Electrocrystallization of an Ordered Organic Monolayer: Selective Epitaxial Growth of β -(ET)₂I₃ on Graphite

Andrew C. Hillier, Jeffery B. Maxson and Michael D. Ward*

Department of Chemical Engineering and Materials Science University of Minnesota, Amundson Hall 421 Washington Ave. SE, Minneapolis, MN 55455

Abstract

We report electrochemical and in situ atomic force microscopy observations of the formation of a new class of crystalline organic monolayer, which consists of a conductive organic salt containing bis(ethylenedithiolo)-tetrathiafulvalene (ET), on highly oriented pyrolytic graphite (HOPG). Growth of this monolayer accompanies the electrochemical oxidation of ET in the presence of the I₃⁻ anion at a freshly cleaved HOPG electrode. The monolayer covers large areas of the graphite substrate (> 100 μ m²) and can be removed at potentials cathodic of the ET/ET⁺ couple. High resolution AFM imaging of the monolayer and a 15.5 Å monolayer thickness are consistent with the formation of a single (001) layer of β -(ET)₂I₃, with the long axes of the ET molecules oriented nearly perpendicular to the graphite basal plane. The preferential formation of β -(ET)₂I₃ over other polymorphs is a consequence of favorable epitaxial interactions between the overlayer lattice and that of the graphite substrate, and is manifest in selective growth of bulk β -(ET)₂I₃ crystals on this electrode surface. These results demonstrate that controlled deposition of conducting mono-and multilayer films can be achieved in the presence of strong interfacial interactions during nucleation, suggesting a route to the fabrication of electronic devices based upon molecular design principles.

The fabrication of highly ordered organic thin films has received considerable attention in attempts to develop materials for molecular based electronic devices, sensors, displays and logic elements.¹ Examples of two-dimensional films with potentially desirable electronic properties include self-assembled mono- and multilayers with redox active components² and thin films of organic dyes grown by molecular beam epitaxy on van der Waals substrates such as graphite, MoS_2 and SnS_2 .³ Successful approaches to the manufacturing of devices based on organic thin films will ultimately rely on the development of convenient fabrication methods as well as rigorous control of the supramolecular structure of the thin film assembly. The importance of supramolecular structure is evident from the behavior of crystalline low-dimensional organic conductors, whose electronic properties, such as conductivity and superconductivity, differ considerably among polymorphs of a given composition.⁴ This is exemplified by charge-transfer salts of the ET-I3 system (ET = bis(ethylenedithiolo)-tetrathiafulvalene), for which fourteen phases are known, four exhibiting superconductivity.⁵ Indeed, the synthesis of these materials by electrochemical oxidation of ET in the presence of I3⁻ is characterized by the simultaneous growth of single crystals of several different polymorphs at the electrode surface.^{4a,6}

ET

Recent observations in our laboratory indicated that the vapor phase growth of certain lowdimensional organic crystals on highly ordered substrates was preceded by the formation of monoand multilayer films with rather large dimensions.⁷ This, along with a report describing the influence of electrode composition on phase selectivity during the growth of (ET)₂I₃,⁸ prompted us to examine whether polymorphism in this compound could be controlled at the early stages of growth by favorable interactions with the substrate electrode. We report herein electrochemical and in situ atomic force microscopy observations of the electrocrystallization of a novel crystalline organic monolayer comprising (ET)₂I₃ on highly oriented pyrolytic graphite (HOPG) electrodes, in which epitaxy between (ET)₂I₃ and the HOPG substrate directs selectivity toward a single polymorpħ. These results suggest a new strategy for the convenient preparation of highly ordered organic films with adjustable electronic properties.

The electrocrystallization of $(ET)_{2}I_{3}$ occurs with the simultaneous formation of several phases, with α and β phases predominating. Previous reports have indicated that the α -phase forms preferentially at large overpotentials (E_{app} >> E_{0,ET/ET}⁺) and in the presence of chemical oxidants, including I₂.^{4a,11} Conversely, β -(ET)₂I₃ is favored at low overpotentials. This selectivity suggests that α -(ET)₂I₃ is kinetically favored, while β -(ET)₂I₃ is thermodynamically preferred and, therefore, grows under conditions closer to equilibrium.⁹ Notably, electrocrystallization of (ET)₂I₃ at graphite electrodes has been shown to favor the formation of β -(ET)₂I₃, whereas electrochemically oxidized graphite electrodes afforded α -(ET)₂I₃.⁸ This behavior suggests that interfacial interactions between β -(ET)₂I₃ and graphite during heterogeneous nucleation may be a significant factor in determining selectivity.

