## FOREWORD

This report summarizes the work accomplished on NASA Contract NAS3-22812 "Compression and Compression Fatigue Testing of Composite Laminates."

The program was sponsored by the National Aeronautics and Space Administration, Lewis Research Center, Cleveland, Ohio. Mr. G. T. Smith, NASA Lewis Research Center, was project manager.

Performance of this contract was under the direction of the Advanced Airplane Branch of the Boeing Military Airplane Company. Dr. R. R. June, who heads Advanced Composites Development, was the program manager. Mr. T. R. Porter was the technical leader, Pete Smith coordinated specimen fabrication, J. R. Vosper and M. C. Riley provided testing support, and L. R. Hause was responsible for ultrasonic inspection support.

## INTRODUCTION

The objective of this program was to obtain data to experimentally evaluate the effects of moisture and temperature on the integrity of fiber composite components. In particular, the static and cyclic performance of composite laminates containing flaws was investigated at room temperature, 394K ( $250^{\circ}$  F) and 422K ( $300^{\circ}$  F) in wet and dry conditions. This program extends the results developed under contracts NAS3-19709 and NAS3-20405 reported in NASA CR-135403 and NASA CR-165213 (references 1 and 2).

The experimental program was performed in three tasks: (1) Static-Compression Tests, (2) Tension-Compression Fatigue Tests and (3) Residual-Compression Tests.

The static-compression fracture strength was evaluated on laminates that had been moisture conditioned and in the as-prepared condition. In addition to unnotched specimens, panels containing through-the-thickness slits 3.18 mm (0.125 in), 9.52 mm (0.375 in), and 15.87 mm (0.625 in) long were tested.

The tension-compression fatigue testing was performed on specimens that had 15.87 mm (0.625 in) slits and impact-produced delaminations. As-manufactured and moisture-conditioned specimens were evaluated at room and elevated temperatures.

The residual-compression strength was evaluated for test specimens after cyclic loading. Both tension-compression and compression-only cyclic loading ratios were included.

Previous testing under NASA Lewis Contracts NAS3-19709 and NAS3-20405 with The Boeing Company had demonstrated the importance of compressive loading on the fatigue and static response of these graphite-epoxy structural laminates. The compression loads were especially critical for the elevated-temperature and wet environments.

Test materials available from NASA Contract NAS3-20405 were used for this program. These results are directly comparable to the available data since they are from the same material batch and have the same processing history.

## SPECIMEN DESIGN AND MANUFACTURE

The specimens used in this test program were cut from panels that had been fabricated under Contract NAS3-20405 (reference 2). The majority of the available materials were the general purpose laminate (L1) with a small panel of the all-graphite turbine engine fan-blade laminate (L3-B). The list of these available materials is given on table 1.

### Laminate Materials

The materials used for the program were Thorne T-300 graphite fiber, and Fiberite 934 epoxy resin. This is an intermediate stiffness graphite-epoxy composite and was selected as the basic material for the program because of its wide use, moderate cost, and established structural performance. The Fiberite 934 resin system satisfied the requirements of a general purpose epoxy and also has a wide range of applications in aerospace structures. The stacking sequence selected for layup L1, based on symmetry and load transfer requirements, was  $((0/\pm 45/0/90)_S)_2$ . Note that this stacking is not quasi-isotropic since it contains twice as many  $0^\circ$  plies as the other orientations.

The stacking sequence for layup L3 is representative of those considered for use in composite turbine engine fan blades. Two possible layup approaches are the dispersed-ply approach and the core-shell approach. The dispersed-ply approach was used because such layups are less subject to delamination from foreign object impact.

### Specimen Configuration

Two test specimen configurations were used. A 76-mm (3.0-in) wide specimen shown in figure 1 was used for the notched tests and a 12.6-mm (0.5-inch) wide specimen (figure 2) was used for the unnotched compression tests.

The 76-mm (3.0-in) width used for the majority of the tests was chosen to provide specimens large enough to preclude significant interaction between the stress concentration and stress-free specimen boundaries. The specimen was designed so that the stress concentration factor for the largest defect would be within 5% of the corresponding stress concentration factor for a plate of infinite width. The potential effect of the free edge on the fracture behavior has been investigated experimentally by static testing specimens of various widths that contained the largest defects (reference 2). The 0-degree laminate direction corresponds to the axial direction of the specimen. Woven fiberglass grip tabs were secondarily bonded to the specimen using a 394K ( $250^{\circ}$ ) cure adhesive. The 12.6-mm (0.5-in) compression coupon has been shown to produce reliable results for unnotched laminate testing.

