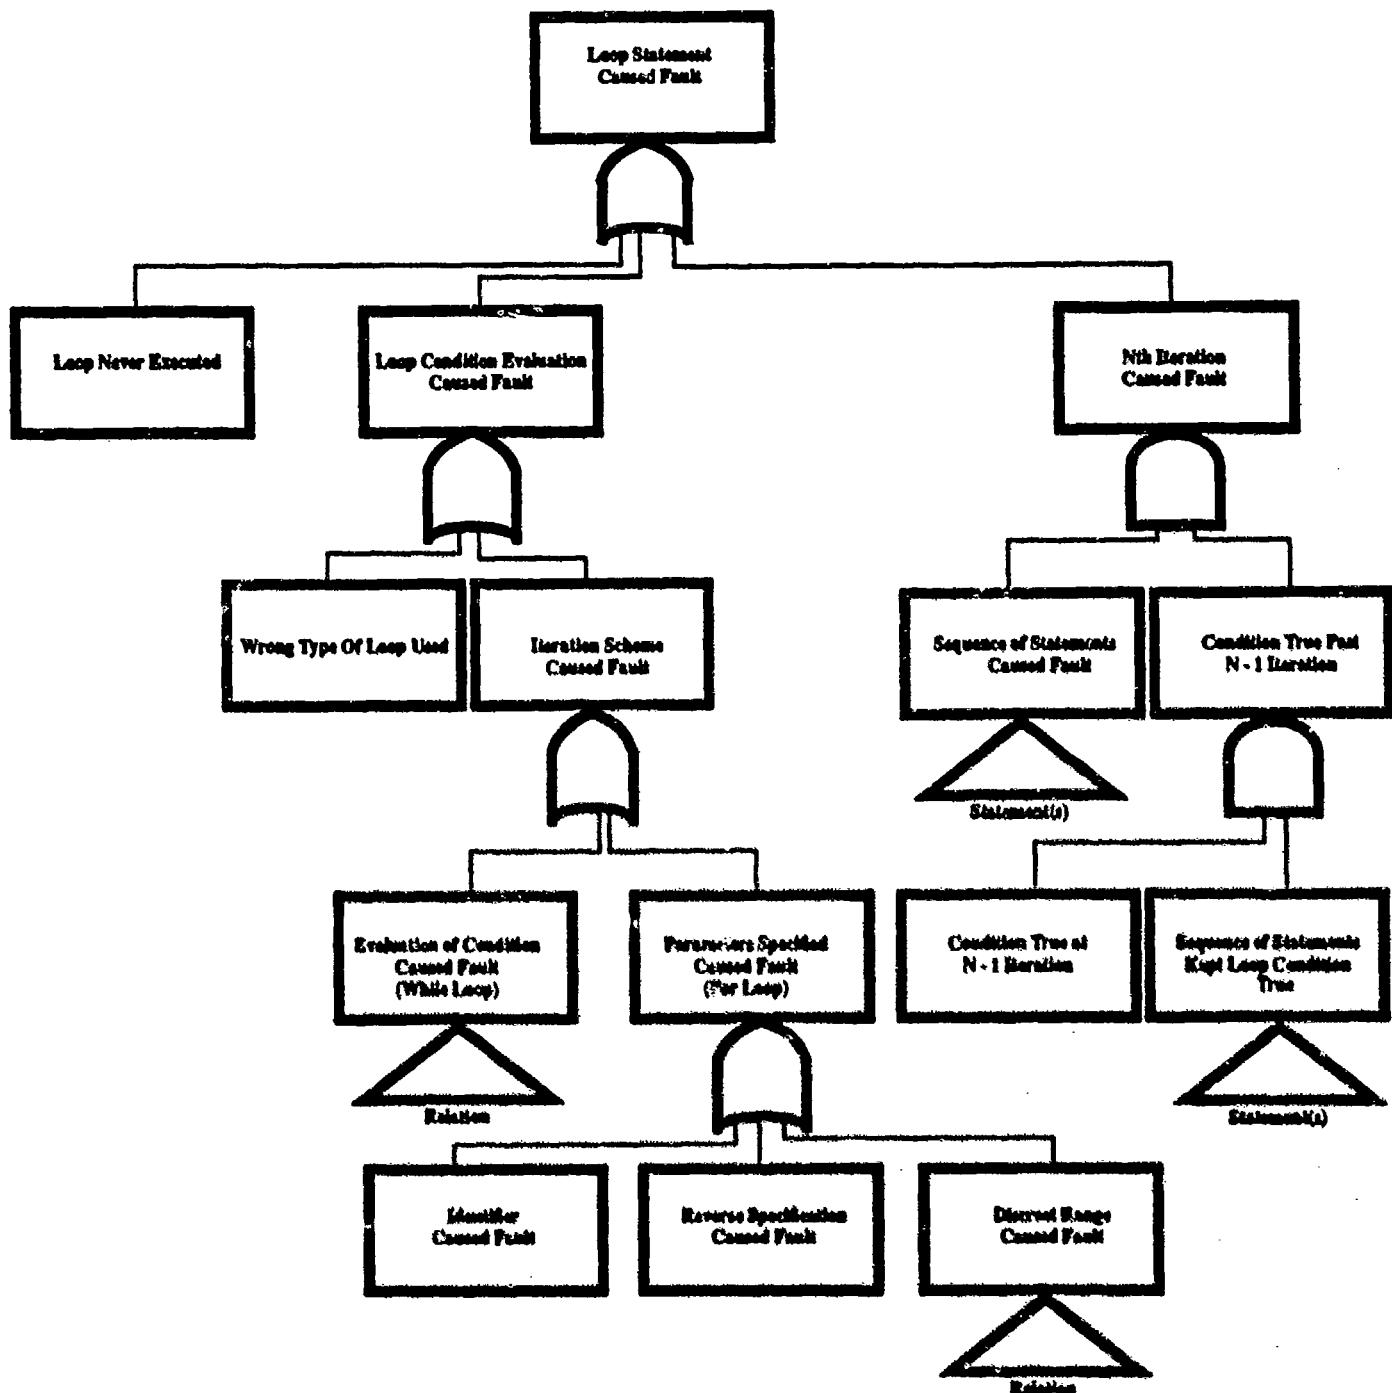

\* There is no difference between the tool generated Assignment Template and the Leveson, Cha, and Shimeall template.