In acetonitrile, ET exhibits two reversible oxidations (eqns. 1, 2), whereas I₃⁻ exhibits a single reversible oxidation to I₂ (eqn. 3). The oxidation of both ET and I₃⁻ at a freshly cleaved HOPG electrode (Figure 1A and B) occurs at potentials similar to those observed at polycrystalline electrodes, with slight electrochemical irreversibility. This irreversibility is typical of redox processes occurring at highly crystalline graphite and is attributed to slow kinetics at the exposed basal plane.¹⁰ Cyclic voltammetry performed in acetonitrile containing both ET and I₃⁻ (Figure 1C) indicates the oxidation of ET (peak 1) and I₃⁻ (peak 2). Crystallization of (ET)₂I₃ occurs following the oxidation of ET (eq. 4). Consequently, (ET)₂I₃ forms at the foot of the I₃⁻ oxidation wave, where the concentration of I₂ at the electrode surface is not substantial, although I₂-mediated oxidation of ET cannot be explicitly ruled out.¹¹

$ET> ET^+ + e^-$	$E_0 = 650 \text{ mV} (\text{vs Ag/AgCl})$	(1)
$ET^+> ET^{2+} + e^-$	$E_0 = 890 \text{ mV}$	(2)
$2I_3^> 3I_2 + 2e^-$	$E_0 = 860 \text{ mV}$	(3)
$2(ET) + I_3^ > (ET)_2I_3 + e^-$	$E_{cryst} \approx 650 \text{ mV}$	(4)

Reversing the scan direction following excursions into the I₃-/I₂ couple results in four reduction peaks. The first peak (peak 3), corresponds to the reduction of I₂ (eq. 5). This is followed by a shoulder and a peak at slightly more cathodic potentials, corresponding to the reduction of free ET⁺ remaining in the depletion layer near the electrode surface (peak 4, eq. 6) and reduction of bulk (ET)₂I₃ on the electrode surface (peak 5, eq. 7). The assignment of peak 5 was corroborated by the observation that scanning the potential at a faster rate, which decreased the time available for crystallization, resulted in a decrease in the magnitude of peak 5 and a corresponding increase in peak 4. A fourth and final reduction peak (peak 6) is attributed to the reduction and dissolution of a (ET)₂I₃ monolayer (eq. 8) on the graphite surface. Integration of the current under peak 6 gives a coverage of $\Gamma = 4.39 \times 10^{-10} \,\text{mol cm}^{-2}$ for (ET)₂I₃.

$3I_2 + 2e^> 2I_3^-$	E' = 800 mV	(5)
$ET^{+} + e^{-}> ET$	E' = 670 mV	(6)
$(ET)_{2}I_{3} + e^{-}> 2(ET) + I_{3}^{-}$	E' = 620 mV	(7)
$(ET)_{2}I_{3} (monolayer) + e^{-}> 2(ET) + I_{3}^{-}$	E' = 500 mV	(8)

[Figure 1]

In situ atomic force microscopy (AFM) of a freshly cleaved HOPG electrode confirms that a monolayer of (ET)₂I₃ forms upon the application of an anodic potential (Figure 2).¹² Imaging of the substrate prior to electrodeposition reveals an atomically smooth surface over the length scale under examination (2.5 μ m), with a single 7 Å step oriented along one of the graphite lattice

vectors corresponding to the {1210} family of directions. Following the application of an anodic potential step of $E_{app} \approx 650 \text{ mV}$ (vs Ag/AgCl), clusters exhibiting a 15.5 Å (Figure 2E) height form at discrete locations on the surface. These clusters nucleate directly upon substrate terrace sites and grow laterally along the surface with their facet directions exhibiting an azimuthal orientation of $\approx 10^{\circ} \pm n60^{\circ}$ with respect to the graphite lattice (Figure 2C). Eventually the entire HOPG surface becomes covered, with grain boundaries appearing between individual clusters and at substrate step sites. These grain boundaries anneal with time to provide a monolayer that appears to be defect free by AFM observation and is stable indefinitely at E > 650 mV. The monolayer can be formed and removed repeatedly upon potential cycling.

