Experimental

Two samples of silver chromate (Ag_2CrO_4) were prepared by admixture of solutions of AgNO₃ and K₂CrO₄:

Sample A: $AgNO_3$ solution in water added dropwise to solution of K_2CrO_4 in water, resulting in immediate precipitation of a red-brown powder. This was isolated by filtration and washed with water, then ethanol, then diethyl ether, affording the Ag_2CrO_4 as a brown powder in high yield.

Sample B: AgNO₃ dissolved in 0.5 mL water, then diluted with 4 mL ethanol and added dropwise to a solution of K_2CrO_4 in ethanol (6 mL) containing 3 equivalents of 18-crown-6, resulting in immediate precipitation of a red powder. This was isolated by filtration and washed with ethanol, then water, then ethanol, then diethyl ether, affording the Ag₂CrO₄ as a red powder in high yield.. (Note that K_2CrO_4 appears completely insoluble in ethanol in the absence of 18-crown-6.)

Each sample was examined by x-ray powder diffraction and shown to be the (known) orthorhombic phase of Ag_2CrO_4 . Each appeared crystalline; however, sample A (prepared from water) appeared to be composed of significantly larger crystallites, as evidenced by sharper lines in the powder diffraction pattern.

Scanning electron microscopy confirmed this observation: Sample A was comprised entirely of apparently well-faceted crystallites approximately 0.5 - 1 micron in size, while sample B displayed no clearly identifiable crystallites, being composed instead of aggregates of visually amorphous (but, recall, still crystalline as shown by x-ray powder diffraction) material.

Discussion

Silver chromate serves an important role as a cathode material for nonaqueous-electrolyte batteries. It has also appeared in the patent literature as an alkene polymerization catalyst, as a potential optical recording material, and as a component in anti-fouling agents. It is generally prepared by a simple metathesis reaction between, e.g., potassium chromate and silver nitrate. Such metathesis reactions are universally carried out in aqueous solution, as the precursors display negligible solubility in nonaqueous solvents. We have found that use of 18-crown-6 as a complexing agent allows preparation of solutions of potassium chromate in ethanol. Dropwise addition of ethanolic silver nitrate (containing a few percent water in order to solubilize the silver salt) to such an ethanolic solution of solubilized potassium chromate results in immediate precipitation of silver chromate which, as demonstrated by visual inspection (color of the bulk sample), X-ray powder diffraction, and electron microscopy, is of significantly smaller crystallite size than silver chromate prepared from aqueous solution. The ability to effect such a significant alteration in crystallite size simply through alteration of crystallization medium, made possible through application of our technique of complexation-mediated crystallization, may prove of profound importance in, e.g., the area of semiconductor nanoparticle technology.