# If Then Elsif Else Template

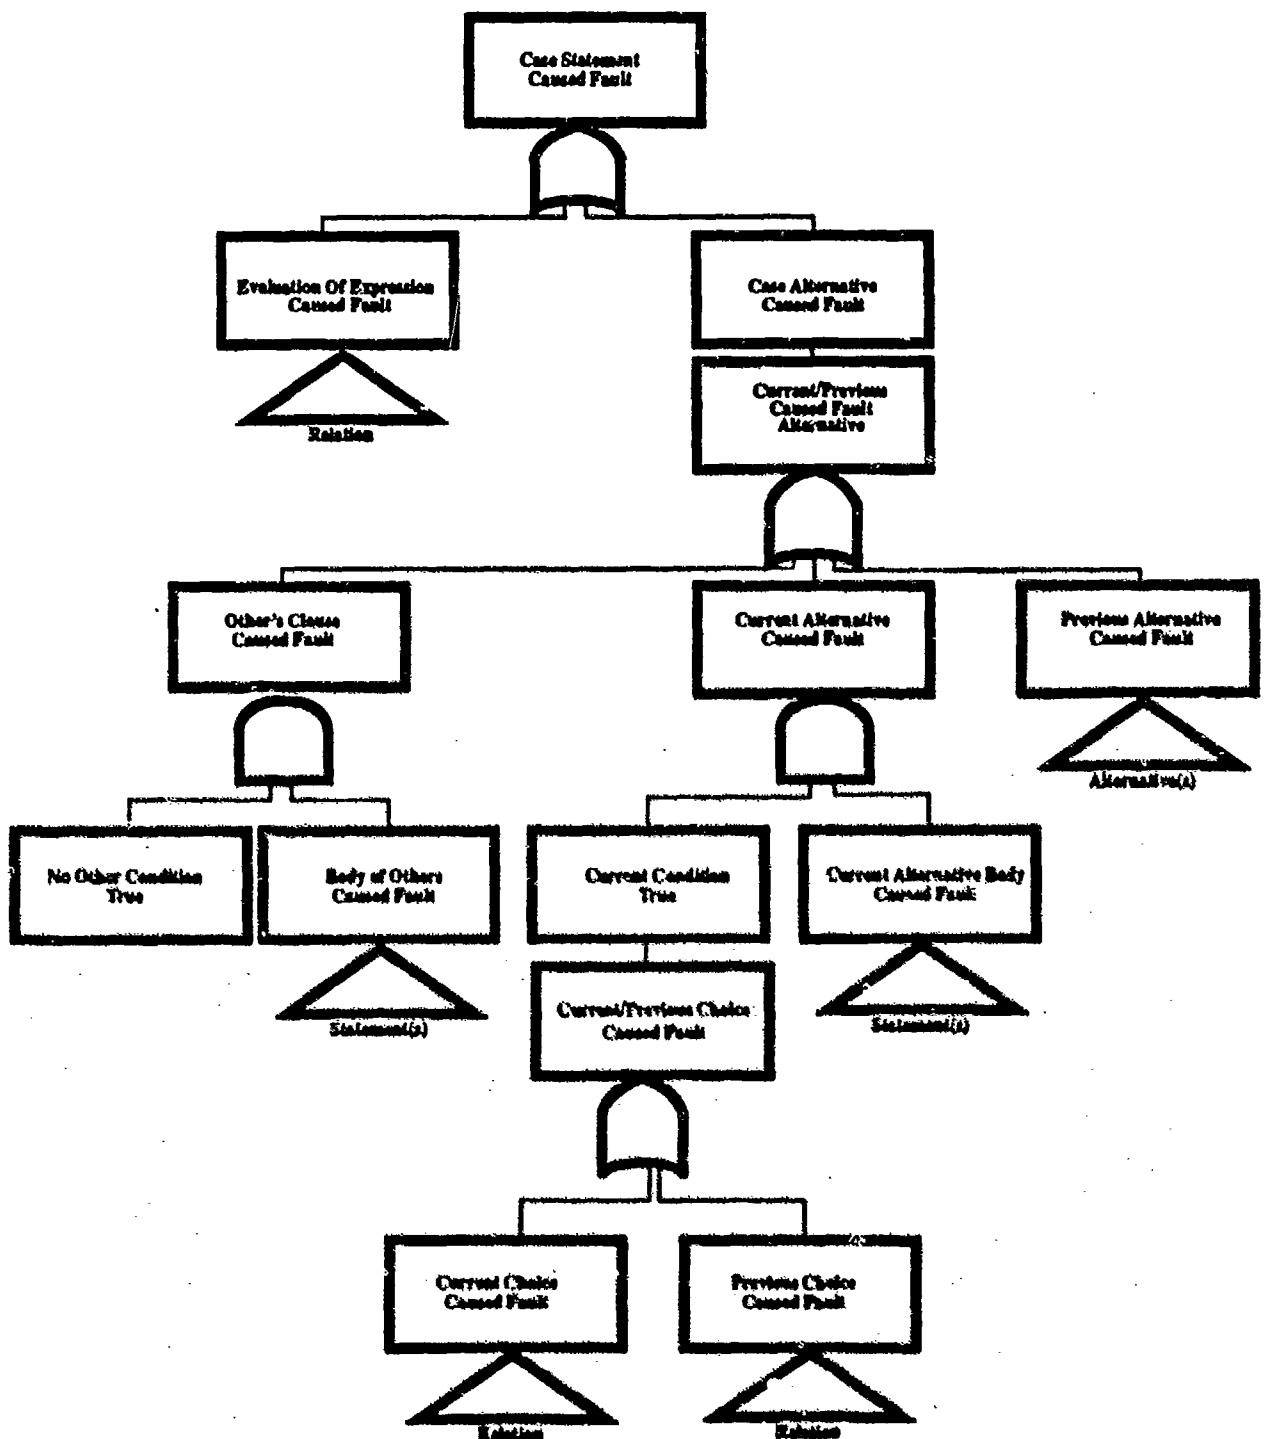

\* The Leveson, Cha, and Shimeall template did not distinguish between the "if" associated nodes and the "elsif" associated nodes, but the tool generated template presented the two separately.

