16. Abstract (Limit: 200 words) Thermal and mechanical properties of expanded plastics, foams, are reported. The system studied was rigid, closed cell, CC_2F blown, polyether based polyurethane. The primary temperature range of study was 100 to 300 K; however, several properties were determined to 4 K. The nominal densities of the foams tested were 32, 64, and 96 kg/m^3 . Properties reported are thermal conductivity, thermal expansion, strength and moduli in tension and in compression, proportional limit, yield strength, ultimate strength, and shear strength. Physical properties were determined both parallel and perpendicular to the orthogonal axes of the bulk supplies. The gas content of the specimens was determined using a gas chromatograph-mass spectrometer and with a gas displacement pycnometer. Empirical procedures for estimating the temperature dependent thermophysical properties were developed. These procedures are based on the experimental data and utilize the characterization parameters for molar gas concentration, gas pressure, and cell morphology. Regulations affecting vapor dispersion in the area around liquefied natural gas facilities make it attractive to construct dikes and impounding areas out of materials having low thermal conductivities. Several insulating concretes have the general properties required for such applications. Screening tests were done to determine the thermal conductivity, modulus of rupture, and the compressive strength of several polyester based materials with glass bead or perlite aggregate and of portland cement based materials with vermiculite or polystyrene aggregate. A bibliography resulting from an extensive literature survey of lightweight concretes is presented. Seven of the references which were particularly applicable are presented in annotated form.

RESEARCH SUMMARY

Title Thermal and Mechanical Properties of Polyurethane Foams and a Survey of Insulating Concretes at Low Temperatures

Contractor National Bureau of Standards
GRI Grant Number 5081-352-0425

Principal Investigator L. L. Sparks

Report Period January 1979 - February 1984
(Final Report)

Objective To determine the thermal and mechanical properties of polyurethane foams and, whenever possible, to develop predictive techniques for the low temperature properties. To survey existing data for and to conduct screening tests on several insulating concretes in order to allow selection of the most viable candidate materials for further use and development. The temperature range of interest for both foams and concretes is that encountered in the transfer and storage of liquefied natural gas (LNG).

Technical Perspective Expanded plastics or foams are used extensively as thermal insulation materials in liquefied fuel facilities. The widespread use of these materials can be attributed to low thermal conductivity, high strength-to-weight ratio, low cost of production, and ease of installation. The properties of foam insulations, which are

essential to the design of facilities and production of foam, are not adequately predictable at this time. The needed predictability must be based on either theoretical or empirical representations that include the dependence on temperature and the effects of critical parameters such as cell size, gas content, and density.

Regulations concerning vapor dispersion in the event of a spill at a LNG storage facility make it attractive to use an insulating material in the construction of dikes and impounding areas. Several types of insulating concretes are candidates for such applications. Identification of one or more of these materials, along with the development of an adequate data base for the selected materials, is necessary for confident design.

Results The effort involving plastic foams has resulted in the following experimental data for each of the three polyurethane foams studied: thermal conductivity, thermal expansion, strength and moduli in compression and in tension, proportional limit, yield strength, ultimate strength, and shear strength. Foam specimen densities were nominally 32, 64, and 96 kg/m³ and the basic temperature range of the study was 100-300 K. Empirical techniques were established to predict thermal conductivity, thermal expansion, and compressive and tensile strength and moduli. The empirical nature of these relationships and the small number of foam systems involved in their development mean that applicability to polyurethane foams in general has not been established.

A survey of existing data for insulating concretes has been completed. The survey yielded approximately 300 pertinent references, of which 30 contained data applicable to LNG facilities. Screening tests, done to supplement data from the literature, have been completed. These tests resulted in comparative data for thermal conductivity, modulus of rupture and compressive strength for several polyester-based materials with glass bead or perlite aggregate and for portland-cement-based materials with vermiculite or polystyrene aggregate. Thermophysical properties and low water absorption required for dike insulation materials recommend polymer-based materials over portland-cement-based materials. Portland-cement-based materials could also be produced which, with waterproofing and proper grading of dike/basin surfaces, would be suitable.

Technical
Approach

The thermophysical properties of expanded plastics depend on morphology, gas content, and chemical composition. A wide variety of techniques have been used to determine these parameters. The most fruitful methods are gas chromatography/mass spectrometry, optical analysis of polarized photomicrographs and pycnometry. These analyses yield statistical information on cell size, cell shape and orientation, and cellular gas content. In addition to specimen characterization, the experimental study consisted of determining thermal conductivity (ASTM C177 dry-nitrogen environment), $\Delta L/L$ in an optical-lever dilatometer (helium-gas environment), and the mechanical properties in a system utilizing a specially designed capacitance extensometer (helium-gas environment). All properties

studied depend, in varying degrees, on cell gas, morphology, and chemical composition of the resin.

The effort directed to insulating concretes is a study of these materials, as a class, for applications to dikes and impounding areas at cryogenic temperatures. The literature survey resulted in very limited data applicable to the projected use of these materials. An experimental screening program was conducted on three polyester resins with glass-bead and perlite fillers and two portland-cement mixes with vermiculite and polystyrene fillers. The screening consisted of determining the thermal conductivity at several temperatures between 76 and 285 K (high vacuum environment) and determining the modulus of rupture (MOR) and compressive strength at 76 and 300 K.

ASTM standard methods C78 and C513 were used to determine MOR and compressive strength respectively at both ambient and cryogenic temperatures.

Project
Implications

A large data base on thermophysical properties of foams at cryogenic temperatures has been generated. Empirical relationships were developed to predict thermal conductivity, thermal expansion, and strength properties of the foams utilizing experimental data. These parameters will be used in insulation design for cryogenic fluid transfer pipes and storage tanks.

From a literature survey and from limited experiments, six potential materials for dike insulation at LNG facilities have been identified. Two of the recommended materials composed of polymer binder with perlite or glass nodules as the aggregate are being extensively tested in a GRI-sponsored project at Brookhaven National Laboratory.

Thermal and Mechanical Properties of Polyurethane Foams and a Survey of Insulating Concretes at Cryogenic Temperatures

INTRODUCTION

Safe and economical storage and transport of cryogenic fuels such as liquefied natural gas (LNG) depend to a large extent on the materials used in the construction of storage tanks, transfer terminals, liquefiers, pipelines, and ships. Thermal insulation constitutes a critical link in the materials for use in LNG- and LPG (liquefied petroleum gas)-oriented energy efforts because of the cryogenic nature of the liquids. Two types of insulating material are being studied --expanded plastics and lightweight concretes. Insulation systems utilizing expanded plastics (foams) are used in many LNG-oriented facilities. An insulating concrete can satisfy requirements for dike and impounding areas of LNG storage tanks.

The data bases and knowledge based on experience for both types of material being considered are inadequate for reliable design. Most data for insulating foams are based on essentially uncharacterized specimens. Consequently, it is not generally possible to reliably relate existing data to a particular foam. Inefficient overdesign and failures may occur because the material actually used is different than the material used to determine the design properties. Insulating concretes have not been used extensively in applications where they must be functional at cryogenic temperatures. There is not enough information available to allow a particular type of lightweight material to be chosen with confidence. Unanswered areas of concern are application difficulties, initial cost, maintenance costs, deterioration, and thermal and mechanical properties.

This project was designed to alleviate these difficulties. The portion of the project devoted to foams will be discussed first and will be identified by (IF) for insulating foams. Discussion of insulating concretes will follow and will be designated by (IC).

INSULATING FOAMS

Overall Project Objective (IF)

There are four major objectives of the foam project:

- (1) To improve the existing data base and the test procedures relating to expanded plastics at low temperatures.
- (2) To develop test methods and characterization procedures for general application to foam insulations.
- (3) To provide a basic understanding of the observed low-temperature behavior and to develop procedures that can be used to predict low-temperature properties of insulating polyurethane foams.
- (4) To serve as a center for insulation information for GRI and associated users of cryogenic fuels.

Project Description (IF)

The work performed on insulating foams can be correlated with the major tasks shown in figure 1.

(1) Assessment of Materials - A literature search was made. Companies and technical societies involved in the production and/or use of insulating foams were contacted. The results of this phase of the project were reported by Sparks (1979, 1980). Based on the information obtained, three densities of expanded polyurethane foam were chosen as materials for detailed study. The densities span the range normally used in insulating applications.

(2) Assessment of Methods - This effort was performed concurrent with task (1) since the same literature survey and industrial contacts were involved. With the exception of thermal conductivity, there are no existing standard test procedures

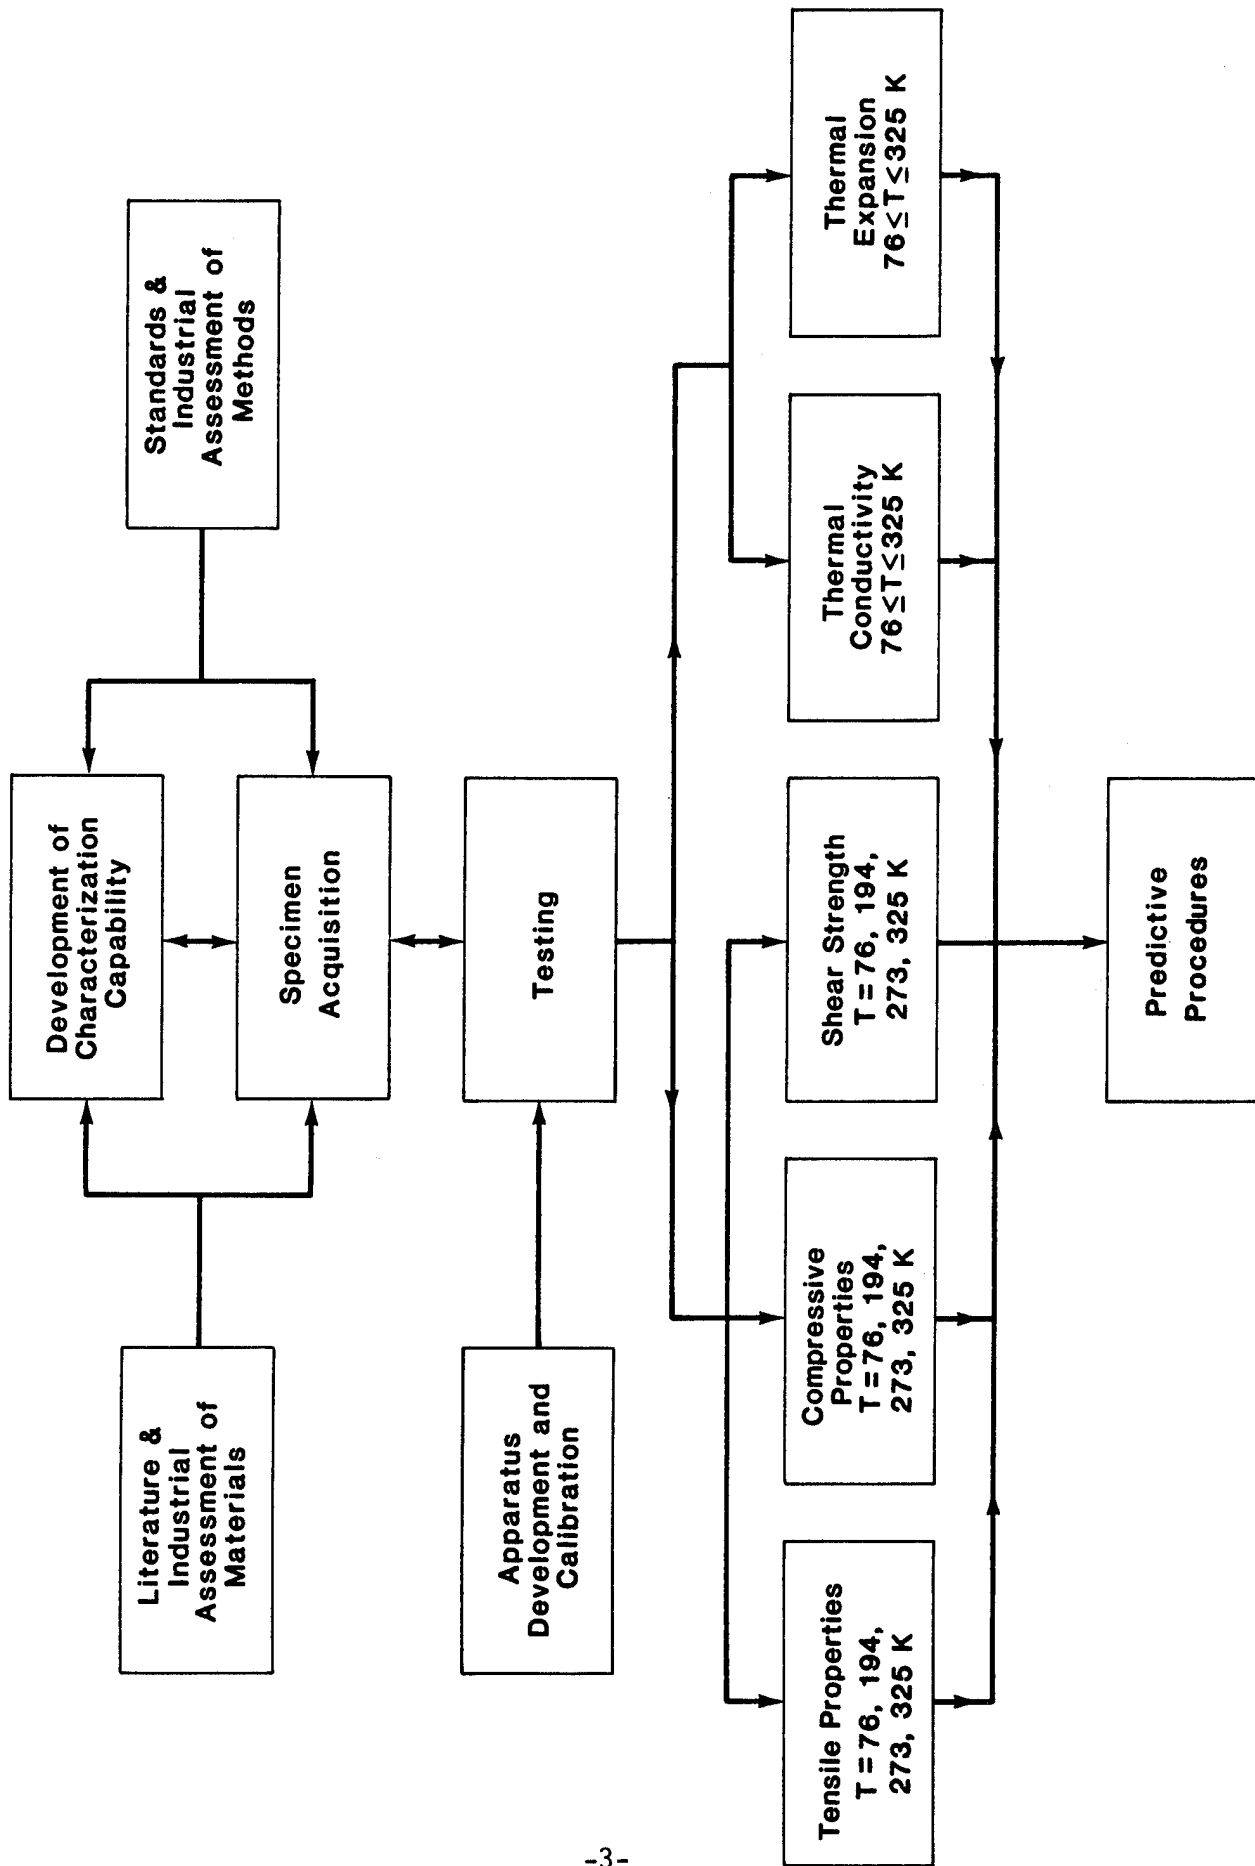

Figure 1. Tasks associated with the insulating foam project.