[Figure 2]

High resolution AFM imaging of the (ET)2I3 monolayer (Figure 3A) reveals a structure resembling that observed for the (001) face of single crystal β -(ET)2I3. The most prominent contrast in the direct space AFM data exhibits a periodicity having lattice parameters of **b1** = 12.0 (± 0.8) Å, **b2** = 8.5 (± 0.8) Å, and γ = 108° (± 3). This lattice corresponds to the smallest reciprocal cell observed in the Fourier analysis of the data. These parameters compare favorably to the single crystal x-ray parameters of the β -(ET)2I3 (001) face of a = 6.6 Å (=1/2 **b1**), b = 9.1 Å (= **b2**), and $\gamma = 110^{\circ}$ (Figure 4A). Although **b1** is twice the expected crystallographic **a** value, Fourier analysis also reveals a larger reciprocal cell corresponding to a unit cell in real space with **b3** = 6.0 (± 0.4) Å, **b2** = 8.5 (± 0.8) Å, and $\gamma = 108^{\circ}$ (± 3), in near exact agreement with the crystallographic parameters of the (001) face of β -(ET)2I3. The direct and Fourier space data also reflect the p1 plane symmetry of the (001) plane of β -(ET)2I3. The ordered nature of the monolayer is evident from the symmetry of the higher order components in the Fourier data. The assignment of the monolayer to a β -like structure is further corroborated by the 15.5 Å monolayer height (Figure 2E), which is identical to the (001) layer height of 15.3 Å for β -(ET)2I3 (Figure 4B). The monolayer coverage determined from this high resolution image is $\Gamma = 3.3 \text{ x } 10^{-10} \text{ mol} \text{ cm}^{-2}$, which is similar to that deduced from voltammetry (*vide supra*) and from the molecular density of the (001) plane of β -(ET)₂I₃, which gives $\Gamma = 3.00 \text{ x } 10^{-10} \text{ mol} \text{ cm}^{-2}$.

[Figure 3] [Figure 4]

At applied potentials exceeding 650 mV, and after the (ET)₂I₃ monolayer is completely formed, microscopic single crystals emerge at discrete locations on the HOPG substrate. At moderate to low overpotentials, growth of these crystals occurs by a layering mechanism wherein 15.5 Å thick β -(ET)₂I₃ (001) layers emerge from a single screw dislocation and spread across the crystal surface. These microcrystals were identified as β -(ET)₂I₃, based upon AFM goniometry¹⁴ and from high resolution imaging of the exposed (001) face of these crystals. Notably, the AFM contrast and Fourier analysis for these crystals were identical to that observed for the monolayer. This growth mechanism resembles the classical Stranski-Krastanov growth mechanism,¹⁵ in which bulk crystallization is preceded by the formation of a single monolayer as a consequence of strong interaction between the substrate and the first crystal layer. Full details of the crystal growth of β -(ET)₂I₃ on HOPG will be presented in a later publication.¹⁶