Both test specimens were prevented from buckling by using support plates against the specimen faces. The support plates for the 76-mm. (3.0-in) wide specimen had a 50.8-mm (2.0-in) diameter central hole located over the defect to allow local out-of-plane deformations and monitoring of damage growth.

## Test Specimen Fabrication and Processing

Specimen layup and fabrication steps are illustrated in figures 3 and 4. Laminates were laid up and cured in 81-cm (32-in) wide panels up to 293 cm (120-in) in length. After curing, fiberglass end tabs were bonded to the basic laminates and then the panels were sawed into specimen blanks. The laminates were debulked after 4th, 8th, 12th, 16th, and 20th ply by holding the laminate under vacuum for 15 to 20 min. The autoclave cure cycle used was:

1. Apply vacuum.
2. Increase autoclave temperature so that laminate temperature increases at a rate of  $0.5^{\circ}\text{C}$  to  $2.8^{\circ}\text{C}$  ( $1^{\circ}\text{F}$  to  $5^{\circ}\text{F}$ ) per min.
3. Hold 60 min at  $121^{\circ}\text{C} \pm 5.5^{\circ}\text{C}$  ( $250^{\circ}\text{F} \pm 20^{\circ}\text{F}$ ).
4. Apply 689 kPa (100 lb/in<sup>2</sup>) pressure 15 min after the laminate reaches temperature.
5. Increase laminate temperature to  $177^{\circ}\text{C} \pm 5.5^{\circ}\text{C}$  ( $350^{\circ}\text{F} \pm 10^{\circ}\text{F}$ ) at a rate of  $0.5^{\circ}\text{C}$  to  $2.8^{\circ}\text{C}$  ( $1^{\circ}\text{F}$  to  $5^{\circ}\text{F}$ ) per min.
6. Hold at temperature for 120 min  $\pm 5$  min, then cool under pressure.

The specimens were tested with no defects, full-penetration slits, half-

penetration slits, and impact-produced delaminations. These defects were selected from a more extensive list used in the previous (reference 1 and 2) programs shown in table 2. For the data presentation in the tables and figures a code is used to identify the type and nominal size of defect as defined in table 2. Figure 5 illustrates the defect types tested in this program.

The slit sizes selected for test were 3.18 mm (0.125 in), 9.52 mm (0.375 in), and 15.87 mm (0.625 in). These sizes, coded as 1/8, 3/8, and 5/8 (in) respectively encompass most practical fastener diameters. They are also at the threshold of detectable damage sizes for many common inspection procedures. The same sizes were used for the surface length of the half-penetration defects, because when partial penetration damage exists in structures, the most obvious dimension is the length of the damage on the surface. All slits were perpendicular to the primary load-carrying direction of each laminate. This means that they were perpendicular to the 0-degree fibers.

The slits were fabricated by ultrasonic machining. Circular cutter tips were machined to a thickness of 1.52 mm (0.06 in) and a sharp radius. The ultrasonic vibrations of the cutter produce a lapping action in an abrasive slurry that carries away the excess material as the cutter penetrates the part. The slit radius in the composite laminate was typically about 0.127 mm (0.005 in) with a smooth surface. Figure 6 shows a typical partial penetration flaw that has been sectioned to illustrate the root geometry.

The impact-damage defect was produced by impacting the specimens with a 0.91-kg (2-lb) weight dropped from a height of 0.38m (15 in). Figure 7 is a photograph of the impact stand used. There was almost no visible evidence of damage to the test specimen after impact. The surface dent depth was less than 0.13 mm (0.005 in) and there was no evidence of broken filaments. The test specimen was supported on a circular support containing a 15.9 mm (0.625-in) hole. This support condition, together with the 15.9 mm (0.625-in) diameter hemispherical impactor, produced a delamination damage diameter of approximately 15.9 mm (0.625 in). Examination of sectioned specimens damaged in this manner showed delamination damage throughout the laminate thickness. Figure 8 shows the typical impact produced delaminations.

## MOISTURE CONDITIONING

The specimens in this program were tested in two moisture conditions: dry and wet. The dry condition resulted from office-room-air storage of the laminates from the time of cure until specimen fabrication and laboratory storage before testing. Since these laminate materials were fabricated for a previous program, the storage time for the materials was approximately two years between cure and test. The humidity during this storage was generally in the range of 40% to 50%.