for expanded plastics at low temperatures. This task, therefore, necessarily involved evaluation of apparatuses and procedures used at NBS and in industry. Special apparatuses were ultimately required for adequate testing of thermal expansion and mechanical properties of these viscoelastic, anisotropic materials.

(3) Characterization - The development of predictive techniques for foam properties requires knowledge of morphology, cell gas, and chemical composition of the test specimens. Several methods of determining these parameters were evaluated during the course of the project. The criteria used in determining the final role of the various techniques was quality and usefulness of the output and whether or not the procedure could be reasonably applied by producers and users of polyurethane foams. The following procedures were evaluated: (a) Gas chromatograph/mass spectrometer - used to determine the composition of the gases present in the foam cells. (b) Scanning electron microscopy (SEM) - reflected beams of electrons produce photographs with depth of field much superior to optical photographs. (c) Photomicrography - an optical microscope designed specifically to observe grain structure in metals was used to study the cell structure of the 32-kg/m³ foam. (d) Polarized photomicrographs-polarized light enhances resolution of cell structure and was used to study the cell structure of the 64- and 96-kg/m³ foams. (e) Thermogravimetric analysis (TGA) - used to determine mass loss as a function of temperature. The results were used to identify constituent materials in the foams. (f) Differential scanning calorimetry (DSC) - used to determine heat capacity as a function of temperature. Temperature dependent phase changes can be detected using this technique. (g) Gas comparison pycnometry - used to study foam morphology.

(4) Specimen Acquisition - Bulk supplies of 32- and 64-kg/m³ specimens were obtained from the Products Research Committee (1980) through the Office of Standard Reference Materials of NBS. The 96-kg/m³ material was purchased from a commercial producer.

(5) Testing - Several basic properties were considered to be essential to the use of insulating foams in the LNG industry. In addition to the characterization tests, the following types of data were obtained for each of the three polyurethane specimens: thermal conductivity, thermal expansion, coefficient of thermal expansion, tensile, shear, and compressive strengths, Young's modulus, proportional limit, yield strength at 0.2% offset, and elastic and plastic elongation. The temperature range of study always included 100 to 300 K, and in several instances, data were obtained from considerably outside this range.

Project Rationale and Projected Benefits (IF)

Expanded polyurethanes are complicated composite materials. The values of most thermophysical properties depend on the direction of heat flow or stress application relative to the direction of free foam expansion during polymerization. Aging affects the properties both due to gas diffusion and to resin changes. The net result is that current use of insulating foams in cryogenic applications involves costly overdesign and, in some instances, undesirable results. Much of the existing low temperature data for foams is based on uncharacterized materials and were determined with experimental methods unsuited for low temperature testing.

The rationale for the study of insulating foams was to alleviate the problems currently faced by designers of foam insulation systems. The three-fold thrust to accomplish this was: (1) to generate reliable low temperature data for

three polyurethane foams whose densities span the range of practical insulating foams; (2) to utilize these data to develop predictive procedures for low temperature properties; and (3) to establish a direction for further low temperature research on expanded plastics. Important complimentary research includes examination of test procedures and design of special equipment to study foam-like materials. Also, the possibility of developing a foam standard reference material needed to be examined.

The benefits of items (1) and (2) above are clear and immediate. The data can be used as an engineering guide for initial design of polyurethane insulation systems. The predictive procedures can be used to further refine expected behavior when used in conjunction with specific foam characteristics. The highest quality design data for a specific foam must be based on information about the particular foam formulation and on an understanding of the effect of different foam characteristics on the low temperature properties. In order for this to be done in a practical way, standardized tests and materials must be readily available. Ultimately, the economic and safe utilization of these insulating materials in LNG applications depends on further research to bring expanded plastics to the level of development of other materials used in LNG facilities.

TECHNICAL DISCUSSION (IF)

Work Plan (IF)

The work plan for the duration of the foam study followed the general steps outlined in the Project Description section. The early stage of the work was devoted to selecting the most useful type of insulation for LNG applications and to determine what, if any, standard procedures existed to allow reliable low temperature data to be generated. A significant literature search had been done and industrial contacts were already established for an earlier project. Evaluation

of data and procedures indicated that most materials tested previously could not be identified well enough to be of use in developing predictive procedures and that the only standard procedure that could be readily applied at cryogenic temperatures was ASTM C177 for thermal conductivity. Two experimental systems suited to testing viscoelastic anisotropic foams were near completion at NBS. Characterization of the foams presented another obstacle. The literature and fundamental parameters in thermophysical properties suggested that the morphology of a foam and the statistical size, shape, and orientation of the cells was of primary importance. Several papers dealing with measurement techniques and interpretation (Smith and Guttman, 1953; Harding, 1960; Schael, 1967; and Thompson, 1972) were evaluated and utilized, in part, to characterize the polyurethane specimens.

A large number of procedures for determining various attributes of the materials were evaluated. The primary characterization effort centered on determining the cellular structure optically and determining the cellular gas content using a gas chromatograph backed by a mass spectrometer. An important consideration in both testing and characterization was that the procedures be such that they could be adopted for general use. This is particularly important for characterization of foams: predictive procedures will be more useful if the parameters can be determined with reasonable effort.

After proving the experimental systems and acquiring and characterizing the specimens, the following thermophysical properties were determined for each of the three polyurethane foams: thermal conductivity, thermal expansion, tensile, shear, and compressive strengths, Young's modulus, proportional limit, yield strength at 0.2% offset, and elastic and plastic elongation. The results of the testing program were to be assessed for the possibility of describing the measured values with analytical models.

Work Performed and Experimental Results (IF)

The nominal densities of the polyurethane foam specimens were 32, 64, and 96 kg/m³ (PU32, PU64, and PU96). PU32 and PU64 were obtained from the NBS Office of Standard Reference Materials (OSRM), Washington, D.C. The OSRM distributed these and other expanded plastics for the Products Research Committee (1980). These materials were commercially produced and distributed by OSRM as General Materials. The third material, PU96, was purchased from a commercial manufacturer, since OSRM did not stock a General Material in this density range. The bulk supplies of these materials were in the forms shown in figure 2. The coordinate axes assigned to the bulk materials are indicated in this figure. The thermal expansion, thermal conductivity, and longitudinal mechanical property measurements were made parallel to the z-axis. The transverse mechanical properties were measured parallel to the y-axis.

Densities - The densities of the bulk supplies were determined for four specimens of each material. After conditioning at 23 °C and 50% relative humidity, the densities were found to be 33.56 ± 0.14 , 62.52 ± 0.11 , and 99.03 ± 3.4 kg/m³. The uncertainties represent estimates of one standard deviation. The large uncertainty in the PU96 density results from a density variation in the bulk supply.

Optical characterization - Optical characterization involved three general procedures: (1) examination of the bulk supplies by means of a binocular microscope with an extension arm, (2) maximum-cell-dimension analysis of polarized photomicrographs of the principal orthogonal planes, XY, XZ, YZ in (fig. 3), and (3) analysis of cell-wall intercepts at 30° rotations for the planes XY, XZ, and YZ (fig. 3).

Bulk examination - This examination was intended to reveal the existence of nonvertical flow lines, i.e., foam rise directions not parallel to the z-axis.

All dimensions in meters.

Figure 2. Bulk supplies of polyurethane foam and orientation of axes. Numbered rectangles indicate areas used for characterization.

Figure 3. Configuration of the planes studied by optical methods.

This type of examination of PU32 indicated that the elongated cell axes were not vertical at any place in the bulk supply, and that the cells near the long edges (approximately 0.3 m in from each long edge) were inclined about 35° in the XY plane, 45° in the XZ plane, and 55° in the YZ plane (fig. 4). Cells in the center portion had 0° inclination in the XY and YZ planes, but retained the 45° inclination in the XZ plane. These qualitative assessments were confirmed in the quantitative intercept analysis discussed below.

The bulk supply of PU64 consisted of three slabs. Nonvertical flow lines were observed in each of the pieces but the angle of inclination was smaller than that found in PU32. The cellular inclinations of two of the three slabs were consistent and identical within the uncertainty of the measurements (fig. 4). The inclinations found in the third slab were not uniform, i.e., the inclination was significantly different for parallel planes. No additional tests were performed on this slab. The slab designated PU64-1 was used for mechanical property tests and PU64-3 was used for thermal property tests.

Non-vertical alignment of the long cellular axes of PU96 was found only in an 0.08 m thickness around the perimeter. A 0.2 m thickness around the perimeter was marked as scrap, and no test specimens were taken from this material. The cellular orientation for all planes of PU96 are shown in figure 4.

Maximum-cell-dimension analysis - This procedure was used to determine the ratios of maximum cellular dimensions parallel to the major axes. Microscope slides were made by passing a blade through the foam at a given orientation. This procedure was done with the cutting planes parallel to the principal planes: XY, XZ, YZ. Photomicrographs were prepared with a minimum of two different sections per plane for each foam. It was found that a magnification of 50 was suitable and that the contrast achieved using incident, polarized light produced clearly defined cell boundaries. Maximum cell dimensions parallel to the

Figure 4. Orientation of the elongated cell axes. These results are from optical examinations of the bulk supplies of these materials.

principal axes were determined from the length calibrated photographs. Results of these measurements are given in table 1. The lengths measured and presented

Table 1. Maximum intercepted cell dimensions parallel to the orthogonal principal axes of the XY, XZ, and YZ planes for four specimens of PU32 and two specimens each of PU64 and PU96. Locations of the specimens are indicated in figure 2.

Specimen	X Axis (μm)	Y Axis (μm)	Z Axis (μm)
PU32-2	527	406	488
PU32-3	492	380	510
PU32-6C1	482	356	458
PU32-6C2	461	364	457
PU32-average	490	376	478

PU64-average	210	220	340
PU96-1	272	240	257
PU96-2	226	250	300
PU96-average	249	245	278

in this table represent the maximum intercepted dimension which is somewhat smaller than the actual maximum cell dimension. Several authors (Hensler, 1968; Exner, 1969; and Thompson, 1972) have proposed multiplicative factors needed to arrive at actual maximum cell dimensions from maximum intercepted cell dimensions. These factors range from 1.5 to 1.68 with the differences being due to assumptions about cell shape and packing factors. The ratios given in table 2 eliminate this source of uncertainty.

Intercept analysis - The procedure used to arrive at these data also utilizes photographs of foam cells and follows the acquisition scheme suggested by Smith and Guttman, 1953. This approach assumes randomly oriented sections.

Table 2. Ratios of averaged maximum intercepted cell dimensions parallel to the orthogonal principal axes of the XY, XZ, and YZ planes for four specimens of PU32 and two specimens each of PU64 and PU96. Locations of the specimens are indicated in figure 2.

Specimen	Z/X	Z/Y	X/Y
PU32-average	0.98	1.27	1.30
PU64-average	1.62	1.55	0.95
PU96-average	1.12	1.13	1.02

Randomness was approximated by seven planes, XY, XZ, YZ and planes P_1 through P_4 in figure 3, for each of two locations per material, i.e., 14 photographs for each of the three polyurethane foams. Each photograph was evaluated by superimposing a grid of parallel lines and counting the intersections of grid lines and cell walls. Data were taken for grid rotations of 0, 30, 60, and 90 degrees. Statistical evaluation of these data, as suggested by Schael, 1967, results in the cross-sectional areas listed in table 3. The quality of these data depend strongly on how nearly the sampling procedure produces a random cross section of the foam. If randomness is assumed, these data are independent of cell shape.

Gas comparison pycnometry - Acquisition of cellular data by optical means is tedious and its interpretation is time consuming. Gas comparison pycnometry (GCP), as discussed by Harding (1960), Rice and Nunez (1962), and Schael (1967), can theoretically be used to obtain similar data more rapidly. This technique requires only commercially available equipment and, after adopting an appropriate experimental procedure, could be done on a routine basis.