# Loop Template

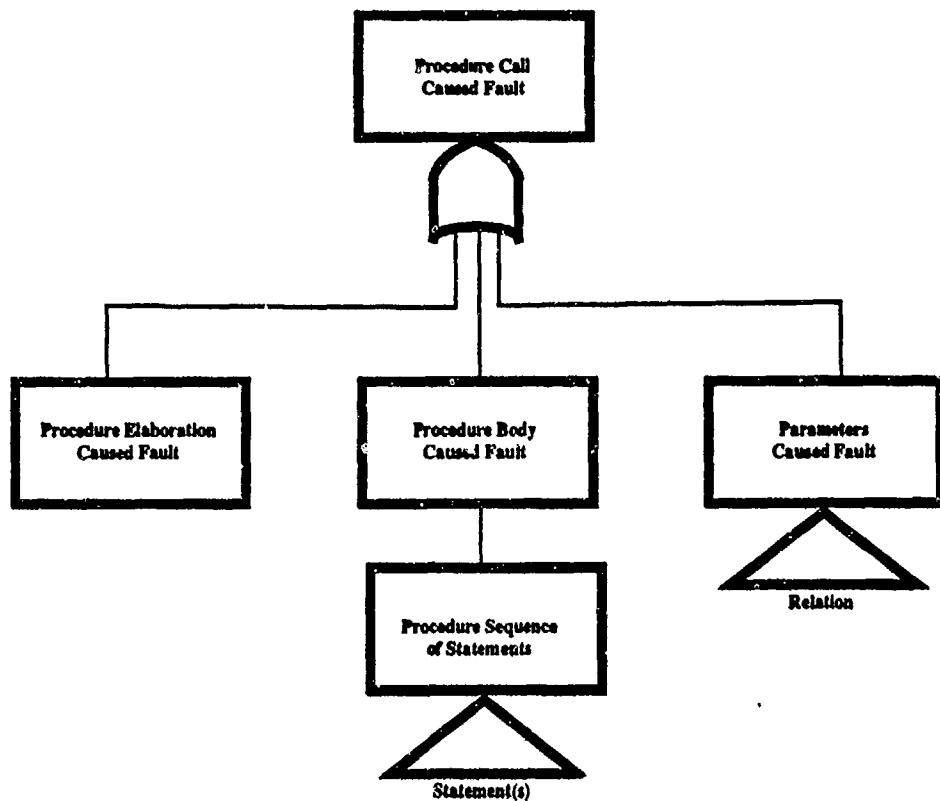

\* The tool generated Loop Template distinguished between the different types of loops and expanded the associated "condition" nodes and the Leveson, Cha and Shimeall template did not.

