Director's Foreword

The results of numerous published studies, both within and outside of the psychophysiological detection of deception (PDD) literature, are based on observation groups which are too small to provide results that are representative of the general population. Such studies are described as having low or insufficient statistical power. These publications not only represent a misuse of potentially useful resources, but may lead to unjustified, if not erroneous, conclusions. Among the potential reasons for the prevalence of such studies in the literature are the limited awareness of statistical power analysis, and difficulty associated with the calculation of statistical power.

This manuscript is the first of several computational guides to statistical power analysis to be developed at the Institute. It is designed to assist the investigator in designing, and understanding the analysis of, fixed effects in balanced factorial analysis of variance statistical designs. Future guides will address statistical power calculation for the commonly used student- \underline{t} and chi-square inferential statistics. This and future documents should assist others, as they have the DoDPI faculty, in both the design and evaluation of PDD investigations.

John R. Schwartz

Acting Director

Acknowledgments

The author would like to express special thanks to James L. Bavry, Ph.D. for his many suggestions; Victor L. Cestaro, Ph.D. for his supportive comments throughout the process of deciphering and understanding the notation used by various authors; and Stephen E. Edgell, Ph.D. who, in addition to providing many useful suggestions, wrote and ran computer programs to simulate and verify the accuracy of the equations and procedures presented on pages 5 through 8 of this manuscript. This project was supported by funds from the Department of Defense Polygraph Institute as project DoDPI95-P-0007. The views expressed in this manuscript are those of the author and do not reflect the official policy or position of the Department of Defense or the U.S. Government.

Abstract

DOLLINS, A. B. <u>A computational quide to power analysis of fixed</u> effects in balanced analysis of variance designs, September 1995, Report No. DoDPI95-R-0003. Department of Defense Polygraph Institute, Ft. McClellan, AL 36205.--This manuscript provides a step-by-step guide to statistical power calculation for the fixed effects of analysis of variance (ANOVA) designs with an equal number of observations in each cell. A brief history of ANOVA hypothesis testing theory is included to explain why power calculation is important and how the results can be used. The relationship between lambda (λ) , the noncentrality parameter used to calculate power in the ANOVA, and Cohen's (1988) measure of effect size is provided. Algorithms are provided for power calculation and for conversion between λ , Cohen's measure of effect size, and phi--the parameter used in many tables of the noncentral F distribution. The appendices contain power calculation examples for the main and interaction effects of 2 x 3 x 3 between- and withinsubjects designs.

Key Words: Computation guide, analysis of variance (ANOVA), statistical power, lambda (λ) , alpha (α) , beta (β) , effect size, algorithm.

. .

Executive Summary

DOLLINS, A. B. <u>A computational quide to power analysis of fixed</u> <u>effects in balanced analysis of variance designs</u>, September 1995, Report No. DoDP195-R-0003. Department of Defense Polygraph Institute, Ft. McClellan, AL 36205.

The power of a statistical test is the probability that the test will correctly reject the null hypothesis. Statistical power is commonly used to calculate the number of observations necessary to yield statistically significant results or to calculate the probability that a statistically significant effect would have been found if one existed. The power of a statistical test should not be confused with the significance of a statistical test--which is the probability that a true null hypothesis is falsely rejected. It is possible to obtain statistically significant effects with low or high power. Most text books concerning statistics describe power calculation procedures, but they are usually brief, sometimes difficult to understand, and occasionally misleading. This manuscript is an attempt to provide a clear, easy to understand, step-by-step guide to the calculation of statistical power for fixed effects of analysis of variance (ANOVA) designs with an equal number of observations in each cell. A brief history of ANOVA hypothesis testing theory is presented to explain why power calculation is important and how its results can be used. The confusing issue of whether a hypothesis may only be rejected, versus rejected or accepted, is explained. The relationship between lambda (λ) , the noncentrality parameter used to calculate power in the ANOVA, and Cohen's (1988) measure of effect size is provided. Algorithms are provided for power calculation and for conversion between λ , Cohen's measure of effect size, and <u>phi</u>--the parameter used in many tables of the noncentral F distribution. The appendices contain power calculation examples for the main and interaction effects of 2 x 3 x 3 between- and withinsubjects designs.