The principle of GCP operation is Boyle's law: the product of pressure and volume of an ideal gas is constant at a given temperature. The quantity actually determined is specimen volume as measured by gas displacement, i.e., volume of foam as determined by GCP would be smaller than the physical dimensions of the

Table 3. Intercepted cell section area computed from cell wall intercept data for two specimens each of PU32, PU64, and PU96. The method of computation follows that described by Schael (1967). Locations of the specimens are indicated in figure 2.

Specimen	XY ₂ Plane (cm ² /cell)	XZ ₂ Plane (cm ² /cell)	YZ ₂ Plane (cm ² /cell)
PU32-2	1.27 x 10 ⁻³	1.21 x 10 ⁻³	1.25 x 10 ⁻³
PU32-3	1.02 x 10 ⁻³	1.32 x 10 ⁻³	1.11 x 10 ⁻³
PU32-average	1.15 x 10 ⁻³	1.27 x 10 ⁻³	1.18 x 10 ⁻³
PU64-1	2.90 x 10 ⁻⁴	4.23 x 10 ⁻⁴	4.59 x 10 ⁻⁴
PU64-2	2.59 x 10 ⁻⁴	4.19 x 10 ⁻⁴	4.83 x 10 ⁻⁴
PU64-average	2.75 x 10 ⁻⁴	4.21 x 10 ⁻⁴	4.71 x 10 ⁻⁴
PU96-1	5.51 x 10 ⁻⁴	5.53 x 10 ⁻⁴	4.69 x 10 ⁻⁴
PU96-2	4.74 x 10 ⁻⁴	4.69 x 10 ⁻⁴	5.88 x 10 ⁻⁴
PU96-average	5.13 x 10 ⁻⁴	5.11 x 10 ⁻⁴	5.29 x 10 ⁻⁴

specimen would indicate because of open cells. By sectioning a foam specimen in a particular sequence and making multiple determinations of the resulting specimen GCP volumes, information on open cell content, cell size, and axial dimensions can be calculated. Several GCP operating procedures were evaluated. The procedure selected for use involved subjecting the test specimens to a pressure variation from 0.4 to 200 kPa of nitrogen gas. An individual GCP test required only minutes to complete so that diffusion of gas and concomitant changes in internal pressure were assumed to be negligible. Results of the GCP analysis and a comparison to optically obtained values are given in table 4.

The optical data are internally consistent, i.e., if elliptical cross sections are assumed, the axial dimensions can be used to compute the cellular cross sectional area to within the uncertainty of the data. This is not true for the GCP data for either the cellular volume or cross section. However, as will be

Table 4. Results of gas comparison pycnometer (GCP) characterization of PU32, PU64, and PU96. Comparable results from optical evaluations of the same materials are also given.

Parameter	PU32		PU64		PU96	
	GCP	Optical	GCP	Optical	GCP	Optical
Average Cell Volume, 10^{-5} cm^3	11.7	5.76	4.06		4.05	
Fraction Open Cells, %						
Plane XY	5.9		0.9		2.4

Cellular Cross-Section, 10^{-3} cm^2						
Plane XY	4.75	1.15	1.40	0.275	1.55	0.513
Plane XZ	5.06	1.27	2.25	0.421	2.67	0.511
Plane YZ	3.24	1.18	2.59	0.471	2.10	0.529
Axial Dimensions, μm						
X Axis	247	490	123	210	153	249
Y Axis	224	376	142	220	120	245
Z Axis	338	478	227	340	207	278
Axial Ratios						
Z/X	1.37	0.98	1.85	1.62	1.35	1.12
Z/Y	1.51	1.27	1.60	1.55	1.72	1.13
X/Y	1.10	1.30	0.87	0.95	1.28	1.02

seen later, the essential quantities in the predictive procedures are the axial ratios. These ratios, computed using GCP and optical data, are in reasonable agreement.

Cell-gas analysis - An important component of thermal conductivity of closed-cell foams is gas conduction. The composition of the gas in the cells was determined in order to allow this component of the apparent conductivity to be assessed. Gas samples were obtained using the system shown in figure 5. The procedure was as follows: (1) A 3.5 cm^3 specimen was placed in the crushing device (fig. 5b) and sealed using an indium ring. (2) The crusher was attached to the purge system (fig. 5a). (3) System pressure was reduced to 50 kPa absolute followed by a helium-gas backfill to 115 kPa. This step was repeated 20

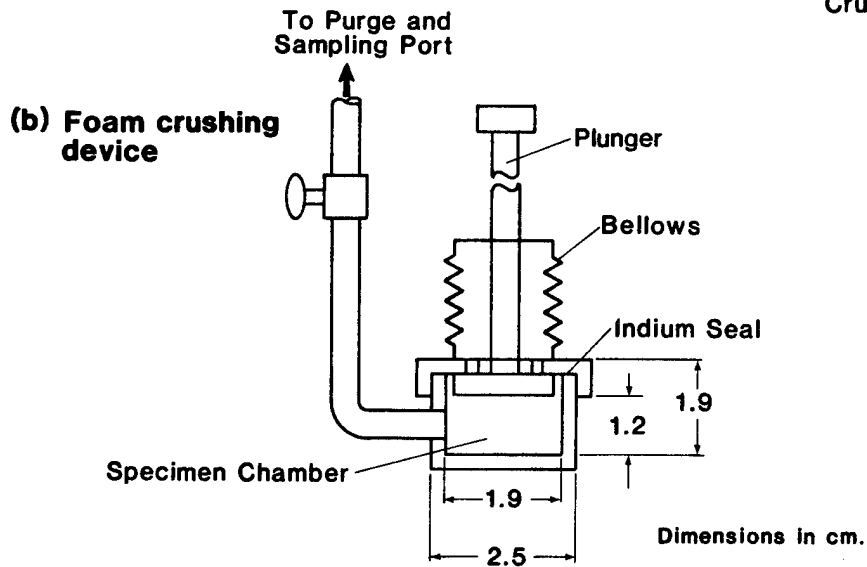

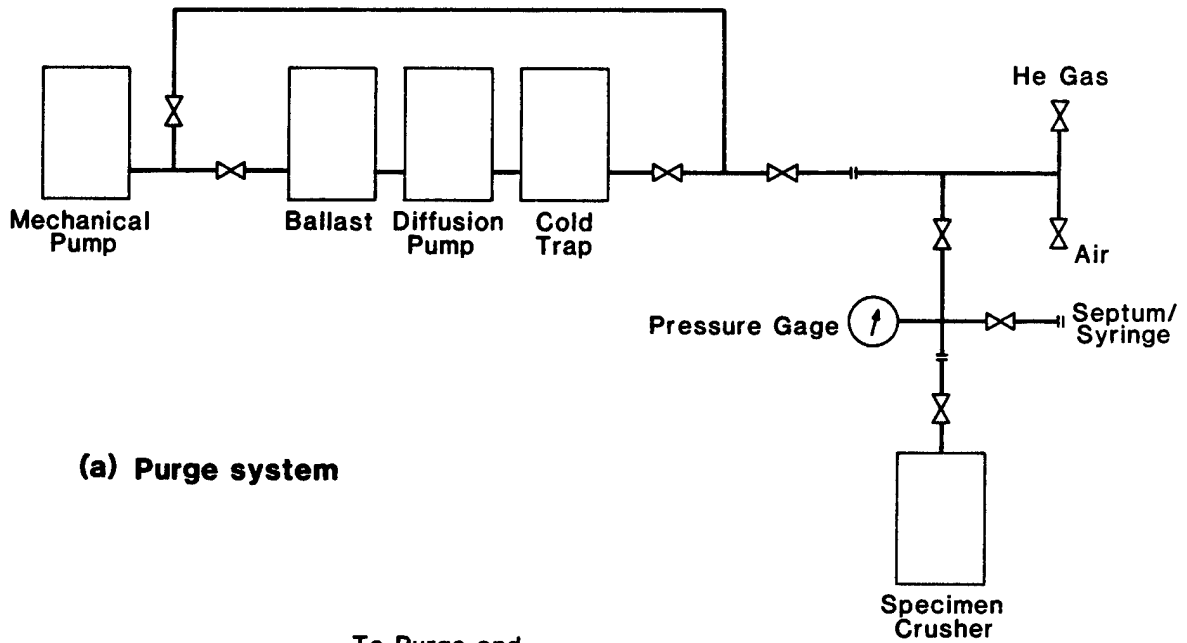

Figure 5. Schematic of the system used to obtain samples of cell gas from fluorocarbon blown polyurethane foams.

times and resulted in an air content, external to the foam, of 1 ppm.

(4) Crusher and foam were cooled to liquid nitrogen temperature and the plunger depressed. The brittle foam specimens were reduced to a compacted powder assuring that essentially all cells had been fractured. (5) A gas specimen was drawn into a gas-tight syringe and inserted into the analysis system. Steps (1) through (5) were repeated on four specimens from each of the three polyurethane foams.

The analysis system consisted of a gas chromatograph column with a mass-spectrometer detector (Barkley, 1983). The averaged results of the analysis are shown in table 5.

Table 5. Cell-gas composition of PU32, PU64, and PU96 (Barkley, 1983). One standard deviation for the CCl_3F contents is $\pm 10\%$.

Thermal conductivity - The apparatus used to make the thermal conductivity (k) measurements is shown schematically in figures 6 and 7. The path of the

Figure 6. Schematic of the guarded-hot-plate thermal conductivity apparatus.

Figure 7. Schematic of guarded-hot-plate specimen configuration and environmental chamber

cooling fluid is shown in figure 6 and the details of the specimen configuration are shown in figure 7. This type of system is commonly known as a guarded-hot-plate and is described in the American Society for Testing and Materials Standard C177 (ASTM, C177). This method allows an absolute determination of k and is considered to be the most accurate method available for insulations. The particular apparatus used to make the k measurements reported here is described by Smith, Hust, and Van Poolen (1981); a very brief description is included below.

The basic operation of this type of apparatus involves supplying a measured amount of power, Q , from the main heater plate to the two specimens (fig. 7) and measuring the resulting steady-state temperature differences across the specimens. The thermal conductivity is then given by

$$k = \frac{\Delta X}{2A} \cdot \frac{Q}{\Delta T} \quad (1)$$

where ΔX is the sample thickness, A is the area of the metered section of the main heater plate, and ΔT is the steady-state mean temperature difference across the specimens. The absolute temperatures and temperature differences are measured with type K thermocouples.

The accuracy of the k results is dependent on the accuracy of measurement of the parameters shown in eq (1) and on establishment of unidirectional (vertical in this case) heat flow in the metered area of the specimens. The inner-guard heater plate is controlled at the temperature of the main heater in order to minimize radial heat flow in the metered area. Somers and Cyphers (1951) and ASTM C177 indicate that when the diameter-to-thickness ratio of a specimen is greater than four, the errors in k due to edge losses should be less than 1%. The metered diameter of the foam specimens was 10.2 cm and the thickness was 2.54 cm.

The most difficult parameter to determine is the specimen temperature difference (ΔT); ΔT averaged 10 K for PU32 and 25 K for PU64 and PU96. The

correctness of ΔT measurements depends on plate-to-specimen thermal contact, on unidirectional heat flow, and on thermocouple calibration and referencing sources of error. The diverse materials which can be tested in this type of system cause a wide range of plate-to-specimen contact situations. Tye and Spinney (1976) found that embedding the thermocouple wires in the specimen, as opposed to the measuring plates, resulted in higher calculated conductivities. This effect is due to better specimen-to-thermocouple contact which results in smaller measured ΔT and larger k (eq (1)). They also found that the effect of thermocouple placement was dependent on the conductivity of the specimens. As the conductivity of the specimen increases, the relative effect of an air gap in the specimen-to-plate interface becomes larger.

Thermocouple placement used in obtaining the data reported below consisted of cementing the wires into machined grooves in the measuring plates (plates adjacent to the specimens shown in figure 7) so that the thermocouples were flush with the plate surfaces.

The accuracy of measurements made with this system on fiberglass and fiberboard reference materials is discussed by Smith, Hust, and Van Poolen (1981). In a qualitative sense the plate-to-specimen contact should be similar for low-density foams and the fibrous materials tested by Smith, et al. Based on the percentage errors given by Smith, et al. for each parameter in eq (1) and the magnitude of these parameters for the PU foam experiments, uncertainties in the PU foam data (k) are estimated to be 0.2 mW/m·K random and 0.4 mW/m·K systematic near room temperature; near 80 K the random and systematic components are 0.1 mK/m·K.

The specimen environment throughout the testing period was dry-nitrogen gas. The gas surrounding the specimen was maintained at a slight positive pressure of 260 to 660 Pa (2 to 5 mm Hg) relative to atmospheric pressure. The plate emittance was 0.82.

Thermal conductivity as a function of temperature is shown in tables 6 and 7 and in figure 8. Each number given in tables 6 and 7 represents an average of three or more determinations of $k(T)$; the determinations were separated by a minimum of 15 minutes.

Thermal expansion - The apparatus used to make the thermal expansion measurements presented below was developed to allow large specimens, which may be inhomogeneous and/or anisotropic, to be studied.

A schematic of the dilatometer is shown in figure 9. Operation of the system involves reflecting a laser-light beam onto a mirror inside the environmental chamber. The mirror is balanced on tripod fulcrum points with two points resting on a reference material and one point on the specimen. As the relative lengths of the reference and specimen materials change with temperature, inclination of the mirror changes and the reflected beam is deflected. The beam deflection is sensed with a photocell. This deflection can be related to the relative change in lengths of the specimen and reference materials.

The invar hang rods, which support the specimen-reference-mirror group, change length as the system temperature profile changes. Small corrections based on temperature measurements along their length are made in the analysis of the

Figure 9. Schematic of dilatometer developed for inhomogeneous, anisotropic materials.

data. A small correction due to the temperature dependent change in length of the reflecting mirror is also made.