The wet moisture condition was produced by soaking in a 355K (180°F) water bath for 8 weeks. This time and temperature, established from previous testing, produces a near-equilibrium condition with a weight gain of about 1.3% to 1.5%. During the elevated-temperature soak, test specimens were taken from the water bath at intervals, towel dried, and weighed to determine the amount of moisture gain. To minimize variances due to conditioning procedures, all specimens were conditioned together in one tank. Previous exposure testing of similar configuration specimens has shown that the glass tabs absorb moisture at a higher rate than the graphite-epoxy, making the actual weight-gain values hard to interpret. To offset this problem, untabbed test laminate traveler material from each of the laminate types was soaked and weighed along with the test samples. The weight of these traveler coupons was used to monitor the conditioning treatment.

Figure 9 shows the weight gain for these traveler coupons. Similar moisture absorption data developed in previous conditioning is included for

comparison. The data indicate that the coupons conditioned in this program absorbed slightly less moisture (about 0.1% to 0.2% less) during conditioning than those conditioned previously. The result is anticipated because of the moisture absorbed by the panel during storage between programs.

## STATIC FRACTURE RESULTS

The static-fracture strength under compression loading was evaluated for laminate L1 and a limited number of L3-B laminate specimens. The test conditions are presented in table 3. The testing included room and elevated temperatures. All static tests were performed in a load-controlled test machine using friction specimen grips. The specimens were loaded at a rate of 1100 N/S (250 lb/s). This rate resulted in failure in about 1 min after the onset of loading. The flawed test specimens were instrumented using a crack opening displacement (COD) gage across the defect. The COD gage was placed across the defect against bonded knife-edge supports. COD versus load was recorded for each test. These curves are included in appendix D.

The specimen heating procedures were developed in previous testing using temperature survey specimens. The test specimens were heated through a combination of resistance heaters on the stabilizing plates and a radiant heater. In this manner the specimen temperature is controlled to within 3K ( $5^{\circ}\text{F}$ ) of the desired temperature in the region of the defect. These procedures allowed access to the specimen for inspection and COD instrumentation. Access to the specimen face was through the 50.8-mm (2-in) diameter central holes in the stabilization plates.

The compression-fracture test results and how they compare with previous tension results are presented in figures 10 through 18.

The effect of defect size on the dry-compression-fracture strength is shown in figure 10. The results show there is a significant effect of defect size in the compression strength at all test temperatures with temperature having only a minor effect. With the wet-test specimens however, elevated temperatures significantly degrade the compression strength (figure 11).

These wet- and dry-test results are compared with the available tension data (reference 1 and 2) in figures 12, and 14. At room temperature (figure 12) the tension and compression results are similar in magnitude. The compression data specimens are slightly lower in strength when wet while the tensile data specimens are lower in strength when dry. At elevated temperature (figure 14) the dry specimen compression strength is lower than the tension strength and the wet compression strength is greatly reduced.

These temperature effects are illustrated for dry and wet laminates in figures 15 and 16 for the through slits (FP) and figure 17 for the half penetration (HP) slit. As shown in figure 17, elevated temperature can reduce the notch effect for tension-loaded HP slits leading to an increase in fracture strength. Under compression loading, however, the elevated-temperature dry and the elevated-temperature wet specimens display a significant reduction in strength.

The test data for laminate L3 (figure 18) shows the notch effect was similar for both tension- and compression-loaded specimens. In general, the compression strength was lower than the tension strength.

Comparison of typical crack opening/closing records from these compression tests with results from previous tension testing are shown in figure 19.

## FATIGUE RESULTS

Tension-compression ( $R = -1.0$ ) and fatigue testing was conducted to extend the available tension fatigue test data. Table 4 presents the test matrix for these specimens. All testing was with specimens from laminate L1 containing 5/8-in defects.

The fatigue data for the wet- and dry-slit specimens at 394K (250°F) is shown in figure 20. The test data indicate that the absorbed moisture has a greater effect on the initial strength than on the long-life fatigue behavior. The hot wet reduction in static strength was shown earlier in the results in figure 16. The long cyclic life in the hot wet condition could be the result of specimen drying during cyclic test.