Scheffe (1959, p. 3) roughly defines the analysis of variance (ANOVA) as "a statistical technique for analyzing measurements depending on several kinds of effects operating simultaneously, to decide which kinds of effects are important and to estimate the effects." Scheffe (1959, p. 3) attributes the development of ANOVA techniques chiefly to R. A. Fisher (1918, 1935), who was attempting to address agricultural rather than psychological research.

In practice, the ANOVA is a set of procedures for calculating the probability that a particular set of observations could have occurred by chance (i.e., randomly). Thus, a hypothesis may be rejected, with some degree of confidence, that a similar set of observations would not occur by chance. The hypothesis tested is usually the null hypothesis that two or more means (dependent variables), observed during two or more experimental manipulations (independent variables) are equal. This hypothesis may only be rejected (i.e., the groups of values are not equal) based on the ANOVA of the observed values. It is important to note that failure to reject a hypothesis does not, according to Fisherian logic, indicate acceptance of the hypothesis (Fisher, 1966, p. 16). (Cohen [1990] argues that this is a flaw in Fisherian logic because the null hypothesis is always false in the real world - given a large enough sample size.) If the probability that the observed values could have occurred by chance is less than a preset probability level (i.e., referred to as the significance criterion or <u>alpha</u> $[\alpha]$), the null hypothesis is rejected.

Neyman and Pearson (1928a, 1928b) proposed that the specification of an alternative hypothesis be added to the (This concept was, according to Cohen [1990, p. 1307], ANOVA. violently opposed by Fisher.) Inclusion of an alternative hypothesis, to be accepted if the null hypothesis was rejected, revolutionized the decision process associated with the ANOVA. Now the ANOVA could be used to both support and reject Including an alternative hypothesis, with an hypotheses. associated effect size, allows the calculation of the probability that the null hypothesis is not rejected when it is false, as well as the probability of rejecting the null hypothesis, given that the alternative hypothesis is true-referred to as beta (β) or Type II error. Calculation of β allows calculation of its compliment (i.e., $1 - \beta$), power, the probability that the null hypothesis is correctly rejected. The second secon The probability that the null hypothesis will be rejected when it is true, alpha (α), is referred to as the Type I error rate.

The number of observations necessary to support a hypothesis can thus be calculated--given the desired α and β probabilities and the magnitude of the difference between the null and alternate hypotheses. The power of an ANOVA test can also be calculated--given the desired α level, the number of

observations, and the magnitude of the difference between the null and alternate hypotheses. Power analysis is primarily used to determine the probability that a statistically significant difference will be obtained, given a specified difference among the observations, and a specified number of observations; or the probability that a statistically significant effect would have been obtained (where none is found) if one had existed. While it is possible to calculate and use the parameters necessary to support a hypothesis with a relatively high degree of confidence it is, apparently, rarely done. This is documented by the relatively low power (< .60) of the majority of studies, in numerous research fields, to detect small and medium effects (Bones, 1972; Brewer 1972; Brewer & Owne, 1972; Brown & Hale, 1992; Chase & Tucker, 1975; Chase & Chase, 1976; Chase & Barnum, 1976; Christensen & Christensen, 1977; Cohen, 1962; Crane, 1976; Daly & Hexamer, 1983; Fagley, 1985; Frieman, Chalmers, Smith, & Kuebler, 1978; Haase, 1974; Haase, Waechter, Solomon, 1982; Hall, 1982; Jones & Brewer, 1972; Julnes & Mohr, 1989; Kosciulek, 1993; Kosciulek & Szymanski, 1993; Kroll & Chase, 1975; Orme & Combs-Orme, 1986; Orme & Tolman, 1986; Ottenbacher, 1982; Penick & Brewer, 1972; Rossi, 1990; Rothpearl, Mohs, & Davis, 1981; Sawyer & Ball, 1981; Sedlmeier & Gigerenzer, 1989; Wolley, 1983; Wooley & Dawson, 1983). According to S. E. Edgell (personal communication, August 14, 1995) the main problem with low power is that the researcher wastes time by running studies that have little chance of finding the result desired.