The thermal environment is established by balancing joule heating from an electrical heater surrounding the specimen-reference-mirror group and refrigeration obtained from either liquid nitrogen or liquid helium in the cryogen dewar (fig. 9). The electrical heater, not shown in this figure, is wrapped on a right-elliptical cylinder made of 1/8 inch copper and situated around, but not touching, the specimen or reference. Temperatures along the length of the 10 cm specimen can be maintained within a few millidegrees for a minimum of an hour.

The results of a calibration test using two reference materials, OFHC copper (Kirby and Hahn, 1975) and fused-silica (Kirby and Hahn, 1971), indicate that the total error in measuring the thermal expansion of OFHC copper relative to that of fused silica was $\pm 5 \mu\text{m}$ for a 10 cm OFHC specimen. The 2σ random error for this calibration was $\pm 3 \mu\text{m}$.

Experimental values of thermal expansion for the polyurethane foams are shown in figures 10, 11, and 12. Discrete points represent the experimental data and the solid curves result from three-term, second-order polynomial fits to these points. The reference material was OFHC copper in the tests on PU32 and PU96, and fused-silica in the tests on PU64.

Polynomial coefficients, obtained by least squares, are listed in table 8. The polynomials are of the form

$$\Delta L/L = \sum_{i=1}^3 A_i T^{(i-1)} \quad (2)$$

Figure 10. Thermal expansion of a 32-kg/m³ polyurethane foam specimen. Experimental data are represented by discrete points and the solid line represents a three-term polynomial fit to these data. The reference temperature is 281.997 K.

Figure 11. Thermal expansion of a 54-kg/m³ polyurethane foam specimen. Experimental data are represented by discrete points and the solid line represents a three-term polynomial fit to these data. The reference temperature is 295.180 K

Figure 12. Thermal expansion of a 96-kg/m³ polyurethane foam specimen. Experimental data are represented by discrete points and the solid line represents a three-term polynomial fit to these data. The reference temperature is 292.227 K.

Table 8. Polynomial coefficients representing the measured thermal expansion of 32-, 64-, and 96-kg/m³ polyurethane foams. Reference temperature is 293 K.

Coefficient	PU32	PU64	PU96
A ₁	-1.1825396 x 10 ⁻²	-1.1348273 x 10 ⁻²	-1.1727014 x 10 ⁻²
A ₂	1.0877846 x 10 ⁻⁵	2.3112134 x 10 ⁻⁵	1.4204079 x 10 ⁻⁵
A ₃	1.0062071 x 10 ⁻⁷	5.3307753 x 10 ⁻⁸	8.8122390 x 10 ⁻⁸

The constant terms, A₁, have been algebraically shifted to reference the fitted data to 293 K. Adjustments to the original constant coefficients were -7.56 x 10⁻⁴, 1.19 x 10⁻⁴, and -5.09 x 10⁻⁵ for PU32, PU64, and PU96 respectively.

The coefficient of thermal expansion (CTE) is given as the temperature derivative of Delta L/L and is of the form

$$CTE = \sum_{i=1}^3 (i-1) A_i T^{(i-2)} \quad (3)$$

Tabulated values of Delta L/L and CTE, obtained using eqs (2) and (3) and the appropriate coefficients from table 8, are given in tables 9, 10, and 11.

Composite curves of Delta L/L and CTE for the three foams are given in figures 13 and 14.

Mechanical properties - The tensile, compressive, and shear properties of the polyurethane foams were determined using the test fixtures shown in figure 15. These fixtures consist of concentric overlapping cylinders and operate on the principle that capacitance between the cylinders changes as a function of overlapping areas (Reed, Arvidson, and Durcholz, 1973). The systems were specifically developed for use with soft viscoelastic materials such as expanded plastic foams.

This type of extensometer does not attach directly to the specimen so that the effect of instrumentation on the experimental results is negligible. The extensometer works well in cryogenic environments and is linear for large strains (Roberts, Herring, and Hartman, 1968 and NASA, 1975). The capacitance extensometer system had a linearity range in excess of 2.5 cm when used with the tensile specimens shown in figure 15 (5.1 cm diameter by 10.2 cm long). These specimen geometries were used to determine all tensile properties. Foam cylinders, epoxied to polycarbonate grip ends, 9.9 cm in length and 2.9 cm in diameter were used to determine Young's modulus, proportional limit, yield strength, and elongation. Reduced-section specimens with gage lengths of approximately 5.1 cm, and 1.9 cm in diameter, were used to determine ultimate tensile strength. This geometry forced failure to occur within the gage length, thus avoiding a premature failure elsewhere due to biaxial stresses at the epoxied polycarbonate grips.

The compression specimens were rods 2.54 cm long and 2.54 cm in diameter. No grips were required for these specimens and therefore all compressive material properties were determined using this geometry.

The shear specimens, 1.9 x 2.54 x 0.4 cm, were epoxied to flat plates and each plate was attached to the tensile pull-rod system. An aluminum cylinder with a built-in resistive heater and thermocouple was slipped over the specimen plates and used for temperature control and alignment during the tests.

Tests were conducted at 295 K (air), 111 K (nitrogen gas), 76 K (liquid nitrogen), and 4 K (liquid helium). A minimum of three samples were tested at each temperature, and in some cases several more were tested to determine material variability. Minimization of thermal shock to the sample was accomplished by using very slow transfer rates of liquid helium or nitrogen. A given test temperature was held for a minimum of 15 minutes prior to testing, in order to ensure that the specimen was isothermal.

Each specimen was conditioned in an environmental chamber for at least four days at 23 °C and 50 percent relative humidity prior to testing. Tension, compression, and shear tests were conducted using a conventional tension/compression test machine at a strain rate of $5 \times 10^{-3} \text{ min}^{-1}$. Preliminary tests indicated that there was no measurable effect on the mechanical properties due to varying the strain rate from 5×10^{-2} to $5 \times 10^{-4} \text{ min}^{-1}$.

The results are presented in tables 12 through 20 and in figures 16 through 40. The error bars on the figures show the data spread from repeated tests. Scatter is typically higher for compression and shear tests than for tensile tests, since the former tests are more sensitive to misalignment. Two orientations, longitudinal and transverse, are designated in the data. These orientations are relative to the axes of the bulk supplies, with longitudinal being parallel to the z-axis and transverse being parallel to the y-axis (fig. 2).

Discussion of Results and Modeling

Thermal Conductivity - Heat is conducted through a foamed material via solid and gaseous conduction, by radiation, and by convection. Skochdopole (1961) has shown that convective heat transfer will not occur in cells whose dimensions are less than 3 mm. The cells of undamaged polyurethane foam with density of 32 kg/m³ or greater are at least a factor of three smaller than this threshold size. The foams studied here have cell dimensions smaller than 0.5 mm (see table 1). The convective mode will therefore be ignored in the remaining discussion. It is important to keep in mind that if cracks develop in the foam, either due to thermal or mechanical stresses or debonding, convection can become a dominant mode of heat transfer.

Radiant heat flow through foam insulation is due to both transmission and to absorption and reradiation. Resins used for making foams are partially transparent in the 2 to 30 μm range of wavelengths (Skochdopole, 1961). Sections associated with thermal insulations are normally optically thick (thickness \gg photon mean free path), however, so that direct transmission will

be small. The effective conductivity due to radiant heat transfer (k_r) can be estimated by

$$k_r = 4 \sigma e \lambda T^3 \quad (4)$$

where σ is the Stefan-Boltzman constant ($5.67 \times 10^{-8} \text{ W}\cdot\text{m}^{-2} \text{ K}^{-4}$), e is the emissivity of foam, λ is the cell dimension parallel to heat flow, and T is the temperature of the warmer side of the specimen.

Solid conduction (k_s) takes place through the cell walls and membranes of the foam. Since PU resins are disordered (noncrystalline) insulators, heat is transported by lattice vibrations (phonons) and is nearly a linear function of temperature. The relationships describing the solid conductivity of the foams tested here are

$$\begin{aligned} k_s &= 0.90 + 0.0190 T && \text{for PU32,} \\ k_s &= 3.08 + 0.0172 T && \text{for PU64,} \\ \text{and } k_s &= 4.36 + 0.0278 T && \text{for PU96.} \end{aligned} \quad (5)$$

Temperature is in kelvin and thermal conductivity in $\text{mW}/\text{m}\cdot\text{K}$. The steric factors, which arise due to elongation of cell axes parallel to the direction of heat flow, are included in these relationships by virtue of their experimental basis.

The remaining mode of heat transfer is conduction through the gas (k_g) occupying the foam cells. Figure 41 indicates the conductivity of gases sometimes found in insulating foams. When a mixture of gases is present, k_g can be estimated by

$$k_g = k_{\text{mixture}} = \sum_{i=1}^n X_i k_i \quad (6)$$

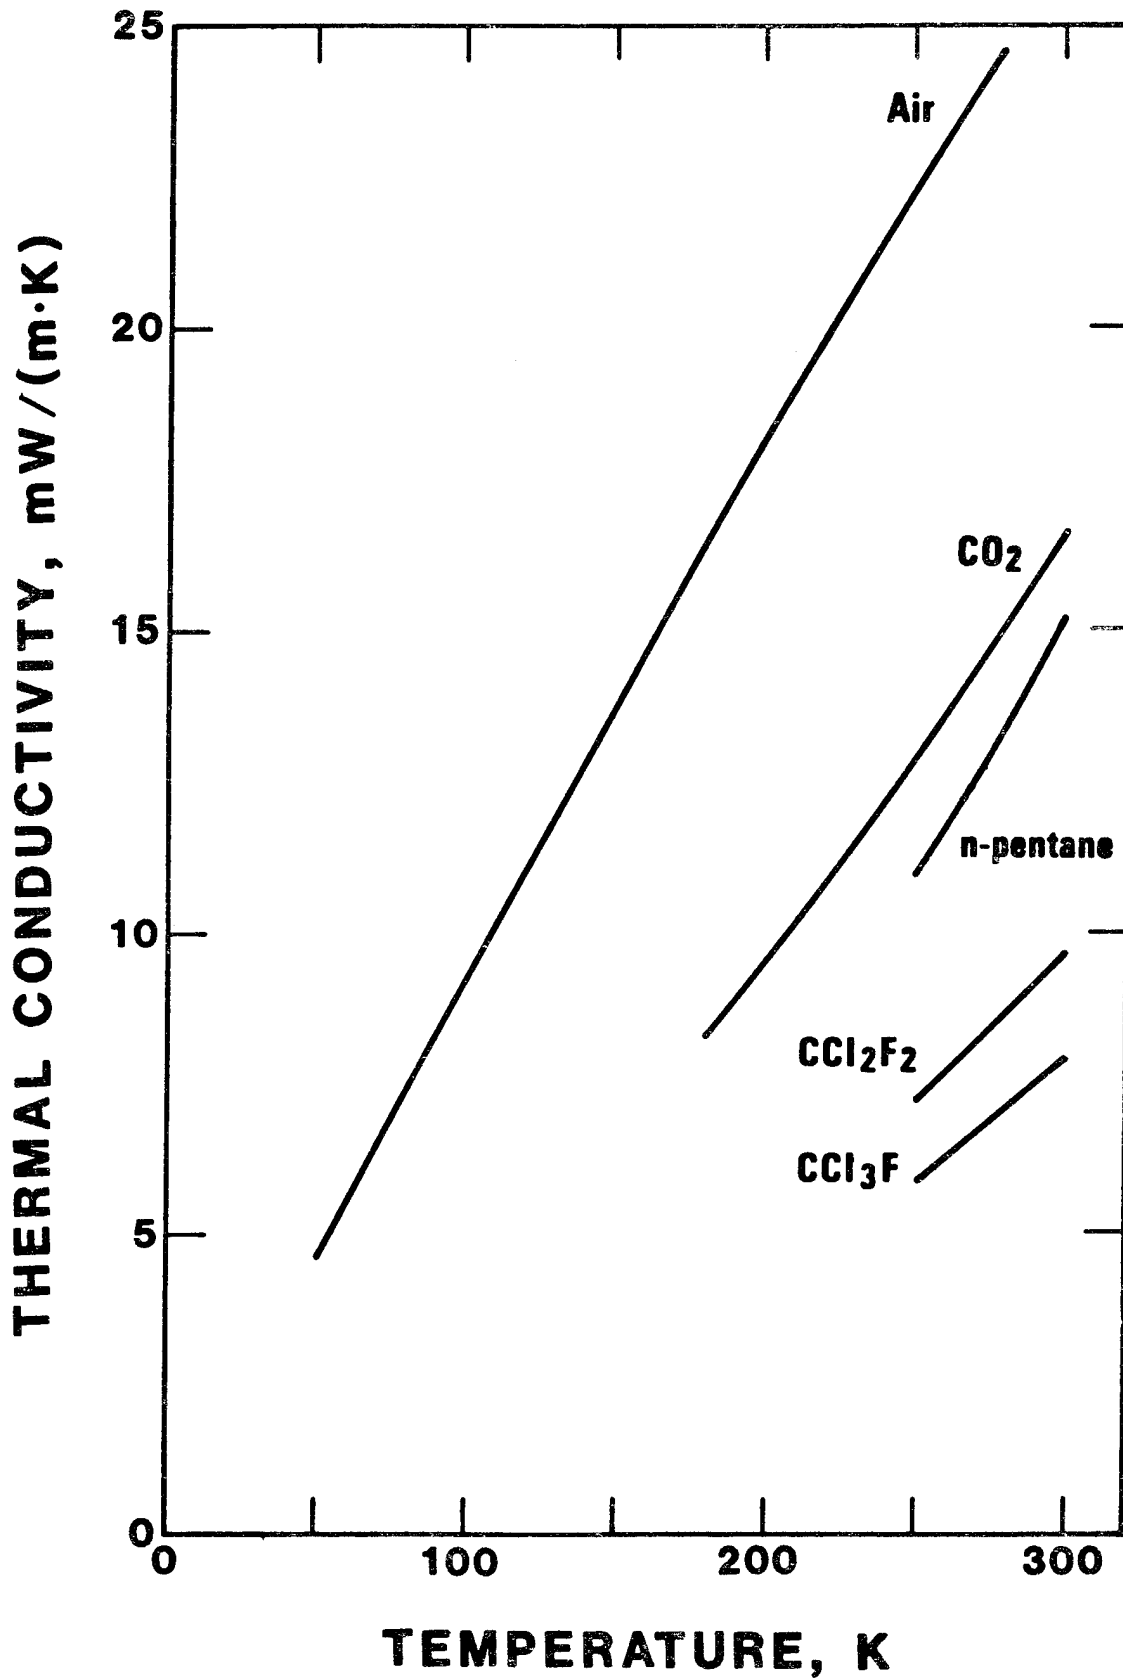

Figure 41. Thermal conductivity as a function of temperature for gases commonly found in polyurethane foams (Touloukian, Liley, and Saxena, 1970).

where thermal conductivities of the individual species are given by k_j , X_j represents the corresponding mole fraction, and n is the number of species present. The k_j are temperature dependent and, as seen in figure 41, are nearly linear functions of temperature. The gases present in PU32, PU64, and PU96 are CCl_3F and air. Their conductivities can be approximated by (Touloukian, Liley, and Saxena, 1970)

$$k_{CCl_3F} = - 4.1 + 0.04 T, \quad 250 \leq T \leq 300 \text{ K} \quad (7)$$

$$k_{air} = - 0.661 + 0.103 T - 0.469 \times 10^{-4} T^2, \quad 100 \leq T \leq 350 \text{ K}$$

in units of $mW/m \cdot K$. Total gas conduction is given by

$$k_g = X_{CCl_3F} k_{CCl_3F} + (1 - X_{CCl_3F}) k_{air} \quad (8)$$

Harding (1964) indicates that the values predicted by this simple molar mixing approach tend to be slightly higher than those computed using kinetic theory (Tsederberg, 1965).