The impacted test specimen fatigue data is presented in figure 21 and the HP slit data in figure 22. Because there were only limited test specimens for each condition, when the test specimen did not fail in  $1.5 \times 10^6$  cycles the cyclic load was raised to a higher level for continued test. This permitted cyclic test failure data to be developed for all conditions. These points are labeled as a retest in the figure.

A comparison of fatigue results for different types of 5/8-in defects is shown in figure 23. These results are for room air tests of dry specimens cycled under tension-compression loading ( $R = -1.0$ ). These data indicate that a built-in disbond (a circular teflon insert 1/4 thickness from surface) was the least severe of all defects tested and a through-the-thick-

ness slit was the most severe. The results indicate that an impact-produced delamination is relatively more critical to the static-compression strength and less critical to the fatigue life than the other defects. This result may be true only for those tests with a tension cyclic component ( $R = -1.0$ ). The tension portion of the cycle would contribute to damage growth in the slit and hole specimens, but would not contribute to damage growth when the delamination defect was produced by impact.

## RESIDUAL STRENGTH RESULTS

The compression static strengths of cyclic-loaded test specimens were evaluated as defined in table 5. In these tests, cyclic load levels were selected to produce an estimated life of  $10^6$  cycles. The testing was stopped at the defined lives and the residual static-compression strength was evaluated. Through-transmission C-scan records before and after cycling were used to monitor damage. Figure 24 presents the C-scan results after cycling for room temperature, dry-test specimens. The longer life test specimens show delamination growth in the region of the initial slit. The residual-compression strengths for these specimens are shown in figure 19. There is a reduction in the compression-residual strength in specimens where the C-scans show damage growth.

The available tension-residual strength results and cyclic-fatigue-life data are also included in figure 25 for reference. From these results it can be seen that the initial tension and compression strengths in these panels are nearly identical. With cyclic loading, however, the tension-residual strength raises while the compression-strength lowers.

Figures 26 through 30 present similar residual strength results for the other test conditions. Similar conclusions apply to the other test conditions with the exception that the compression strengths did not always decrease. This was most evident for the elevated-temperature test data. A potential reason could be specimen drying during the cyclic test.

## CONCLUSIONS

Tests were performed on two composite laminates to provide additional data on the static-compression and tension-compression fatigue behavior. These results extend the data generated in prior programs. The test results apply to the specific laminates and test conditions evaluated but the trends should have a wider application. Some of the conclusions made from the test data, and which are discussed in more detail in the report, are as follows:

- a. Defects in the composite laminates that cut filaments significantly reduced their tensile and compressive strength.
- b. The failure in the test specimens with cut filaments initiated at the stress concentration and propagated across the specimen width. The failure mode and failure stress were similar for both tension and compression loading and the fracture strength was a direct function of defect size.
- c. Absorbed moisture had a small effect on the static-fracture strength at room temperature.
- d. Test temperature had a significant degradation effect on compression-fracture strength and the combination of moisture and temperature had the greatest degradation effect on compression strength.

- e. Moisture and temperature, independently and in combination, had a significant degradation effect on tension-compression fatigue behavior.
- f. Under tension-compression fatigue loadings full penetration slits were the most critical while built-in disbonds were the least critical. Impact-produced delaminations were as critical as slits for compression-static loading, but less severe for longer term cyclic testing under tension-compression loading.
- g. Cyclic-loading of notched test specimens could produce reductions in the compression-residual strength. This is in contrast to the tension-residual strength which would generally increase.

## **APPENDIX A**

### **STATIC AND CYCLIC TEST DATA**

This appendix contains the static and cyclic test data for all specimens. The reported data include specimen geometry, loads, and test parameters. The gross section stresses have been reported for all the critical test conditions.

## **APPENDIX B**

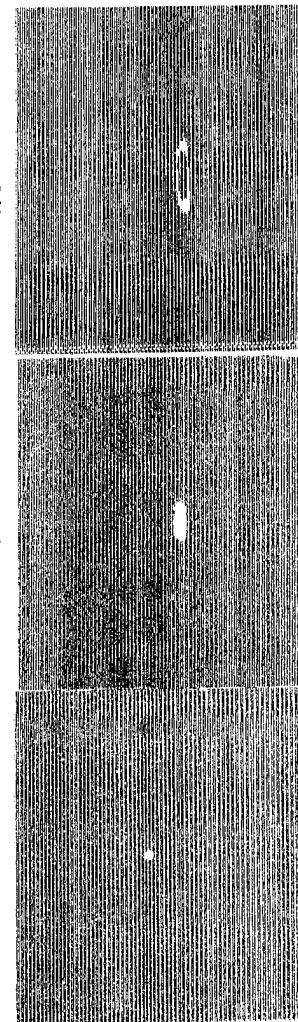

### **ULTRASONIC INSPECTION DATA**

This appendix contains copies of the ultrasonic C-scan records that were developed for the test specimens. The records are identified by the test specimen number, the defect code and a brief description of the point in the test sequence at which the inspection was made. For many of the test specimens, ultrasonic inspection was performed several times during the test showing the progressive development of the damage.