Perhaps one of the reasons that the power of \underline{F} ratios are. not calculated or reported more frequently is the difficulty associated with power calculations. Calculating the power of F ratios in ANOVA designs can be difficult, particularly for designs with more than one factor and/or repeated factors, because the majority of the calculations must be completed by hand. The most complete text on the topic of power analysis is Jacob Cohen's Statistical Power Analysis for the Behavioral Sciences (1988) -- which addresses power calculation for most commonly used parametric and non-parametric statistics. Unfortunately, Cohen's (1988) calculations for the ANOVA (pp. 273-406, 550-551) are appropriate for one-way ANOVA designs but underestimate the power and overestimate the sample sizes of higher level designs (Koele, 1982). (Note: Koele was referring to the calculations described in the 1977 edition of Cohen's book - which remain the same in the more current 1988 version.) As can be seen in Appendices B and C, this is true for betweensubjects designs, but the reverse is true for within-subjects Cohen (1988) does not describe power calculations for designs. repeated measure ANOVA designs in any detail, but suggestions may be found elsewhere (Bavry, 1991, pp. 63-76; Davidson, 1972, p. 448; Koele, 1982; Kraemer & Thiemann, 1987, pp. 45-52; Lipsey, 1990, pp. 79-84; Winer, 1971, p. 516).

Cohen (1988) does, however, note several important observations concerning power analysis. Statistical significance levels have generally been set by convention to .05 or .01 (Cowles & Davis, 1982). No such convention exists for power levels, however, Cohen (1988, p. 56) suggests that the value of .80 be used when the investigator has no other basis for setting the desired power value. Cohen (1988, pp. 284-288, 355) further proposes that ANOVA effect sizes, for the behavioral sciences, be categorized into small (.10), medium (.25), and large (.40) for theoretical purposes. Cohen (1988, pp. 364-367) also notes that it is possible to calculate power for separate effects of a complex factorial design independently. This is somewhat analogous to the independent calculation of the effects in a complex factorial design.

The following quide to calculating the power of fixed effects in balanced ANOVA design \underline{F} tests is designed to summarize what can be a very confusing process. The works of Bavry (1991), Borenstein and Cohen (1988), Cohen (1988), Koele (1982), and Winer (1971) were relied upon most heavily during the development of this guide. It should be noted that the processes described herein are based primarily on statistical theory rather than empirical evidence. Monte Carlo studies of the statistical power of ANOVA designs have, however, been reported (Cole, Maxwell, Arvey, & Salas, 1994; Cornell, Young, Seaman, & Kirk, 1992; Keselman, Rogan, Mendoze, & Breen, 1980; Klockars & Hancock, 1992). The description below pertains only to power analysis of a complex fixed effect between- and withinsubjects factorial ANOVA designs with an equal number of observations in each cell (Cohen's, 1988, case 2). Adjustments for an unequal number of observations in each cell are described by Cohen.

Power Calculation

To calculate the power of the <u>F</u> ratio of a complex fixed effect ANOVA design, it is necessary to know the: significance criterion of the <u>F</u> ratio for which power is calculated (α); degrees of freedom of the numerator of the <u>F</u> ratio for which power is calculated; degrees of freedom of the denominator of the <u>F</u> ratio for which power is calculated; and, the noncentrality parameter associated with the <u>F</u> ratio. As detailed below, the noncentrality parameter can be calculated using Cohen's effect size-<u>f</u> (1988). If predicting the power of a repeated measure design using data from a between-subjects design, it is also necessary to calculate the (assumed constant) correlation between pairs of observations on the same element and factor level, as detailed below.

According to Koele (1982), the power of a fixed effect ANOVA <u>F</u> test is the probability that (<u>F</u> > <u>Fc</u> given <u>df1</u>, <u>df2</u>, lambda $[\lambda]$). Koele defines λ as the noncentrality parameter; <u>df1</u> and <u>df2</u> as the numerator and denominator, respectively, degrees of freedom of the <u>F</u> ratio for which power is being calculated, and <u>Fc</u> as the critical <u>F</u> value (with <u>df1</u> and <u>df2</u> degrees of freedom) that the <u>F</u> ratio must exceed at a given significance level. It is distributed as a noncentral <u>F</u> distribution.