Although it is not rigorously correct to add the modes of heat transfer (they are not independent of one another), the total apparent conductivity (k_T) obtained using this approximation is acceptable for polyurethane foams (Gorring and Churchill, 1961).

$$k_T = k_g + k_s + k_r \quad (9)$$

For temperatures near ambient, only gases exist in the cells and k_T can be estimated using eqs (4), (5), (8), and (9) when X_{CCl_3F} is known. If partial pressures are also known at T_i , eqs (10) and (11) can be used to determine X_{CCl_3F} . The ratio of partial pressure to absolute temperature (eq 10) is constant for each species to the extent that they approximate ideal gases.

$$P_{CCl_3F,T} = P_{CCl_3F,T_i} (T)/T_i, \quad T > T_c \quad (10)$$

$$P_{air,T} = P_{air,T_i} (T)/T_i, \quad T > 100 \text{ K}$$

and

$$X_{CCl_3F,T} = P_{CCl_3F,T} / (P_{CCl_3F,T} + P_{air,T}) \quad (11)$$

At temperatures less than or equal to T_c condensation of CCl_3F occurs and the partial pressure of CCl_3F is given by

$$P_v = P_{CCl_3F} = 8.0875 \times 10^6 / \exp(3340.4/T), \quad T \leq T_c \quad (12)$$

where T is in K and pressure is in kPa (the saturated vapor pressure is more accurately given by a complex relationship in Du Pont, 1979). The temperature of initial liquid vapor equilibrium for CCl_3F (T_c) is indicated by the inflection in thermal conductivity at $T_c = 278$ K, $= 275$ K, and $= 245$ K for PU32, PU64, and PU96, respectively (fig. 8).

The equations given above and the thermal conductivity data were used to independently determine the cellular gas content of PU32, PU64, and PU96 (table 5). Results of the calculations are shown in table 21. The components of the total apparent thermal conductivity were calculated using the relationships given here and are also shown in this table. Comparison of the computed conductivities to the experimentally observed values indicates that the relationships for k_s , k_r , and k_g apply quite well to PU32, PU64, and PU96.

Thermal expansion - Little low-temperature data exists in the literature for Delta L/L or CTE of polyurethane. Materials which have been tested are generally characterized by a nominal density and sometimes a tradename. Comparison of the current values to the existing data base indicates that Delta L/L at 105 K for PU32, PU64, and PU96 fall near the median with a band of approximately $\pm 20\%$ needed to include all of the literature values. A more quantitative comparison is not justified considering the variation of materials involved.

The diagram shown in figure 42 indicates the parameters that can affect the expansion characteristics. Although not indicated in the diagram, none of the

Figure 42. Parameters affecting the measured thermal expansion of expanded plastic foams.

parameters are independent of one another, e.g., the blowing agent will dissolve in the resin to some extent and will alter the resin chemistry. Viscosity will also be affected by dissolved gases and will, in turn, affect the cellular morphology. It is instructive, however, to consider the effect of these parameters on the observed results for PU32, PU64, and PU96.

The detailed chemical makeup of the materials is proprietary information and is not known to these authors. Each is a polyether-based material but the specific isocyanate is not known. PU32 and PU64 were foamed as continuous buns having unrestricted freedom to rise. PU96 was poured in a form which also allowed unrestricted rise. Additives such as fire retardants, elasticizers, surfactants, and coloring agents are unknown as are formulation temperatures. Each of these items can affect the chemistry and/or molecular linkages and therefore the expansion characteristics. Each variable will affect the cell structure, however, so that the net effect of resin chemistry is reflected in the cell morphology and strength properties. As will be shown below, the expansion characteristics of the resins can be calculated. In spite of all foams being polyether based and expanded with fluorocarbon, thermal strains in the three lattices differ significantly.

The difference between the changing internal pressure and the external pressure define a temperature dependent stress on the foam. Internal pressures were computed using the procedure discussed under thermal conductivity and are tabulated in table 22. The experimental external pressures were 89.3 kPa for PU32 and PU96, and 84.0 kPa for PU64. Compressive Young's modulus, E_c , (Arvidson and Sparks, 1981; Arvidson, Sparks, and Guobang, 1983; and Arvidson, Bell, Sparks, and Guobang, 1983) and this pressure stress can be used to compute a strain. These computed strains are parallel to the direction of the experimental determinations and are tabulated in table 22. The uncertainty of the calculated

Table 22. Pressure-induced strain parallel to the measurement direction calculated as a function of internal and external pressures and Young's moduli (longitudinal). External pressures were 89.3 kPa for PU32 and PU96, and 84.0 kPa for PU64.

pressure-induced strains cannot be determined from available data. Straight-line behavior of E_C (figs. 19, 26, and 34) was assumed in the temperature range from 100 to 293 K. Deviations from this behavior could be significant, especially at temperatures far from the experimental data.

The difference between the experimentally observed contractions and the pressure-induced strain is the thermal contraction of the resin. These computed values are tabulated in table 23. If the pressure stress given in table 22 is applied to the foam in the transverse orientation, i.e., the transverse Young's modulus is used, the pressure-induced strain in this orientation can be computed. A value for the total transverse apparent thermal contraction can then be calculated by summing the resin component and transverse pressure induced strain. These values are also given in table 23. Figure 43 shows the comparative values of longitudinal (experimental) and transverse (calculated) thermal expansion. The effect of using a straight line approximation to Young's modulus at higher temperatures is to overestimate the pressure-induced strain and thereby cause the predicted values of resin contraction to be smaller than they actually are. The slightly positive values for resin contraction of PU32 at 250 and 240 K are thought to be caused by this approximation.

Thermal expansion of the resin as a function of density with temperature as a parameter is shown in figure 44. Resin expansion as a function of temperature can be determined from this family of curves for densities between 32 and 96 kg/m³. The second component making up the observed thermal expansion is that caused by pressure-induced strain. This strain can be estimated from a knowledge of internal gas pressure, external gas pressure, and E_C . The internal gas pressure can be computed, as discussed in the thermal conductivity section, when the partial pressures are known. The compressive Young's modulus is discussed below.

Mechanical properties - The strength properties near room temperature are traditionally represented by equations of the form

$$\text{strength property} = A\rho^B \quad (13)$$

which is equivalent to

$$\log(\text{strength property}) = A' + B \log(\text{density})$$

(Hilyard and Young, 1982; DuPont, 1979). DeGisi and Neet (1976) found that $B = 1.75$ for both compressive strength and modulus, and that A' ($A' = \log A$) was a linear function of temperature. Their formulation was limited to $T \geq 298$ K for strength and $T \geq 219$ K for modulus for materials in the density range 153 to 392 kg/m³. Cell size and orientation were not considered in developing their empirical relationship. Menges and Knipschild (1982) present several theoretical developments for strength properties based on various assumptions concerning cell shape and orientations. None, however, have addressed developing relationships describing the strength behavior of foams as functions of temperature at cryogenic temperatures. The strength data and the characterization of cell size and shape reported here was intended to allow this possibility to be explored. A model, based on fundamentals and the current data and which would allow predictive capabilities for the mechanical properties, has not yet been established. The behavior of the compressive Young's modulus (figs. 19 and 26) and the tensile strength (figs. 24 and 31) in the temperature range 76 to 111 K was particularly difficult to incorporate into a model based on current understanding. An entirely empirical approach to establishing a predictive capability was therefore adopted. As is the case with all such relationships, the extent of its applicability to other polyurethane foams will be established through experience. Figures 45 through 48, eq (14), the height-to-width ratio of the foam cells (H/W), and the foam density can be used to estimate average moduli and strength in

Figure 45. Young's modulus of polyurethane foam in tension as a function of density with temperature as the parameter. The modulus obtained here must be modified by a function of (H/W) for a specific material.

Figure 46. Strength of polyurethane foams in tension as a function of density with temperature as the parameter. Strength obtained here must be modified by a function of (H/W) for a specific material.

Figure 47. Young's modulus of polyurethane foam in compression as a function of density with temperature as the parameter. The modulus obtained here must be modified by a function of (H/W) for a specific material.

Figure 48. Compressive strength of polyurethane foam as a function of density with temperature as the parameter. The strength obtained here must be modified by a function of (H/W) for a particular material.

tension and compression. The temperature range is 76 to 295 K and the density range is 32 to 96 kg/m³. DeGisi and Neet (1976) found that crosslink density, urethane to urea bond ratio, and type of isocyanate had no significant effect at temperatures below about 350 K.

Factors for the direction of stress relative to the elongated cell axis are

$$F(\text{longitudinal}) = 1/2 \{ [0.6 + 0.15 (H/W)]^{-1} + (H/W) \} \quad (14)$$

$$F(\text{transverse}) = 1/2 [0.85 - 0.1 (H/W) + (H/W)^{-1}]$$

The temperature dependent values at a particular density, from figures 45 through 48, must be multiplied by this factor. This procedure produces values for the strength properties that are generally within $\pm 20\%$ of the NBS experimental data.

Major Achievements (IF)

The low temperature data base for polyurethane foams has been significantly improved with the addition of the data generated by this effort. These data are unique in that they include all basic thermophysical properties of interest to insulation users, and they are related to materials whose morphologies are also known. The materials used span the range of densities usually considered for thermal insulation applications.

Empirical relationships and procedures were developed for predicting the thermophysical properties of polyurethane foams at low temperatures. A minimum of information, which is relatively easy to acquire, is needed to use with these procedures.

Testing procedures for use on viscoelastic materials were refined. These procedures could be adopted for general use in lieu of standard procedures which are not intended for use at low temperatures. Revised standard procedures are, of course, the ultimate goal in this area. A basis and need has been established for standard materials as well as procedures.

Major Technical Problems (IF)

Three areas presented technical problems which persisted to the end of the program and had significant impact on the results: meaningful characterization of materials, material variability, and anomalous behavior of the physical properties.

The materials studied were obtained from commercial producers because of the experience and expertise required to produce well designed foams. The chemical composition and foaming parameters were proprietary and in essence, only the polyether base could be determined. The characterization technique which best addressed our needs was statistical evaluation of photomicrographs. This procedure is time consuming, and an extreme effort is required to obtain sufficient data for statistical characterization.

Material variability was high for all materials; the concomitant uncertainties can only be assessed by large numbers of repeat measurements. Time and funding caused compromises in this area. The variabilities themselves are of interest since they reflect what a user must expect in batch lots of foam.

The physical property data are complicated at cryogenic temperatures. Modeling based on fundamentals was not possible due, in part, to unexplained temperature effects.

Conclusions (IF)

Thermophysical properties of foams at low temperatures are functions of temperature, cell morphology, and gas content. Empirical procedures have been developed which allow predictions of thermal conductivity, thermal expansion, and tensile and compressive properties at low temperatures for a range of densities. Parameters which must be determined in order to make use of these procedures are indicated in table 24. The empirical procedures are based on the results for three particular polyurethane foams. Application to other polyurethane foams must be evaluated.

Table 24. Parameters needed to estimate the thermophysical properties of polyurethane foams as a function of temperature.

INSULATING CONCRETES

Overall Project Objective (IC)

There are four immediate objectives for the insulating concrete effort:

- (1) To collect information on commercially available insulating concretes.
- (2) To evaluate existing data to determine applicability of test methods, quality of data, and fitness-for-service of insulating concretes.
- (3) To perform thermal and mechanical property screening tests on selected materials.
- (4) To select one or more of the available materials for further testing.

The ultimate objective of the insulating concrete project is to supply the LNG industry with the data base needed to incorporate one or more of the insulating concretes into plant design.

Project Description (IC)

A literature search designed to reveal information from past research on insulating concretes was done. This effort was initiated by a computerized search in the following data bases: COMPENDEX, INSPEC, NTIS, and SSIE (further information in reference section under Data bases). The references cited in the computer identified papers were also selectively collected.

Screening tests performed at NBS to supplement the literature survey consisted of measuring the thermal conductivity of five candidate types and the modulus of rupture and the compressive strength of four candidate types of concretes. The materials were supplied by three private companies and Brookhaven National Laboratory (BNL).

In addition to the information collected from the literature and the screening tests, discussions with users and producers of insulating concretes were also of value in evaluating these materials. The interest generated by this survey for polymer based materials resulted largely from these discussions.