# Case Template

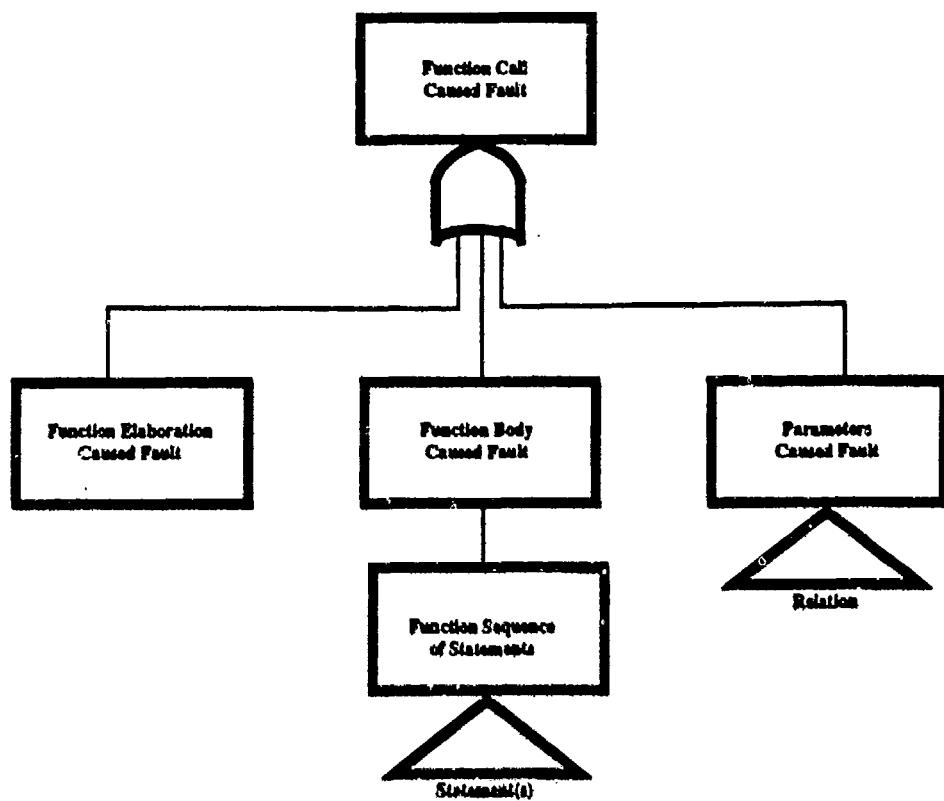

- \* The tool generated Case Template physically placed the "Other's Clause Caused Fault" and associated nodes on a lower level then the Leveson, Cha, and Shimeall template, nevertheless, the two templates are equivalent.