The observed growth mode and the preferred monolayer facetting of $10^{\circ} \pm n60^{\circ}$ with respect to the graphite lattice vectors suggest that the formation of the β -(ET)₂I₃ monolayer is driven by epitaxy with the HOPG substrate. In order to determine the azimuthal relationship between the HOPG and monolayer lattices, the AFM tip was rastered over a small region of the monolayer at a higher force (F > 20 nN) than that used for imaging. This resulted in mechanical removal of the monolayer and allowed high resolution imaging of the HOPG substrate directly beneath the monolayer (Figure 3B). High resolution AFM data of the monolayer and HOPG, along with analysis of the Fourier images, reveals an average azimuthal orientation of the monolayer with respect to the HOPG substrate described by $\mathbf{b1} = 4.9\mathbf{a1} + 1.1\mathbf{a2}$ and $\mathbf{b2} = 3.86$ (a₂ - a₁), where a₁ and a₂ are the graphite lattice vectors of the basal plane ($|a_1| = |a_2| = 2.45$ Å), which are the [$\overline{1210}$] and [$\overline{2110}$] directions. The angular spread about this average orientation was ±10°. This alignment agrees with the orientations of the monolayer with respect to the graphite step directions, which are directed along a₁, a₂ and a₂ - a₁ (Figure 2C). Furthermore, microscopic crystals of β -(ET)₂I₃ that evolve from the monolayer are oriented with their (001) faces parallel to the graphite substrate and exhibit the same azimuthal orientation with respect to the graphite substrate. A geometric analysis of the β -(ET)₂I₃-graphite interface based on x-ray crystallographic data indicated that commensurism is maximized for an azimuthal orientation in which 2a (= b₁) = 5a₁ + a₂ and b (= b₂) = 11/3 (a₂ - a₁). This transforms to a supercell with dimensions of b₁ x 3b₂ (Figure 3). A similar analysis did not reveal any reasonable commensurism of α -(ET)₂I₃ with the graphite lattice, consistent with the absence of α -(ET)₂I₃ during electrocrystallization on graphite.⁹

We note that occasionally a thin (<3 Å) layer is observed on HOPG at open circuit which precedes formation of the β -(ET)₂I₃ monolayer. While in a few instances the 15.5 Å β -(ET)₂I₃ monolayer appears to form on top of this thin layer, most data indicate that this layer is either transformed into or displaced by the 15.5 Å monolayer.¹⁷ For example, a 15.5 Å height with respect to the graphite surface was measured for the monolayer in Figure 3 after mechanical etching of a small region. The identity of this intermediate layer and its role in the formation of the β -(ET)₂I₃ monolayer is under examination.

These observations clearly indicate that an epitaxial interaction between β -(ET)₂I₃ and the basal plane of HOPG is responsible for the observed selectivity on pristine graphite substrates. This interaction results in the formation of a monolayer covering large areas of the substrate and exhibiting structural characteristics that mimic β -(ET)₂I₃, which in its bulk form is a superconductor at low temperature. The ability to prepare large highly ordered organic mono- and multilayers whose structure mimics that of an organic solid that has been demonstrated to exhibit metallic conductivity and superconductivity has interesting implications for the fabrication of electronic devices based on molecular components. Furthermore, the ability to employ

electrochemical means has the advantage over typical vacuum deposition techniques in that deposition can be performed under ambient conditions and on substrates with unusual geometries.

¹² AFM experiments were performed with a Digital Instruments Nanoscope III scanning probe microscope equipped with NanoprobeTM cantilevers (Si₃N₄ integral tips with spring constants of 0.06 nm⁻¹, PARK Scientific). Images were obtained at high feedback, such that the tip tracked the sample at constant force. A scanner with maximum scanning range of 12 x 12 x 4.4 μ m³ was employed for imaging. The tip scan rate during image acquisition ranged from 4 to 12 Hz for large scale images and up to 40 Hz for high resolution images, while the applied tip-sample force was maintained at F_{tip} ≤ 5 nN in solution. AFM experiments were performed in acetonitrile with a fluid cell (Digital Instruments), comprising a quartz body with ports for fluid entry and exit. The

working electrode consisted of a freshly cleaved HOPG wafer. Platinum counter and Ag reference electrodes were inserted through the outlet port of the fluid cell.

13 Crystallographic parameters for a-(ET)₂I₃: a = 9.183 Å, b = 10.804 Å, c = 17.442 Å; $\alpha =$

96.96°, $\beta = 97.93°$, $\gamma = 90.85°$. Emge, T. J.; Heung, P. C. W.; Beno, M. A.; Wang, H. H.;

Figure 1. Cyclic voltammetry of ET and n-Bu4N⁺I3⁻ in CH3CN at a 9 mm diameter freshly cleaved HOPG electrode: (A) 0.5 mM ET in 0.1 M n-Bu4N⁺ClO4⁻; (B) 10 mM n-Bu4N⁺I3⁻ in 0.1 M n-Bu4N⁺ClO4⁻; (C) 0.5 mM ET and 10 mM n-Bu4N⁺I3⁻ in 0.1 M n-Bu4N⁺ClO4⁻. The electrochemical cell consisted of a single compartment with a freshly cleaved HOPG working electrode and a platinum counter electrode. The potential scale is against the reference electrode, which was Ag/AgCl in 0.1 M n-Bu4N⁺Cl⁻/CH3CN.