Project Rationale and Projected Benefits (IC)

Increased use of LNG and other liquid fuels along with more stringent safety regulations, i.e., Congressional Record 193.2059 (Federal Register, 1980) entitled Flammable Vapor-Gas Dispersion Protection, have created a need for an inexpensive, abundant material to be used in the construction of storage tank dikes and basins. One or more of the insulating concretes could be developed to fill the gap existing between the properties of good insulators, such as expanded plastics, and natural materials, such as sand/soil/rock. The general attributes needed for the dike/basin application include a reasonable degree of impermeability to water and liquid fuels, mechanical strength to support service vehicles, long unattended lifetime, ease of installation, material integrity when subjected to thermal shock, a relatively low thermal conductivity, and a relatively low cost. Once developed, use of a material with these attributes will almost certainly not be limited to dike construction.

Insulating concrete is common in the construction industry at the present time and several commercially produced products are available. The primary applications are roof insulations, firewalls, and air conduits. The engineering data developed for these purposes is not sufficient for design of cryogenic fuel storage installations.

The benefits of developing and using such a material are enormous both from the standpoint of safety and efficient land utilization. Insulated dike/basin areas would allow new tanks to be sited in populated areas, i.e., near the users, and in the event of a catastrophic tank failure and fire, would minimize both loss of life and property damage.

TECHNICAL DISCUSSION (IC)

Work Plan (IC)

Three sources of information were available for assessing insulating concretes: open literature, industry files and experience, and new experimental data. The literature search and discussions with industry were to be concurrent and last from beginning to end of the effort. The experimental portion was designed to fill in gaps in information from the other sources. Three screening tests, thermal conductivity, modulus of rupture, and compressive strength were selected. The mechanical tests were to be done at 76 and 300 K. Based on all information available at the end of the survey period, a recommendation was to be made regarding materials and further research.

Work Performed and Results (IC)

The literature search resulted in 301 hard copies and microfiche. Of these, approximately 30 contained data which could be used directly to evaluate and select materials for use in dikes and impounding areas. The number of references containing data for low temperatures is even more restricted. Annotated bibliographies have been prepared for nine of the technical papers: expanded shale-portland cement (Monfore and Lentz, 1962; Lentz and Monfore, 1965), vermiculite-, perlite-, or polystyrene-portland cement (Adams, 1969; Reid and Wang, 1978; Reid, 1980), cellular-portland cement (Richard, Dobogai, Gerbardt, and Young, 1975; Richard, 1977), polymer matrix (Lang, Moorhouse, and Paul, 1980; McClune and Moorhouse, 1981). These bibliographies follow the References (IC) section. The remaining sources are given in the References (IC) section. The information contained in these papers is of a general interest nature. It was not possible to group these diverse papers into meaningful sets so titles were included in the references and can be used as guidelines to the paper's contents. Data from the literature search are shown in figures 49 through 52.

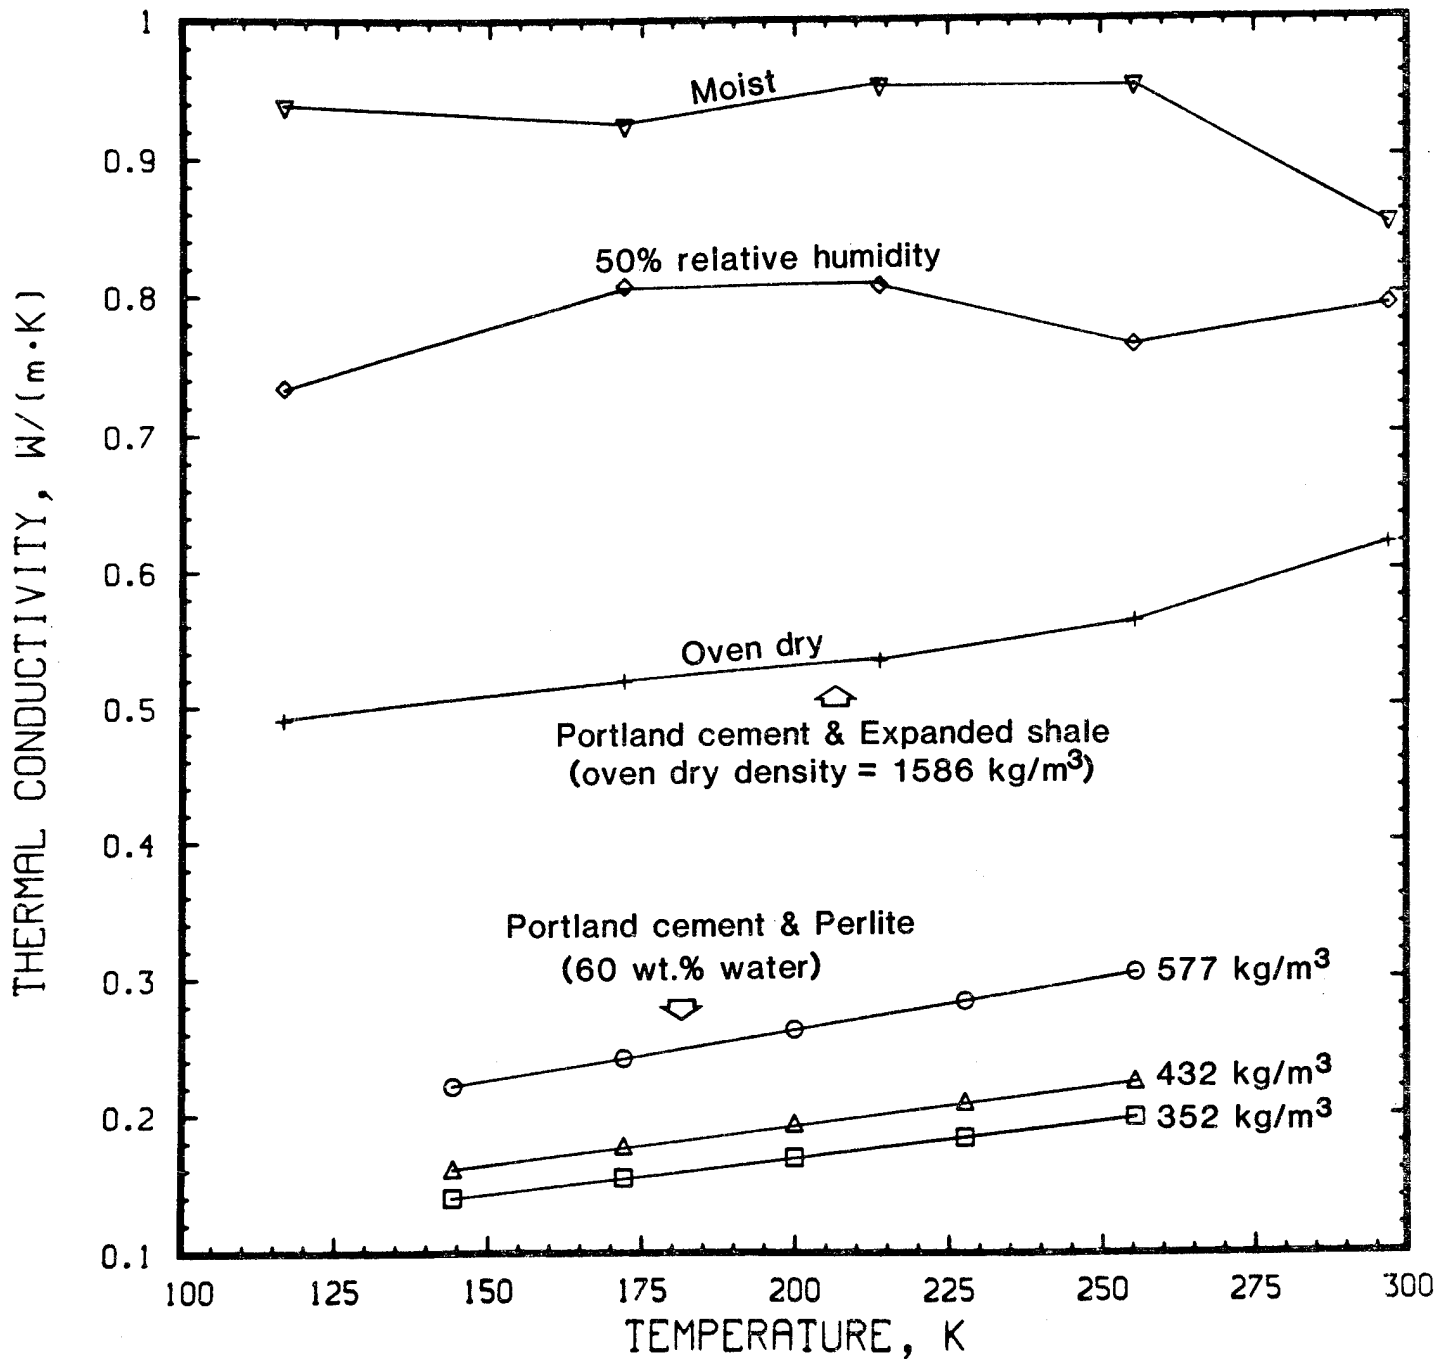

Figure 49. Thermal conductivity as a function of temperature with moisture content (Lentz and Monfore, 1965) and density (Adams, 1969) as parameters.

Figure 50. Splitting strength as a function of temperature for an expanded shale concrete with density of 1554 kg/m^3 (Monfore and Lentz, 1962)

Figure 51. Compressive Young's modulus as a function of temperature for an expanded shale concrete of density 1554 kg/m^3 (Monfore and Lentz, 1962).

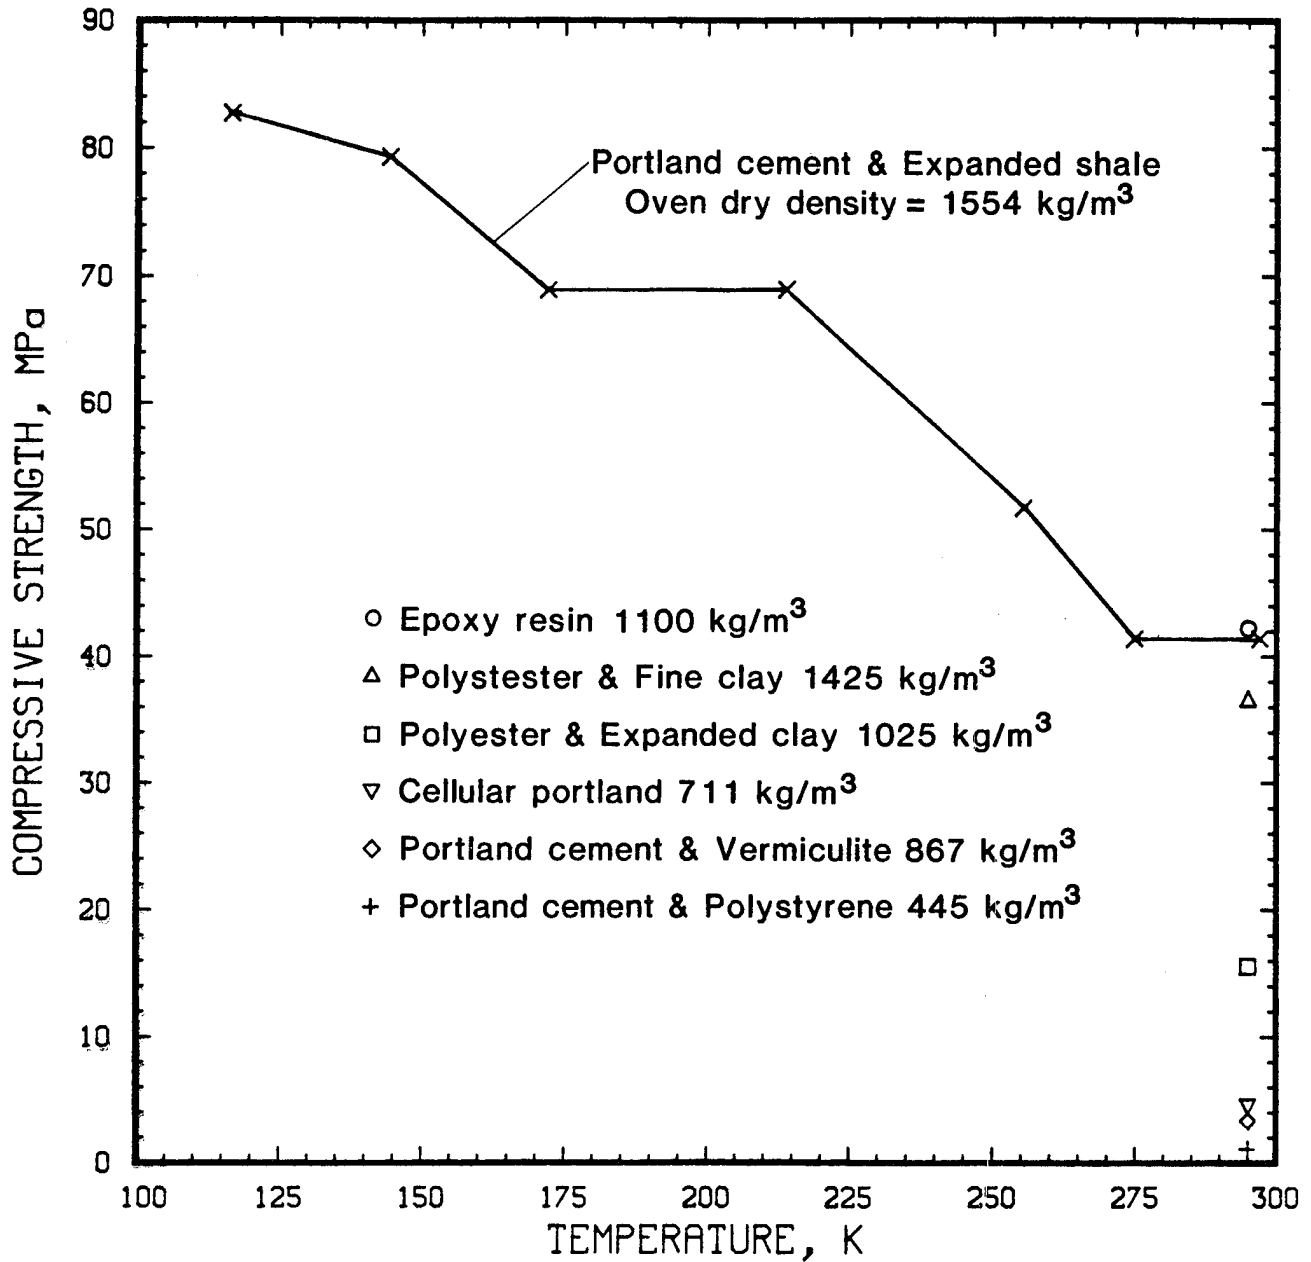

Figure 52. Compressive strength as a function of temperature for expanded shale/portland (Monfore and Lentz, 1962) and for several lightweight concretes at 295 K (McClune and Moorhouse, 1981).