## Procedure Call Template

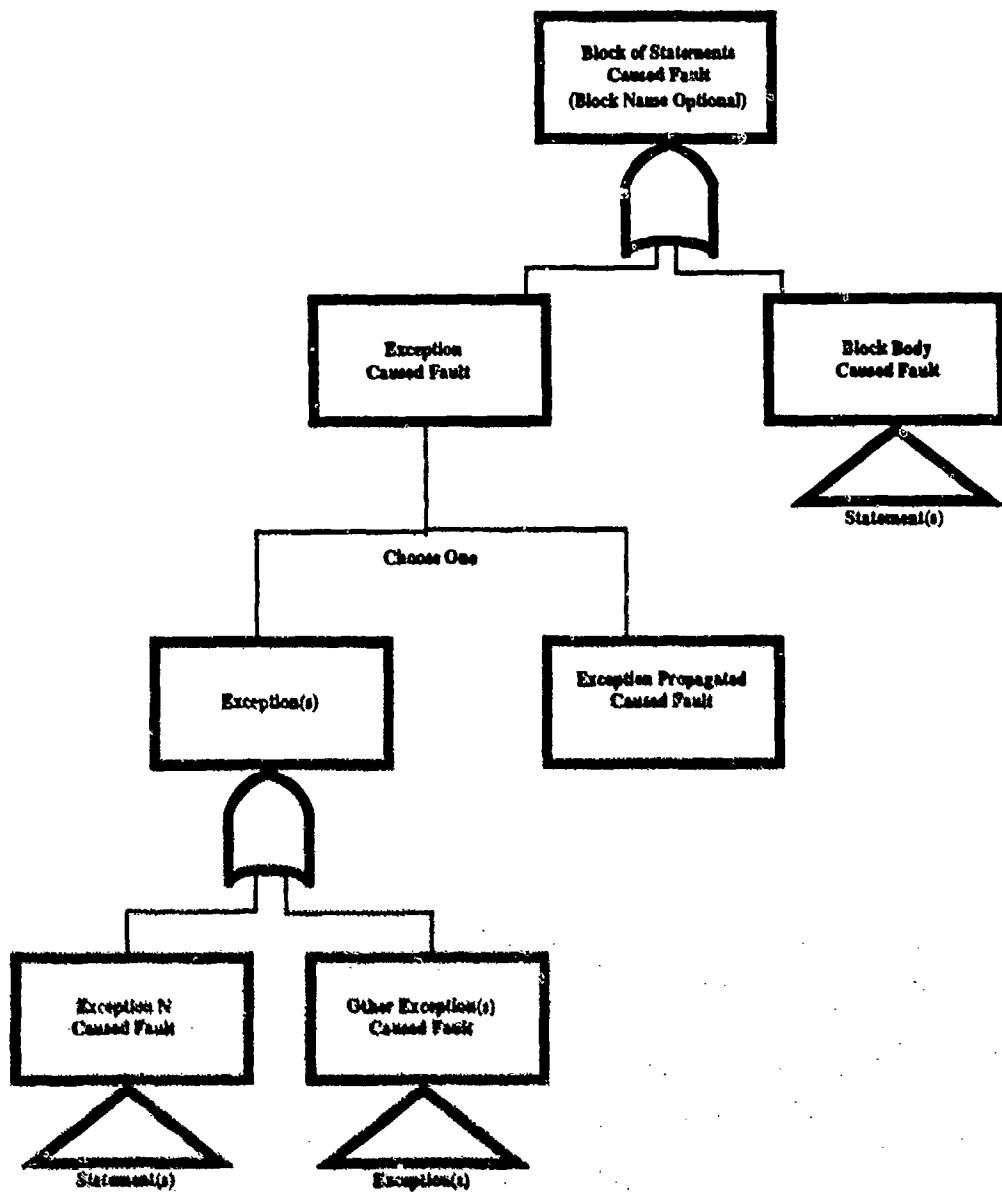

\* The tool generated Procedure Call Template added the node "Procedure Elaboration Caused Fault" to the template from Leveson, Cha, and Shimeall.

## Function Call Template

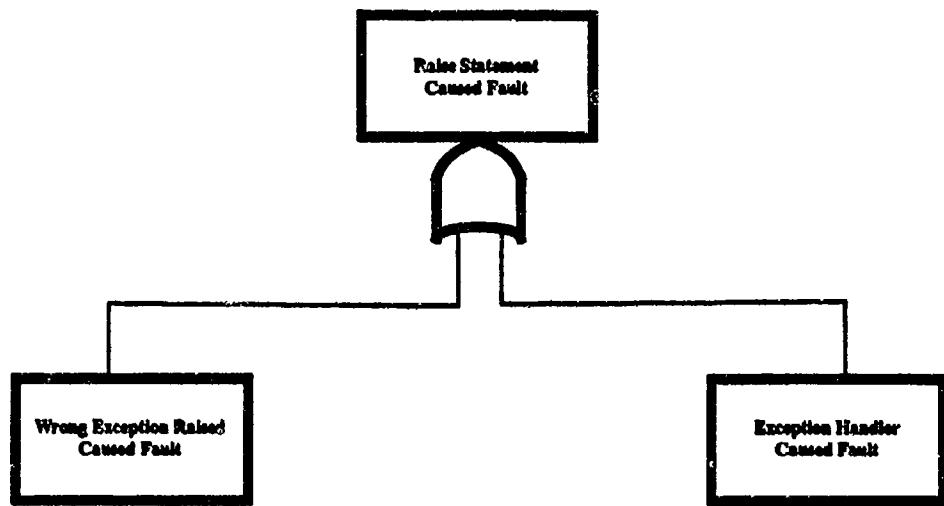

\* The Function Call Template was not depicted in the works of Leveson, Cha, and Shimeall.

## Block Statement Template

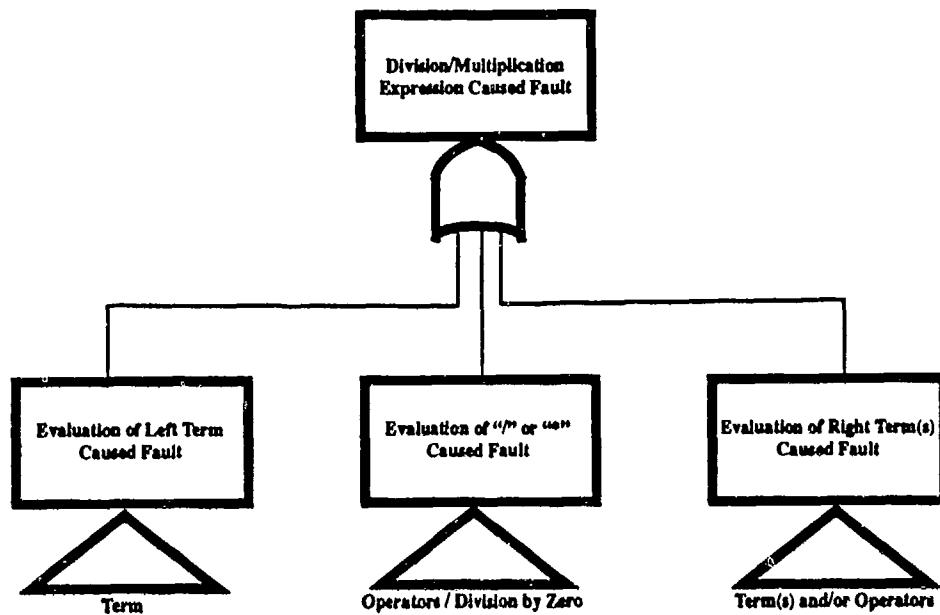

\* The tool generated Block Statement Template elaborated more on the "Exception Caused Fault" node than did the works of Leveson, Cha, and Shimeall.