Figure 2. In situ AFM images acquired during growth of the (ET)₂I₃ monolayer on a freshly cleaved HOPG electrode at (A) t = 30, (B) 90, (C) 150, and (D) 210 seconds following a potential step to 650 mV (vs Ag/AgCl). Note that (A) does not represent the actual beginning of monolayer formation, but the time at which the first image was acquired shortly after the potential step. In (C), the angles between the orientation of a primary HOPG lattice vector (- - -) and the directions of monolayer facetting (--) are indicated. (E) Height profile analysis of the (ET)₂I₃ monolayer and a neighboring graphite step from (D).

Figure 3. (A) In situ high resolution AFM data (raw data) for the β -(ET)₂I₃ monolayer. The data exhibit a contrast periodicity of **b**₁ = 12.0 (± 0.8) Å and **b**₂ = 8.5 Å (± 0.8) with γ = 108° (±3). The variation in contrast corresponds to changes is surface topography, with brighter regions being closer to the AFM tip. Two unit cells are depicted: the larger one corresponding to the smallest reciprocal cell determined from Fourier analysis and the smaller one corresponding to a reciprocal cell having dimensions identical to those of the (001) plane of β -(ET)₂I₃ (see Figure 4A). This cell compares favorably with the (001) plane, for which a = 6.6 Å (\approx **b**₃ = 1/2**b**₁), b = 9.1 Å (\approx **b**₂), and $\gamma = 110^{\circ}$. (B) AFM data (raw data) and (C) Fourier analysis obtained for the HOPG substrate after removal of the monolayer by mechanical etching with the AFM tip. The reciprocal lattice directions, **a**₁ * and **a**₂*, are indicated on the Fourier data, while the real lattice directions, **a**₁ and **a**₂, are shown above the real space image. The HOPG image is rotated to

match the scan direction employed while imaging the monolayer in (A). (D) Fourier data for the (ET)₂I₃ monolayer. (E) Schematic of the Fourier data of (D) depicting the reciprocal lattices corresponding to the two cells indicated in the real space image. The reciprocal lattice vectors $\mathbf{b_1}^*$, $\mathbf{b_2}^*$, $\mathbf{b_3}^*$, corresponding to the real lattice vectors in (A), are depicted. The larger reciprocal cell corresponds to the real cell having the dimensions of the (001) plane of β -(ET)₂I₃. Based on the real and reciprocal lattice vectors, the (ET)₂I₃ monolayer exhibits an average azimuthal orientation, with respect to the HOPG substrate, of $\mathbf{b_1} = 4.9\mathbf{a_1} + 1.1\mathbf{a_2}$ and $\mathbf{b_2} = 3.86(\mathbf{a_2} - \mathbf{a_1})$. The angular spread about this average orientation was $\pm 10^\circ$.

Figure 4. (A) Space-filling representation of the (001) face of β -(ET)2I3 terminated with I3⁻ anions. The unit cell with the lattice parameters given in the caption of Figure 3 is depicted. The lattice constants of the cell agree with those observed in the AFM data of the β -(ET)2I3 monolayer in Figure 3A, with 2**a** = **b**1 and **b** = **b**2. (B) Schematic representation of a (001) layer of β -(ET)2I3 from the single-crystal x-ray structure, on the HOPG substrate. The monolayer height measured by AFM (15.5 Å) is identical to the thickness of this (001) layer in the bulk crystal (15.3 Å). The ET molecules are positioned with their long axis nearly parallel to the HOPG substrate and are separated from the next layer by a sheet of I3⁻ anions. The monolayer is depicted here with I3⁻ anions at the upper surface, although this assignment is not yet definitive.