Significance Criterion / Fc - Critical F Value

<u>Fc</u> is the <u>F</u> ratio, associated with a given probability (α) level which the calculated <u>F</u> statistic must exceed to be significantly different from chance. For instance, an observed <u>F</u> ratio with <u>df1</u> = 3 and <u>df2</u> = 20 must exceed <u>Fc</u> = 3.10 to be statistically significant at an α level of 0.05 and must exceed <u>Fc</u> = 4.94 to be statistically significant at an α level of 0.01. This value can be calculated from the central <u>F</u> distribution given the α level and the numerator and denominator degrees of freedom. It can also be obtained from tables of the central <u>F</u> distribution given in most textbooks of statistical analyses (e.g. Winer, 1971; Keppel, 1991).

Numerator Degrees of Freedom - df1

These are the degrees of freedom associated with the numerator of the \underline{F} ratio for which power is calculated.

<u>Denominator Degrees of Freedom - df2</u>

These are the degrees of freedom associated with the denominator of the \underline{F} ratio for which power is calculated.

<u>The Noncentrality Parameter - λ</u>

The noncentrality parameter is equal to the <u>F</u> statistic numerator sum of squares, with each term replaced by its expectation, divided by the within-cells error variance (i.e., the mean squares error term; Kendall & Stuart, 1966, p. 5; Scheffe, 1959, p. 39). The noncentrality parameter, λ is thus equal to the calculated <u>F</u> ratio times its numerator degrees of freedom. For example, the λ associated with <u>F</u>(2, 8) = 63.389 would be 2 * 63.389 or 126.778, and the λ associated with <u>F</u>(4, 16) = 0.357 would be 4 * 0.357 or 1.427 (see Appendices A, B, and C for more examples).

The Noncentral F Distribution

Once Fc, df1, df2, and λ are determined, power calculation is completed by use of the noncentral <u>F</u> distribution. Tables of this distribution are provided by Rotton and Schonemann (1978), Tiku (1967), and most textbooks on ANOVA. Table powers are usually indexed by df1, df2, and phi (ϕ) -rather than λ . According to Winer, Brown, and Michels (1991, p. 408), λ can be converted to ϕ using the following algorithm.

 $\phi = SQRT[\lambda / (number of effect levels)]$

Laubscher (1960) describes a square root normal approximation of the noncentral <u>F</u> distribution (formula 6) which may be used to calculate the power of an <u>F</u> ratio using a hand calculator and tables of the central <u>F</u> and <u>Z</u> distributions. While both Cohen (1988, p. 550) and Laubscher (1960) describe a cube root normal approximation, Laubscher concluded that the square root approximation was slightly more accurate for the tested data set. Cohen (1988, p. 550) comments that Laubscher's square root normal approximation of noncentral <u>F</u> "gave excellent agreement with exact value determinations given in the literature...except when n and f are small," but does not define small. A somewhat simplified version of Cohen's adaptation of Laubscher's square root approximation of the probabilities given by the noncentral <u>F</u> distribution is:

 $\frac{X1}{X2} = (\frac{df1}{df1} + 2 * \lambda) / (\frac{df1}{df1} + \lambda)$ $\frac{X2}{X2} = (\frac{df1}{df1} * \frac{Fc}{Fc}) / \frac{df2}{df2}$ $\frac{Z}{Z} = \frac{SQRT[2 * (\frac{df1}{df1} + \lambda) - \frac{X1}{2}] - SQRT[(2 * \frac{df2}{df2} - 1) * \frac{X2}{2}]}{SQRT(\frac{X1}{2} + \frac{X2}{2})}$

Power >= 1 - [Probability of (\underline{Z})]

Where:

- df1 = numerator degrees of freedom of the original <u>F</u> ratio.
- $\frac{df2}{df2}$ = denominator degrees of freedom of the original <u>F</u> ratio.
 - λ = the non-centrality parameter.
 - \underline{Fc} = the value of the critical \underline{F} ratio given the original \underline{F} ratio degrees of freedom and significance criterion.
 - $\underline{Z} = A \underline{Z}$ value, the probability of which may be determined using a table of proportions of area under the standard normal curve. This probability is the probability of a Type II error (i.e., β).