## Raise Template

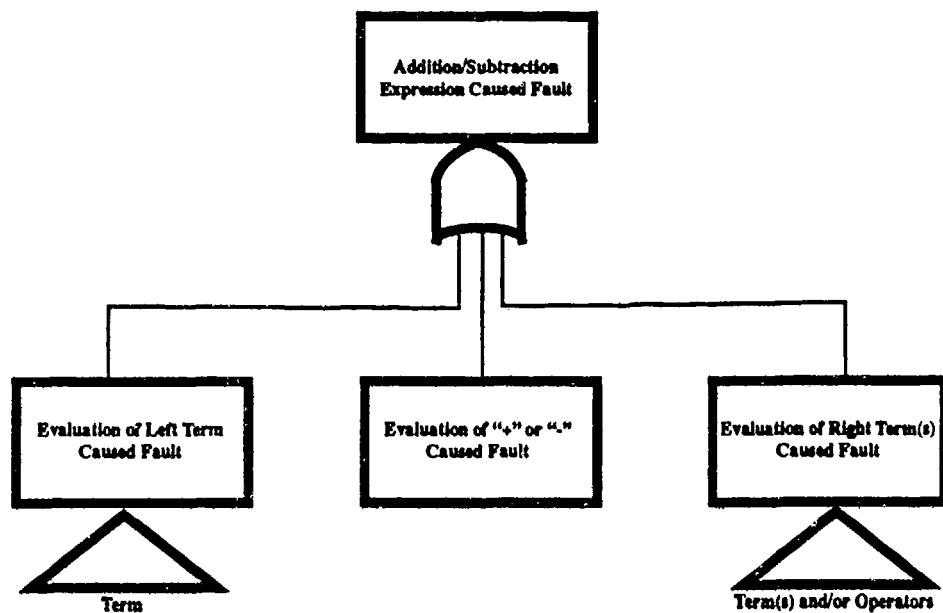

\* There was no difference in the Raise Template between the tool generated and the Leveson, Cha, and Shimeall templates.

# Division and Multiplication Template

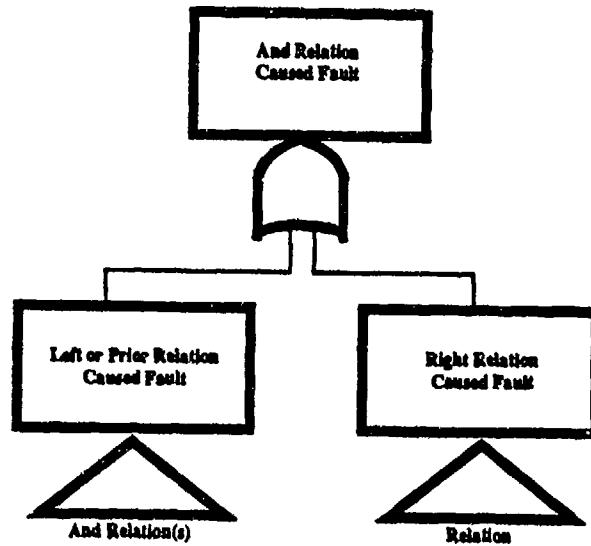

\* Division / Multiplication Template was not depicted in the works of Leveson, Cha, and Shimeall.

# Addition and Subtraction Template

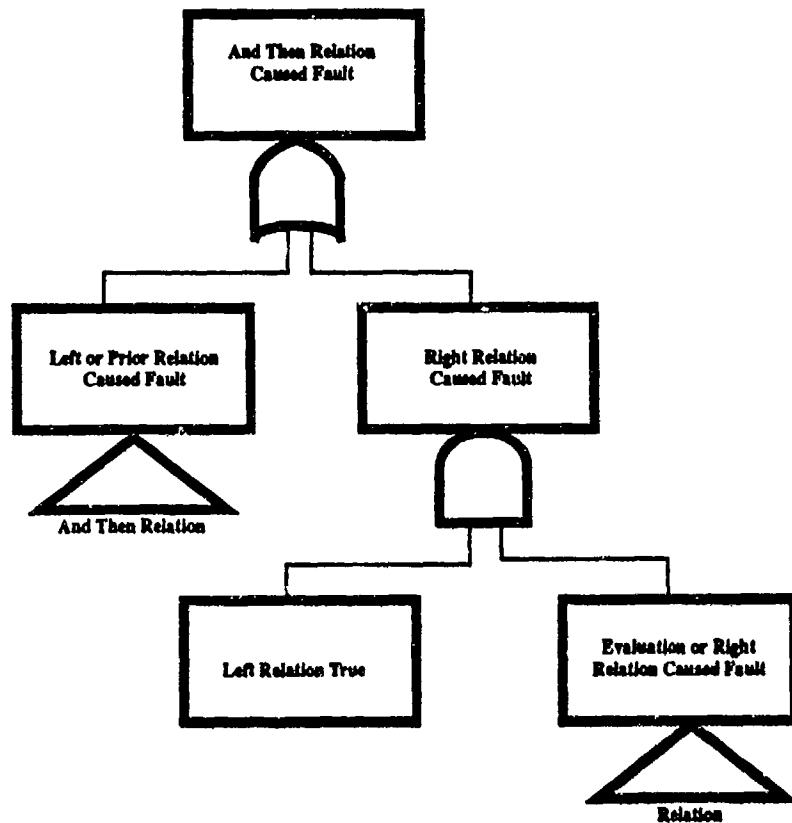

\* Addition / Subtraction Template was not depicted in the works of Leveson, Cha, and Shimeall.