Table 25 lists the companies and people contacted regarding lightweight concrete. Some entries represent a single phone contact, while others involved personal visits and extensive correspondence. Materials used in the experimental phase were acquired from organizations listed in this table. Discussions with members of the GRI Advisory Group were useful in establishing the needs of industry as well as the general state of knowledge of insulating concretes.

Screening tests performed in support of the literature survey resulted in data for thermal conductivity, compressive strength, and modulus of rupture. These data are plotted in figures 53 through 55.

The thermal conductivity data, figure 53, were obtained in an insulating vacuum environment. The values for portland/polystyrene are lower than those usually reported because of porosity and the concomitant lack of gas conduction. The values for the less porous polyester-based materials are not expected to be strongly affected by the vacuum environment. Adjusting the portland/polystyrene values to account for the lack of gas conduction would increase the conductivity at 285 K to approximately 0.07 W/(m·K). The empirical relationship given later in eq (18) yields a conductivity of 0.08 W/(m·K) for this mix.

Discussion of Results (IC)

Although the data base for insulating concretes is very limited, several tentative conclusions can be drawn from the available information. Compressive strength and thermal conductivity can be used to evaluate the relative merits of the candidate materials.

In order to allow tank maintenance, light traffic must be allowed in the tank basin. A minimum compressive strength of 5 MPa (725 psi) is estimated. The screening tests at NBS (fig. 54) indicate that the particular specimen of portland-polystyrene (342-kg/m³ density) is not strong enough for this

Table 25. Industrial sources of information and/or materials used in the NBS/GRI survey of insulating concretes. This list is not comprehensive in regard to companies involved with lightweight concretes and no endorsement is implied.

Figure 53. Thermal conductivity of several insulating concretes as a function of temperature. The testing environment was insulating vacuum.

Figure 54. Average compressive strength of several insulating concretes as a function of temperature (determined at NBS).

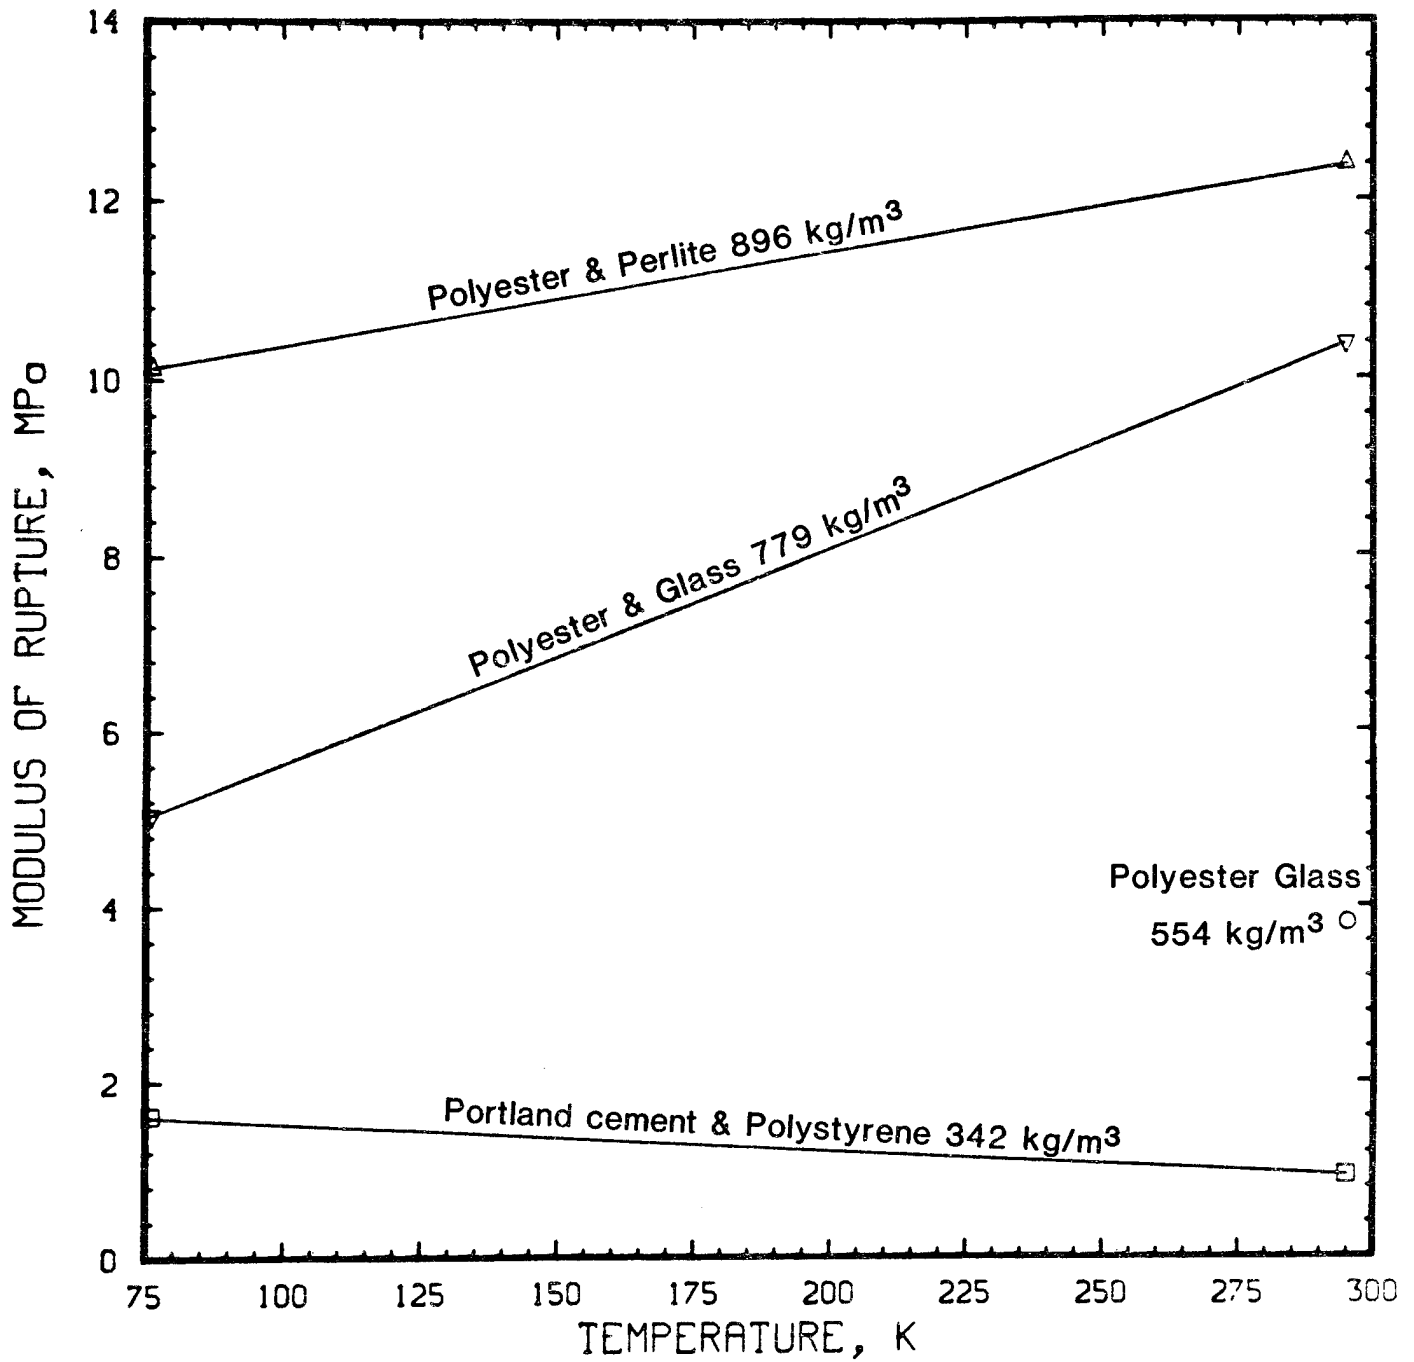

Figure 55. Average modulus of rupture of several insulating concretes as a function of temperature (determined at NBS).

application and that one of the polyester-glass materials (554-kg/m³ density) is marginal in this respect. For portland-cement-based materials this criterion, used in eq (15), establishes a minimum density of about 725 kg/m³. As seen in figures 52 and 54, compressive strength increases or remains approximately constant as temperature decreases. Ambient temperature data can therefore be used as the worst case situation.

Compressive strength as a function of density (in kg·m⁻³) at ambient temperature can be estimated by

$$\text{Compressive Strength} = 4.132 \times 10^{-3} \times \rho + 4.469 \times 10^{-6} \times \rho^2 \quad (15)$$

for portland-cement-based materials. A similar, but much more tenuous relationship

$$\text{Compressive Strength} = 3.174 \times 10^{-3} \times \rho + 1.639 \times 10^{-5} \times \rho^2 \quad (16)$$

can be used for polymeric-based materials. The least-squares fits in eqs (15) and (16) were based on data given by McClune and Moorhouse (1981) and the NBS data given in this report. It must be stressed that these relationships are not intended to be precise but rather to express trends for widely different materials as functions of density.

Selection of material based on thermal properties is more complex. The economics of the site area and material costs would necessarily come into play in making this decision. The relative thermal property merits of the materials and the estimate of the effect of water absorption can, however, be estimated.

The solution to the one-dimensional heat flow equation for infinite slabs leads to the boil off rate for liquefied gas spills

$$\dot{M} = (k\rho C)^{1/2} (\Delta T A) / (H_v \pi^{1/2} t^{1/2}) = (k\rho C)^{1/2} G \quad (17)$$

where G represents a collection of terms not related to the slab material,

\dot{M} is the LNG boil off rate, k is thermal conductivity, ρ is density, C is specific heat, ΔT is temperature difference between the LNG and substrate, A is area, H_v is heat of vaporization of LNG, and t is time. The ambient temperature thermal conductivity for both portland- and resin-based concretes can be estimated by

$$k = 0.1453 - 3.1219 \times 10^{-4} \times \rho + 3.8844 \times 10^{-7} \times \rho^2 \quad (18)$$

for dry materials. The boil-off rate can be expressed as a function of density and specific heat.

$$\dot{M} = [(0.1453\rho - 3.1219 \times 10^{-4} \times \rho^2 + 3.8844 \times 10^{-7} \times \rho^3)C]^{1/2} G \quad (19)$$

For purposes of comparison, specific heat of portland-based materials is 840 J/kg·K (Yoshiwa and Iwata, 1977) while that for resin-based materials is 1000 J/kg·K (Sparks, 1983). For a given density, \dot{M} (polymer base) = 1.1 \dot{M} (portland base). Due to uncertainties in the values of thermal conductivity and specific heat for nonspecific materials, this 10% difference should be considered semi-quantitative.

Absorption of water is of major importance in selecting the dike/basin material. Lang, Moorhouse, and Paul (1980) and McClune and Moorhouse (1981) have studied the rate of water uptake in various materials as well as alternative methods of reducing this phenomenon. Their work is summarized in the annotated bibliography section.

Concern about water uptake is due to the dependence of boil-off rate on ρ , k , and C (eq 17); each of these parameters increase as water content increases. The relationship for thermal conductivity as a function of density (eq 18) applies to dry materials. Valore (1956) has shown empirically that the thermal conductivity for a given specimen will increase by 5% for each 1% increase in

density due to absorption of free water. Specific heat is also increased due to the relatively high heat capacity of water. The net effect of water absorption can be seen by comparison of LNG boil-off for a given material before and after water absorption. Properties of the material in the oven-dry condition are $\rho = 1586 \text{ kg/m}^3$, $k = 0.62 \text{ W/m}\cdot\text{K}$, and $C = 840 \text{ J/kg}\cdot\text{K}$. The resulting LNG boil-off is $\dot{M} = 909 \text{ G}$. After 10 volume percent (6.3% by weight) water absorption, $k = 0.82 \text{ W/m}\cdot\text{K}$, $\rho = 1686 \text{ kg/m}^3$, and, by the rule of mixtures, $C = 1051 \text{ J/kg}\cdot\text{K}$. Boil-off for the damp material is $\dot{M} = 1205 \text{ G}$. $\dot{M}(\text{damp})/\dot{M}(\text{dry}) = 1.33$, or an increase in LNG boil-off of 33%. An increase of this magnitude significantly alters the distance down wind from the tank at which a 5% methane concentration occurs (Arthur D. Little, 1974). McClune and Moorhouse (1981) find absorption in the range 10 to 30 volume percent for untreated portland-based materials so that the effect computed above is approaching a minimum that must be expected.