The following computer programs and associated manuals were used in the preparation of this manuscript: <u>Statistical design</u> <u>analysis system</u> (Bavry, in press); <u>Stat-Power statistical</u> <u>design analysis system</u> (Bavry, 1991); and <u>Statistical power</u> <u>analysis: A computer program</u> (Borenstein & Cohen, 1988). A review of computer programs used to calculate power analyses may be found elsewhere (Goldstein, 1989).

Effect Size

Calculating Effect Size

Calculating the power of a completed <u>F</u> test is thus a relatively straightforward task given the significance criterion, <u>F</u> ratio degrees of freedom, and λ . As mentioned above, however, power analysis is primarily useful in predicting the number of observations needed to obtain a significant

effect, if one exists, with a given power, or the probability that a statistically significant effect would have been obtained if one had existed. In both cases, the \underline{F} ratio necessary to predict λ does not exist and must be estimated. The discerning reader will realize that it may be difficult to estimate λ on an a priori basis. Several investigators have proposed ANOVA-based measures of effect size to assist in λ estimation, as reviewed by Tatsuoka (1993). Probably the most intuitive is Cohen's \underline{f} , which is defined as the standard deviation of the effect means divided by the (common) withincell standard deviation (Cohen, 1988, pp. 274-275). While Cohen (1988, pp. 215-406) provides several examples of the standard deviation of the effect means calculations, a detailed explanation of the (common) within-cell standard deviation is Hedges (1981), however, demonstrated that the square not found. root of the \underline{F} ratio's within-cell mean square error term provides the best unbiased estimator of the within-cell standard deviation. Thus, the terminology of Cohen (1988) and Hedges (1981) are adapted as:

Effect size $(\underline{f}) = \underline{SDm} / \underline{SDe}$

Where:

 \underline{f} = Cohen's ANOVA-based effect size (Cohen uses the letter \underline{f} to indicate effect size - this should not be confused with the uppercase \underline{F} which is used to denote the \underline{F} ratio).

<u>SDm</u> SDe

- = The standard deviation of the effect means.
- = The square root of the within-cell mean square error term.

The effect size numerator (SDm) is calculated using one of three techniques depending on the type of factor (main effect vs. interaction) and the number of levels. Calculation procedures for the effect size denominator (SDe) for a betweensubjects ANOVA design differs from those for a within-subjects ANOVA design. These are detailed below and numerical examples are provided in Appendix D. Before proceeding with the examples, a short description of the notation used is necessary. The capital letter "M" is used to indicate the mean of a cell, lower case letters are used to indicate the factor, and arabic numbers are used to indicate the factor level. A period will be used to indicate that a particular factor has been averaged. Thus: "Ma..." indicates the means associated with factor A; "Mal..." indicates the mean of factor A, level 1; "M.b." indicates the means associated with factor B; "M..c" indicates the means associated with factor C; "Mabc" indicates the cell means associated with the A x B x C interaction; and "M..." indicates the grand mean of all values in the data set. For within-subject designs, the notation for specific observations follows the same pattern where: "Mal..s1" indicates the average of subject 1's scores over level 1 of factor A and "M..c4s3"

indicates the average of subject 3's scores over level 4 of factor C.

The following examples are for an A (2 levels) x B (3 levels) x C (4 levels) design with 5 observations per cell. The <u>SDm</u> is calculated in the same manner for both the within- and between-subjects designs. The same <u>SDe</u> term is used to calculate the effect size of each factor in a between-subject design - in the same manner as a common mean square error term is used when calculating the <u>F</u> ratio for each test of a between subjects design. The <u>SDe</u> term is used to calculate the effect size of each factor is used to calculate the effect are subjects design. The <u>SDe</u> term is used to calculate the effect are a within-subjects design varies, as does the mean square error term used when calculating the <u>F</u> ratios of a within-subjects design.