## And Relation Template

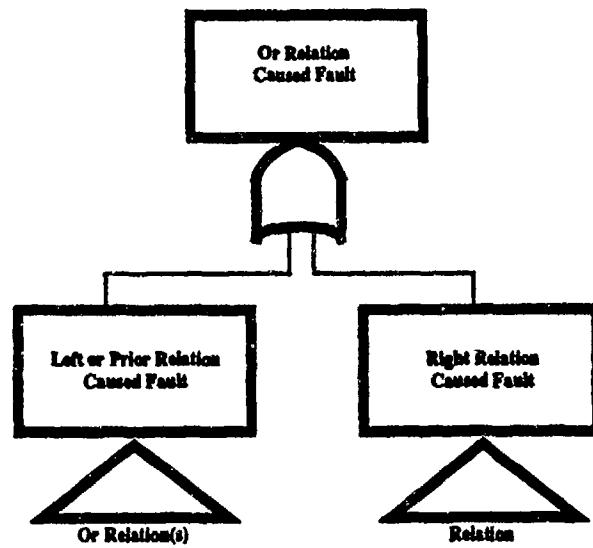

\* And Relation Template was not depicted in the works of Leveson, Cha, and Shimeall.

## And Then Relation Template

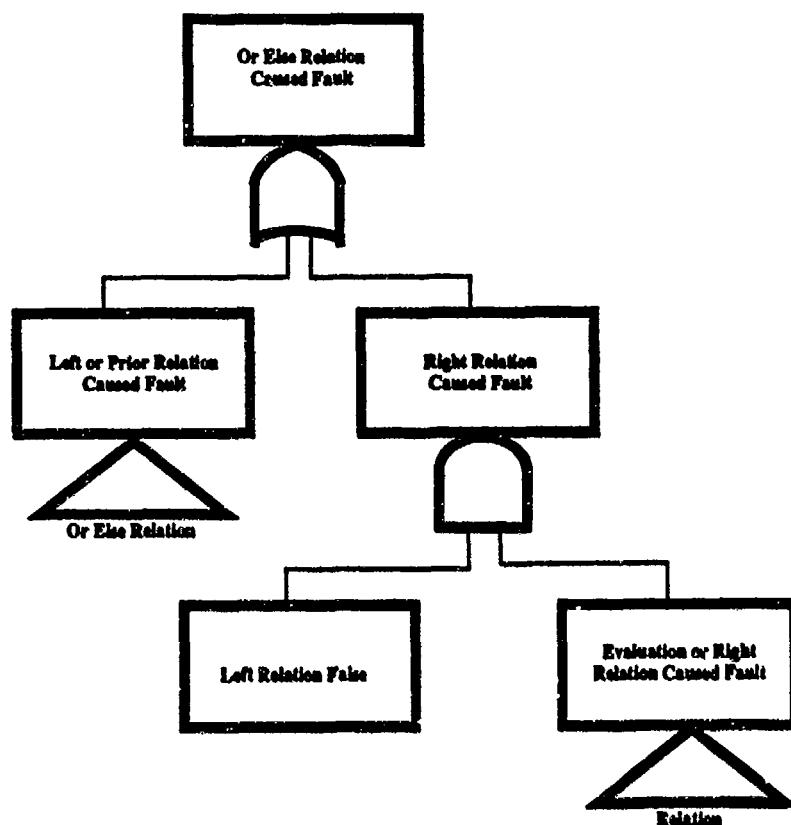

\* And Then Relation Template was not depicted in the works of Leveson, Cha, and Shimeall.