The ratio of compressive strength to thermal conductivity, Q , can be used as an indicator of the relative fitness of materials for use in dike/basin areas. It does not, however, take several very important factors into account, e.g., initial cost, maintenance, flammability, and water absorption. This ratio is given in table 26 for the lightweight concretes tested at NBS and for several materials reported in the literature. Ordinary concretes, which are stronger but have higher conductivity, have Q values on the order of 20. The resin-based materials listed in the table are suggested by this ratio while the portland/polystyrene materials appear to be least usable. Portland/expanded shale is the most dense material considered. The Q for this material approaches that of the resin-based mixes.

Table 26. Density, thermal conductivity (k), compressive strength (CS), and the ratio $Q = CS/k$ for the lightweight concretes tested at NBS and for several materials reported in the literature. The data are for 295 K.

Material	Source	Density ($\text{kg}\cdot\text{m}^{-3}$)	k ($\text{W}\cdot\text{m}^{-1}\cdot\text{K}^{-1}$)	CS (MPa)	Q ($\text{MPa}\cdot\text{m}\cdot\text{K}\cdot\text{W}^{-1}$)

Major Achievements (IC)

The results of the literature survey and the discussions within the user-producer communities emphasized the undeveloped state of the candidate materials for cryogenic applications. Interactions based on the information available has helped to redirect industrial efforts to develop usable material(s). Polymer-based materials are now being evaluated more thoroughly in this country.

Major Technical Problems (IC)

The over-riding problems encountered were the lack of low temperature data in the literature and user inexperience with the candidate materials. This placed an unexpected burden on the experimental screening effort. The term and funding of the survey were not sufficient to obtain and perform necessary tests on the variety of materials and the range of densities needed to establish quantitative selection criteria.

Conclusions (IC)

The thermophysical properties recommend resin-based materials for use in dike/basin applications. The choice of these materials over lightweight portland-cement-based materials is due to high strength-to-weight ratio and low thermal conductivity. Low absorption allows thermal conductivity to remain fixed after exposure to water. There are, however, unanswered questions which must be addressed before these materials can be used in the proposed applications. Resins are organic in nature and are therefore relatively flammable. The effectiveness of fire retarding additives in preventing resin combustion must be thoroughly evaluated before installation around a LNG tank. Resin-based materials are inherently more expensive, at least initially, than portland-based materials. This fact will lead to use of resin-based materials as caps on less

costly substrates. The quality of bond between cap and substrate and the effect of environmental extremes on this bond must also be evaluated.

Strength-to-weight ratios for portland-cement-based materials are lower than those for the resin-based materials. Relatively dense mixes are required to meet the strength requirements and the thermal conductivity is a function of density. Water absorption in these materials also causes thermal conductivity to increase. It has been shown that reasonably low equilibrium levels of free water can be maintained by particular mix treatments. In view of this and the possibility of further alleviation of absorption problems by drainage design, these materials should not be disregarded. Experience in placing the more conventional materials as well as initial costs are definitely in favor of portland-based materials.

Recommendations (IC)

Several unanswered questions relating to resin- and portland-based materials were mentioned in the Conclusions (IC) section above. The following research is needed to provide the necessary answers:

- (1) Concentrated study of the tensile stress-strain relationship, tensile and compressive strengths, thermal expansion, and thermal conductivity of one type of resin with one type of lightweight aggregate. A range of densities of this material would be required. Without this information, thermal stresses expected from an LNG spill could cause fractures and lead to an unacceptable LNG boil-off rate. These data should cover the temperature range from 100 K to ambient. The properties mentioned must be determined on specimens which are large compared to aggregate dimensions.
- (2) Tests involving large slabs of the selected material (same resin and aggregate type as selected for study in (1) above) should be done to

compliment the property determinations discussed in project (1). Placing, large scale batching, and batch-to-batch uniformity would be determined. Specimens for the study in (1) would ideally come from these mixes. Aging in outdoor environments and effects of thermal shock would be assessed.

- (3) Programs similar to (1) and (2) are needed for a portland-cement-based material with one type of aggregate. In addition to the previously mentioned parameters, effectiveness of techniques to prevent water absorption should be examined. Quantitative rates and equilibrium levels of moisture would be determined.
- (4) Flammability tests are needed for the particular resin chosen. Types of gases evolved during combustion should be determined.
- (5) The economics involved in choosing either type of material or combinations thereof should be studied as functions of site particulars. Relative costs of capping, substrate type, maintenance, and drainage facilities are needed and must be expressed in a form which can be related to widely variable site particulars.

A single, best material for use in insulating dikes and impounding areas cannot be selected based on available information. Our assessment indicates that there are six types of materials which would be useful in particular circumstances: (1) expanded shale/portland, (2) perlite/portland, (3) polymer/perlite, vermiculite, expanded shale or expanded clay, (4) polymer/glass, (5) portland/polystyrene, and (6) vermiculite/portland. Although data is not available to establish a figure of merit for all of these materials, (1), (3), and (4) appear to be the best alternatives.

ANNOTATED BIBLIOGRAPHIES (IC)

Expanded shale/portland

Monfore, G. E. and Lentz, A. E. (1962). Physical Properties of Concrete at Very Low Temperatures, J. PCA 4, 33-39.

Narrative: The properties of various concretes were reported by the authors in the period 1962 through 1966. This work is referred to in a large percentage of papers dealing with concrete at low temperatures. The purpose of their study was to develop a data base to use in the design of LNG facilities. The temperature range studied was -157 to 24 °C. The materials of primary interest were ordinary weight concretes, e.g., densities on the order of 2290 kg/m³ (143 lb/ft³). One series of expanded-shale-portland specimens were included; the density of these specimens was 1554 kg/m³ (97 lb/ft³) which puts them in the structural-lightweight category.

Material: Expanded shale/portland; 1554 kg/m³ (97 lb/ft³) density; 334.6 kg/m³ (6.0 bag/yd³) cement content; 0.45 l/kg (5.1 gal/bag) water to cement ratio.

Data: Young's modulus (moist condition); $-157 \leq T \leq 24$ °C.
Thermal contraction (moist condition); $-157 \leq T \leq 24$ °C.
Compressive strength (moist condition); $-157 \leq T \leq 24$ °C.
Splitting strength (moist condition); $-157 \leq T \leq 24$ °C.

Conclusions. Compressive strength, compressive modulus, and splitting strength show essentially no temperature dependence on temperatures above 0 °C. Below this temperature, each increases rapidly with decreasing temperature. Splitting strength exhibits a maximum at -58 °C while the compressive strength and modulus continue to increase monotonically as temperature decreases. These trends were also observed for a moist concrete mortar by Arvidson, Sparks, and Steketee (1982). Thermal contraction also exhibits an inflection at about -58 °C. This behavior has been observed for other types of concrete (Tognon, 1968; Goto and Miura, 1978).

Expanded shale/portland

Lentz, A. E. and Monfore, G. E. (1965). Thermal Conductivity of Concrete at Very Low Temperatures, J. PCA 7, 39-46.

Narrative: This paper is the second of the series by Lentz and Monfore dealing with concretes at low temperatures. One of the materials discussed is expanded shale/portland in moist, 50% relative humidity (RH), and oven-dry conditions. The density of this material is 1586 kg/m^3 which falls in the structural lightweight category. These data, along with those reported in Monfore and Lentz (1962), constitute a complete set of low-temperature properties for a particular formulation and are unique in this regard.

Material: Expanded shale/portland; 1586 kg/m^3 (99 lb/ft^3) density; 334.6 kg/m^3 (6.0 bag/yd^3) cement content; 0.45 μ /kg (5.1 gal/bag) water to cement ratio.

Data: Thermal conductivity (moist, 50% RH, oven dry); $-157 \leq T \leq 24 \text{ }^\circ\text{C}$.

Conclusions: These data emphasize the importance of moisture content on the conductivity of concrete. The general rule of a 5% change in conductivity for each 1% change in density due to free-moisture content is closely followed at $-160 \text{ }^\circ\text{C}$. The separation of data points for these data would preclude identifying possible inflections in the -70 to $-20 \text{ }^\circ\text{C}$ temperature range. The possibility exists for significantly higher conductivities in this range for moist concretes. Rapid changes in splitting strength and thermal contraction were observed by Monfore and Lentz (1962) and in thermal conductivity by Sparks (1981).

Vermiculite, polystyrene/portland cement, soils, corrugated aluminum

Reid, R. C. and Wang, R. (1978). The Boiling Rates of LNG on Typical Dike Floor Materials, Cryogenics 18, 401-404.

Reid, R. C. (1980). Boiling of LNG on Typical Dike Floor Materials, Final Report to Gas Research Institute, GRI-79/0026.

Narrative: Spill tests were conducted to determine the boiling parameters of several candidate dike insulating materials. The boiling rate, \dot{M}/A , was found to be $\dot{M}/A = Ft^{-1/2}$ and $F = (k\pi C/\rho)^{-1/2} \Delta T/\Delta H$. Both coated and uncoated specimens were tested and no difference in boiling rates was detected. Apparent thermal conductivities were computed.

Material: Polystyrene-portland, vermiculite-portland, soil, corrugated aluminum, polyurethane.

Data: Boiling rate, thermal conductivity.

Conclusions: The relative boil-off rates for the insulating concretes were roughly proportional to density. The boiling parameter, F , for these materials is about a factor of two higher than that of the 120 kg/m^3 polyurethane foam tested, and about a factor of eight lower than the compacted soil tested. The problem of moisture uptake was not addressed. The authors found that corrugated aluminum over a sand substrate served to limit the boiling rates to about the level of the insulating concretes.

Narrative: The material studied is a neat-cellular concrete consisting of type I portland cement, water, and a hydrolized waste-protein-foaming agent. Several densities were prepared and properties were studied as a function of density at 23 and -196 °C.

Material: Cellular-portland-cement concrete.

Data: Specific strength as a function of water to cement ratio; ultimate compressive strength, elastic modulus, secant modulus, and thermal conductivity as functions of density.

Conclusions: The data are indicative of moist specimens which tend to make the thermal conductivity data relatively high. No indication of water uptake is given but would probably be high, at least comparable to vermiculite- and polystyrene-portland. The ratio compressive strength/thermal conductivity for a 1200 kg/m³ specimen indicates that this type of material compares reasonably well with other non-resin based concretes.

Perlite-portland cement concrete

Adams, L. (1969). Thermal Conductivity of Perlite Concrete, Cryogenic
Tech. 5, 10-11.

Narrative: This work presents an analytical study of thermal conductivity as a function of temperature with density and free-water content as parameters.

Material: Perlite-portland-cement concrete.

Data: Analytical values of thermal conductivity in the temperature range 144 to 255 K, free moisture content from 0 to 60%, and oven-dry densities from 352 to 577 kg/m³.

Conclusions: The values presented in this paper are useful because the analytical relationship is based on reasonable observations of the behavior of other materials and there are no experimental data for perlite concrete.

Polymer matrix composites and waterproofing

Lang, R. Z. J., Moorhouse, J., and Paul, G. J. (1980). Waterproof Insulation Materials, British Gas Corporation MRS E 372, Institute of Chemical Engineers Seventh Symposium on Process Hazards.

Narrative: This paper reports the continuation of the effort to establish a viable insulating material for dike-impounding systems of LNG-storage facilities (McClune and Moorhouse, 1981). Water uptake in outdoor exposures is reported for several treated and untreated lightweight concretes. Mass rate of boil-off of LNG is experimentally determined and used to compare the various types of specimens mentioned above with varying water contents. Results from tests to evaluate the bond strength of resin based materials to ordinary concretes are reported.

Material: Ordinary (sand and gravel aggregate) concrete, lightweight concrete, and resin concrete.

Data: Comparison of water uptake of treated and untreated lightweight concrete; LNG boil-off rates as a function of water content and as a function of time from spill; tensile bond strength of lightweight-ordinary concretes.

Conclusions: As was shown in a previous publication, resin-based concretes are superior to treated lightweight concretes with regard to water uptake and compressive strength. Data presented here for the bond strength between resin and ordinary concretes indicate that this should not be a major problem in the practical application of resin concretes. In applications where the exposure to water can be reasonably limited, such as well graded or vertical sections, the water uptake in treated lightweight concretes can be kept to levels causing relatively small increases in thermal conductivity, e.g., water content increasing from 0 to 10% by volume increases the conductivity by approximately 50%.

Polymer matrix composites and water uptake

McClune, C. R. and Moorhouse, J. (1981). The Development of Waterproof Insulating Materials Based on Lightweight Concrete, Mag. Concr. Res. 33, 27-36.

Narrative: This paper considers three areas of primary interest in selecting a material for use in the dike-impounding system of LNG-storage facilities. Several methods of reducing water uptake are discussed. The most effective of these is to replace the cement binder with a resin binder. Addition of latex to the portland cement and/or to the aggregates used is also effective. The usual relationship between the compressive strength and density was not significantly affected by the waterproofing in the case of the portland-based concretes. The resin-based materials did not follow this relationship in that their compressive strength was substantially higher than that for a portland-based concrete of comparable density. Thermal conductivity of both resin- and portland-based materials exhibit similar density dependence at 30 °C.

Materials: Aerated, polystyrene, vermiculite and expanded-clay aggregates in portland-cement binder. Epoxy and polyester binders used with several unspecified aggregates and with clay aggregates. Latex, epoxy, and silicon admixtures.

Data: Water uptake and water content as a function of time in wetting and drying environments. Compressive strength and thermal conductivity as functions of density.

Conclusions: Thermal conductivity of concretes increases roughly 5% for each 1% increase in density due to free water content. This trend makes water uptake critical to the performance of these materials. Waterproofing by application of surface sealers is not satisfactory because thin layers of sealer are not effective and thick layers are expensive and are detrimental to the thermal properties. Reactive admixtures are not effective when used with lightweight concretes. Nonreactive admixtures, particularly latex, and treatment of aggregate with waterproofing agents prior to mixing was found to be effective in reducing water uptake. Resin-based concretes were most effective in reducing water uptake. Possible drawbacks to the use of resin binders are flammability, cost, and bondability to substrate materials.