The <u>SDe</u> term for the A (2 levels) x B (3 levels) x C (4 levels) example with 5 independent observations in each cell is:

 $\underline{SDe} = SQRT \begin{bmatrix} 2 & 3 & 4 & 5 \\ \Sigma & \Sigma & \Sigma & \Sigma & (Xaibjcksl - Maibjck.)^{2} \\ i=1 & j=1 & k=1 & l=1 \\ & & & & & & \\ & & & & & & & \\ & & & & & & & \\ & & & & & & & & \\ & & & & & & & & \\ & & & & & & & & \\ & & & & & & & & \\ & & & & & & & & \\ & & & & & & & & \\ & & & & & & & & \\ & & & & & & & & \\ & & & & & & & & \\ & & & & & & & & \\ & & & & & & & & \\ & & & & & & & & \\ & & & & & & & & \\ & & & & & & & & \\ & & & & & & \\ & & & & & & & \\ & & & & & & & \\ & & & & & & & \\ & & & & & & & \\ & & & & & & & \\ & & & & & & \\ & & & & & & \\ & & & & & & & \\ & & & & & & & \\ & & & & & & & \\ & & & & & & & \\ & & & & & & & \\ & & & & & & & \\ & & & & & & & \\ & & & & & & & & \\ & & & & & & & \\ & & & & & & & & \\ & & & & & & & & \\ & & & & & & & & \\ & & & & & & & & \\ & & & & & & & & \\ & & & & & & & & \\ & & & & & & & & \\ & & & & & & & & \\ & & & & & & & & \\ & & & & & & & & \\ & & & & & & & & \\ & & & & & & & & \\ & & & & & & & & \\ & & & &$

Note:
$$\hat{}$$
 = exponentiation, thus $X^2 = X^*X$.

Or, more simply, the square root of the average cell variance:

•

Factor	SDe						
A	SQRT[(VARa1b1c1 + VARa2b1c1 ++ VARa2b3c4) / 24]						
В	SQRT[(VARa1b1c1 + VARa2b1c1 ++ VARa2b3c4) / 24]						
•	SQRT[(VARa1b1c1 + VARa2b1c1 ++ VARa2b3c4) / 24]						
АхВхС	SQRT[(VARa1b1c1 + VARa2b1c1 ++ VARa2b3c4) / 24]						

Where: VAR is the variance.

The general <u>SDe</u> term for a within-subjects ANOVA is the square root of the within-cell mean square error term used in the <u>F</u> ratio for which the power is being calculated. A general example is given below and examples of specific calculations for the various effects may be found in Appendix D:

$$\underline{SDe} = SQRT \begin{bmatrix} 2 & 5\\ \Sigma & [(\Sigma & (Max..sy - Max...)^2] \\ x=1 & y=1 \\ \hline 8 & (i.e., the F ratio denominator df \end{bmatrix}$$

7

(1) Effect size of a main effect with 2 levels is calculated using:

$$\underline{f} = \frac{0.5 * (\text{maximum Ma..} - \text{minimum Ma..})}{\underline{SDe}}$$

Note: The standard deviation of two values is 0.5 * the difference between the two values.

(2) Effect size of a main effect with more than 2 levels is calculated using:

$$\underline{f} = \frac{\underline{N}}{\underline{SDe}} (M..cx - M...)^{2} / \underline{N}$$

(3) Interaction effect sizes are the square root of the summed squares of the contribution of each cell to the effect divided by the number of cells. The contribution of each cell's effect is calculated by removing the contributions of other factors to that cells effect (i.e., using the linear model). The process is similar to that used to calculate the sum of squares for an <u>F</u> ratio interaction. For example, the effect size for Cohen's (1988) example 8.6 (pp. 368-372) A(2 levels) x B(3 levels) interaction would be calculated as:

Xalb1. = Malb1. - Mal.. - M.b1. + M...
Xalb2. = Malb2. - Mal.. - M.b2. + M...
Xalb3. = Malb3. - Mal.. - M.b3. + M...
Xa2b1. = Ma2b1. - Ma2.. - M.b1. + M...
Xa2b2. = Ma2b2. - Ma2.. - M.b2. + M...
Xa2b3. = Ma2b3. - Ma2.. - M.b3. + M...
$$xa2b3. = Ma2b3. - Ma2.. - M.b3. + M...$$

Note: Calculating the cell contributions can become quite complex. A good guide for the factors and signs may be found in Kirk (1968). The X???s used to calculate the <u>SDm</u> for Cohen's example 8.6 A x B x C effect would be:

Xabc = Mabc - Mab. - Ma.c - M.bc + Ma.. + M.b. + M..c - M...

<u>Converting Cohen's Effect Size to λ </u>

Cohen's (1988) ANOVA-based measure of effect size can be converted to λ using the following algorithm.

$\lambda = \underline{f}^2 *$ (the total number of observations analyzed for the effect)

The total number of observations analyzed for an effect is the number of observations used in calculating the error term and will differ for within- and between-subjects ANOVA designs. For example, the number of observations for the effects of an A (2 levels) x B (3 levels) x C (4 levels) ANOVA with 5 observations per cell, analyzed as a within- or between-subjects design would be:

	Total Number of	Total Number of
	Observations	Observations
Effect	Within-subjects	Between-subjects
A	10	120
В	15	120
AxB	15	120
C	20	120
AxC	20	120
BxC	120	120
AxBxC	120	120

A Note Concerning Cohen's Description of ANOVA Power Calculation

The power tables for ANOVA designs provided by Cohen (1988, pp. 273-406) require specification of: a desired significance criterion; an effect size; the <u>F</u> ratio numerator degrees of freedom; and the sample size. Cohen (1988, p. 365) indicates that it is necessary to use an adjusted samples size to cope with the discrepancy in denominator (error) degrees of freedom between one-way and higher-way ANOVA designs. Cohen (1988, p. 365) describes the calculation of sample size (\underline{n}') as follows:

sample size =
$$\underline{n'}$$
 = $\frac{\underline{u} + 1}{\underline{u} + 1}$

Where:

- \underline{u} = the degrees of freedom associated with the numerator of the \underline{F} ratio for which power is to be calculated.
- denominator <u>df</u> = total number of observations in the analysis minus the total number of cells in the analysis.

An example calculation of n for each of the effects in a $2(A) \times 3(B) \times 4(C)$ ANOVA with 5 observations per cell (Cohen's example 8.6, p. 368-372) would be:

Total observations = 120 (i.e., 2 * 3 * 4 * 5) Total number of cells = 24 (i.e., 2 * 3 * 4) Denominator <u>df</u> = 120 - 24 = 96

Numerator

Effect	<u>df</u>	<u>n</u>
A	1	49.0
В	2	33.0
С	3	25.0
АхВ	2	33.0
АхС	3	25.0
ВхС	6	14.7
АхВхС	6	14.7

This adjustment works well for a one-way ANOVA design. However, as noted by Koele (1982), and illustrated in Appendices B and C, using Cohen's technique to calculate the power of effects in higher-way ANOVA designs will result in an underestimation of the power of between-subjects design effects and overestimation of the power of within-subjects effects. It is thus suggested that Cohen's ANOVA-based effect size measure be converted to and/or from λ and noncentral <u>F</u> distribution probabilities be used to estimate power. This will ensure accurate results and is, in addition, less complicated computationally.