## Or Relation Template

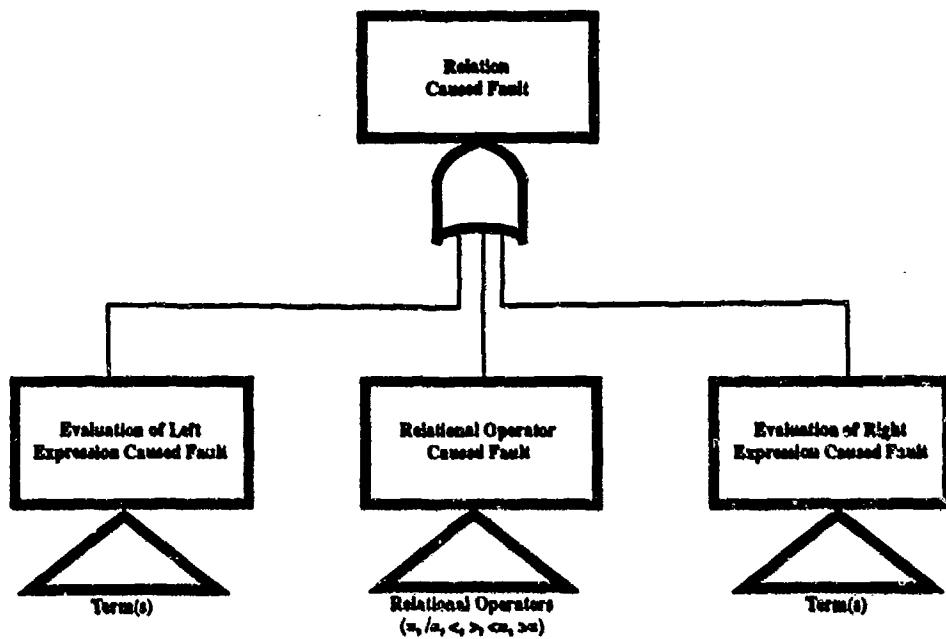

\* Or Relation Template was not depicted in the works of Leveson, Cha, and Shimeall.

## Or Else Relation Template

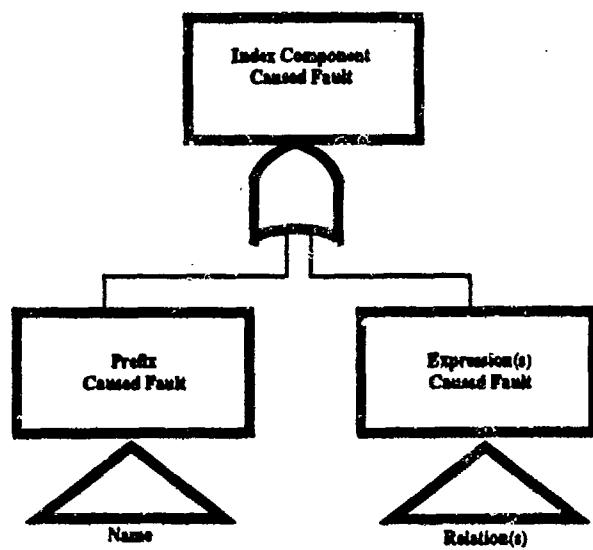

\* **Or Else Relation Template** was not depicted in the works of Leveson, Cha, and Shimeall.

## Relation Template

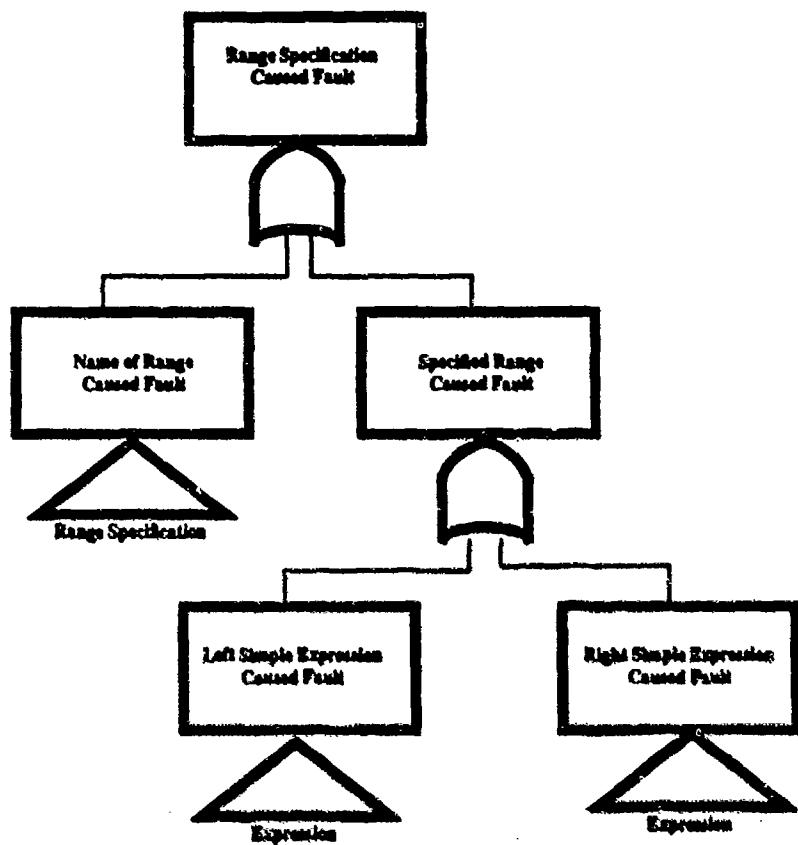

\* Relation Template was not depicted in the works of Leveson, Cha, and Shimeall.

## Index Component Template

\* Index Component Template was not depicted in the works of Leveson, Cha, and Shimeall.

## Range Template

\* Range Template was not depicted in the works of Leveson, Cha, and Shimeall.

## C. PROCEDURE, FUNCTION, AND EXCEPTION LISTING

The number of procedures/functions on the table are 1

The procedures/functions and their root faults on the table  
are the following:

---

FAKE\_OVEN\_CONTROL  
Sequence of statements caused fault

Above are the procedures/functions and root faults.

---

There are no defined exceptions within the input code.

---- Finished Code Translation ----

0 errors found