Constant Correlation

An assumption in repeated measures ANOVA is that there is a "constant" correlation between pairs of observations on the same subject under different conditions (Winer, 1971, p. 516). Winer (1971, p. 516) and others (Lipsey, 1990, pp. 79-84; Davidson, 1972, p. 448; Kraemer & Thiemann, 1987, pp. 45-52) suggest that SDe should be increased or decreased according to the constant correlation when attempting to estimate the <u>SDe</u> for a withinsubjects ANOVA design using existing data from a study with a between-subjects ANOVA design (details below). A problem occurs when deciding how to estimate the constant correlation. When comparing only two observations, the product-moment correlation may be used as an estimate of the constant correlation. Dr. Bavry (personal communication) and others (Silver & Dunlap, 1987; Silver & Hollingsworth, 1989; Viana, 1980, 1993) suggest that the best estimate of the constant correlation is calculated by averaging the Fisher's Z transform (Fisher, 1921) of all of the within-subjects between-cell correlations, then converting that Fisher's \underline{Z} transform average back to a correlation coefficient. An numerical example of constant correlation calculation for data presented in Appendix A is given in Appendix E. Fisher's Z transform and its inverse are as follows (Silver & Dunlap, 1987).

Fisher's \underline{Z} transform is: $\underline{Z} = 0.5 * \log_{e} \left[\frac{1+\underline{r}}{1-\underline{r}} \right]$

The inverse transform is: $\underline{r} = (\underline{X} - 1) / (\underline{X} + 1)$

Where:

 \underline{r} = the correlation coefficient \underline{X} = exp_e (2 * \underline{Z})

Note: The constant correlation correction is only necessary when attempting to estimate the <u>SDe</u> for a within-subjects ANOVA design using existing data from a study with a between-subjects ANOVA design.

According to Winer (1971, p. 516), the following correction should be used to adjust estimates of <u>SDe</u> obtained from betweensubjects designs when calculating power analyses of <u>F</u> ratios involving repeated measures. The <u>SDe</u> of repeated measure interaction and main effects should be adjusted by multiplying <u>SDe</u> by (1-r), where r is the constant correlation for that effect. The <u>SDe</u> of between groups effects which are composed of repeated measures on each member of a group should be adjusted by multiplying <u>SDe</u> by $(1 + \underline{W} * \underline{r})$, where <u>W</u> is the tested effect degrees of freedom and r is the constant correlation for that effect.

Description of the Appendices

Appendix A contains the results of between-subjects and within-subjects ANOVA of data presented by Winer (1962, p. 324; 1971, p. 546). Appendices B and C contain the results of a power analysis of the data in Appendix A using the suggested noncentral \underline{F} distribution and Cohen's tables, respectively. Α comparison of the results obtained using the two methods illustrates the tendency of Cohen's technique to overestimate between-subjects and underestimate within-subjects higher-way ANOVA effect powers. Appendix D contains a numerical example of the calculations necessary to obtain the data presented in Appendices B and C. Appendix E contains a numerical example of the use of Fisher's Z transform to calculate the average correlation of data in Appendix A. Appendix F contains algorithms for converting values among ϕ , λ , and Cohen's effect size for ANOVA (f).

<u>SDe</u> = Sqrt(Σ (Yj²) / denominator <u>df</u>) = SQRT(127.111 / 16) = 2.818 j=1

Power Calculation for the PERIOD*DIAL effect:

 COHEN
 BAVRY

 Effect Size = \underline{f} = \underline{SDm} / \underline{SDe} λ = SSm / MSe

 Effect Size = \underline{f} = 0.444 / 2.818
 λ = 10.667 / (127.111/16)

 Effect Size = 0.157
 λ = 1.343

 \underline{u} = 4.0
 \underline{DFm} = 4.0

 $\underline{n'}$ = (49 / (4 + 1)) + 1 = 10.8
 \underline{DFe} = 16.0

 Effect power = 0.117
 Effect power = 0.1068

Power Calculation for the NOISE*PERIOD*DIAL Effect:

 COHEN
 BAVRY

 Effect Size = \underline{f} = \underline{SDm} / \underline{SDe} λ = SSm / MSe

 Effect Size = \underline{f} = 0.458 / 2.818
 λ = 11.333 / (127.111/16)

 Effect Size = 0.163
 λ = 1.427

 \underline{u} = 4.0
 \underline{DFm} = 2.0

 $\underline{n'}$ = (49 / (4 + 1)) + 1 = 10.8
 \underline{DFe} = 16.0

 Effect power = 0.123
 Effect power = 0.110

Note: Denominator df = (54/5 - 1) * 5 = 49