RESIDUAL COMPRESSION STRENGTH SPECIMENS

## FATIGUE TEST SPECIMENS

## **APPENDIX D**

### **STATIC TEST CRACK OPENING DISPLACEMENT RECORDS**

This appendix contains copies of the machine records giving the crack opening displacement gage reading versus the static-test machine load. The curves are identified by specimen number. The value of the maximum test machine load as read from the test machine dial is also recorded on the record.

Graph showing the relationship between Strain Rate and Load Rate at  $+250^{\circ}\text{F}$ .

X-axis: Strain Rate  $\sim \text{IN/IN/MIN}$

Y-axis: Load Rate  $\sim \text{IN/IN/MIN}$

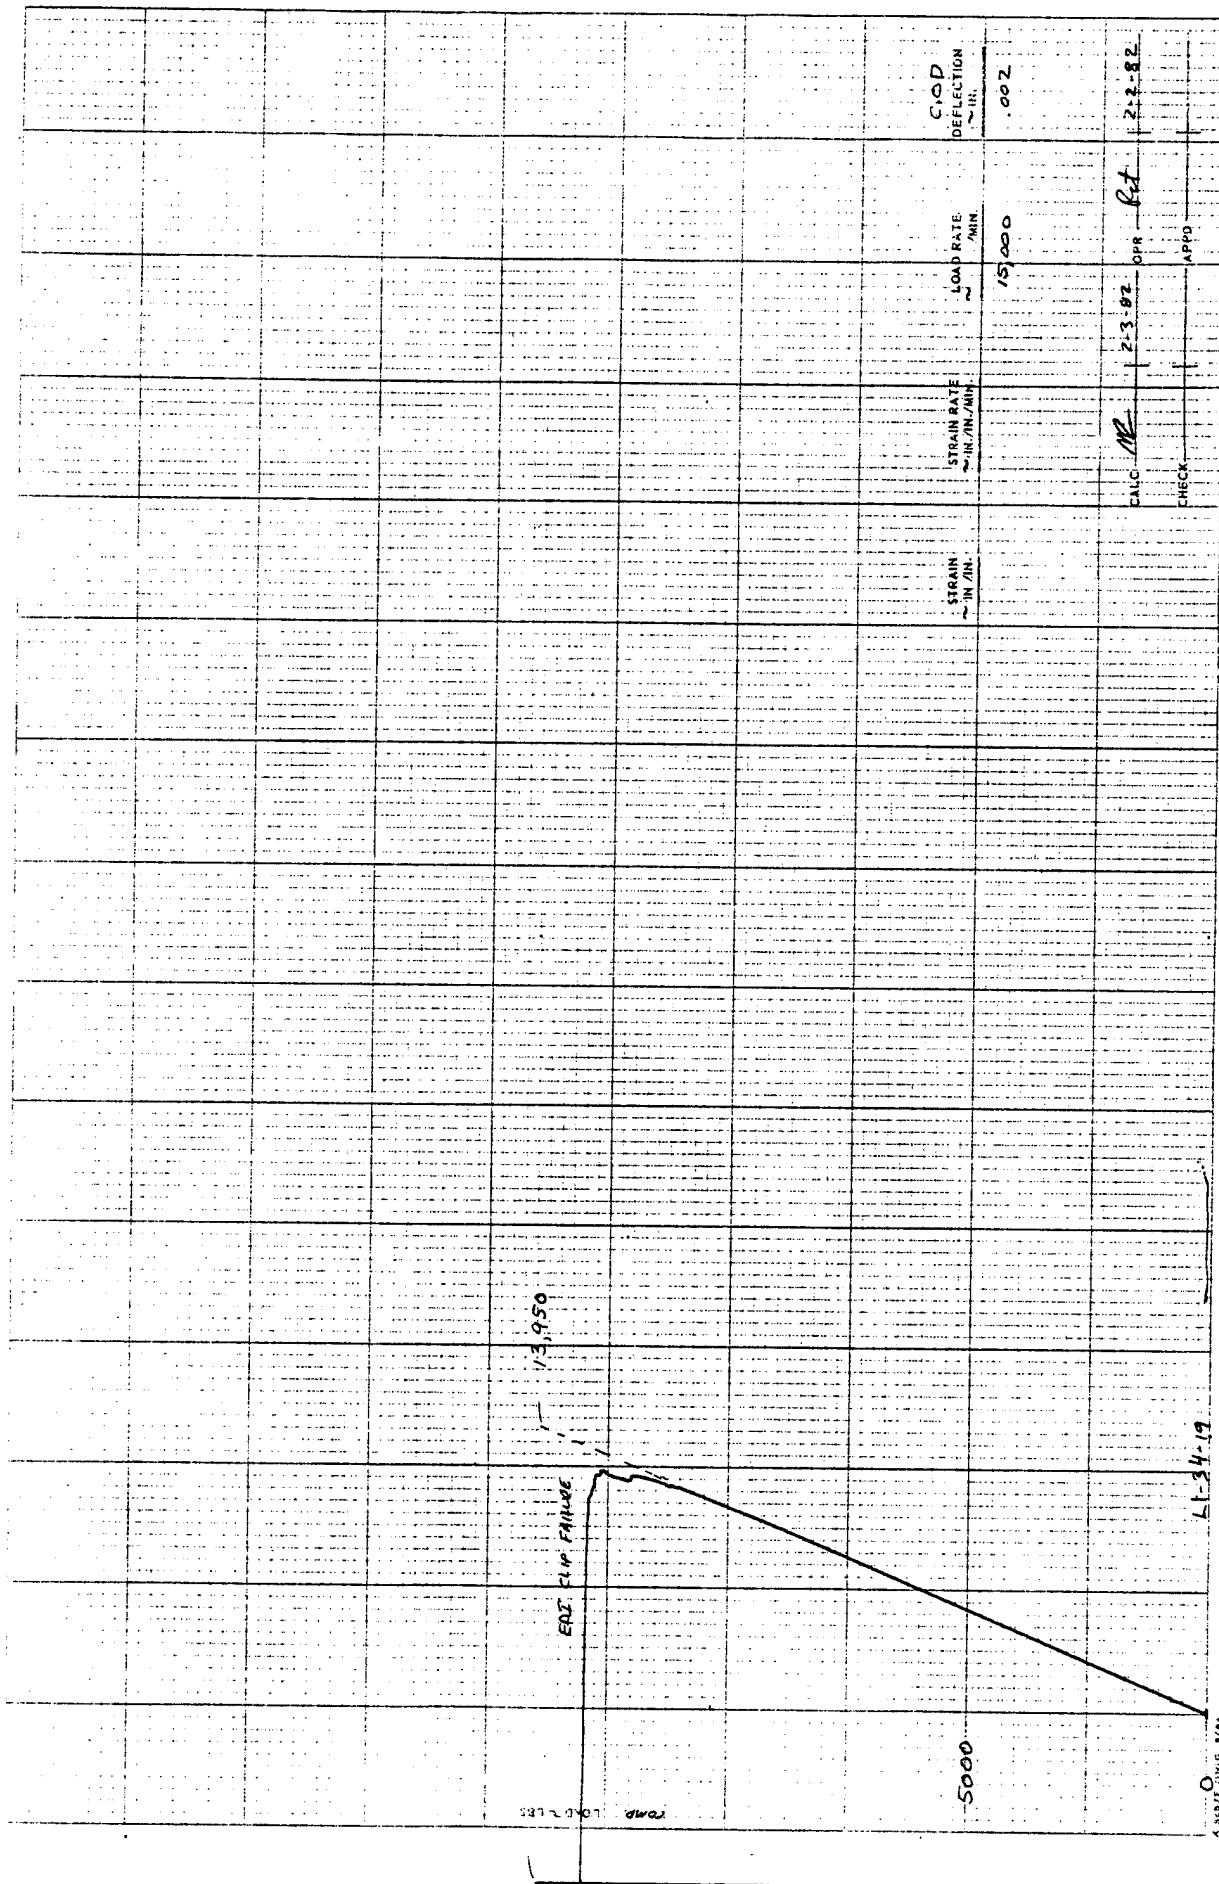

Temperature:  $+250^{\circ}\text{F}$

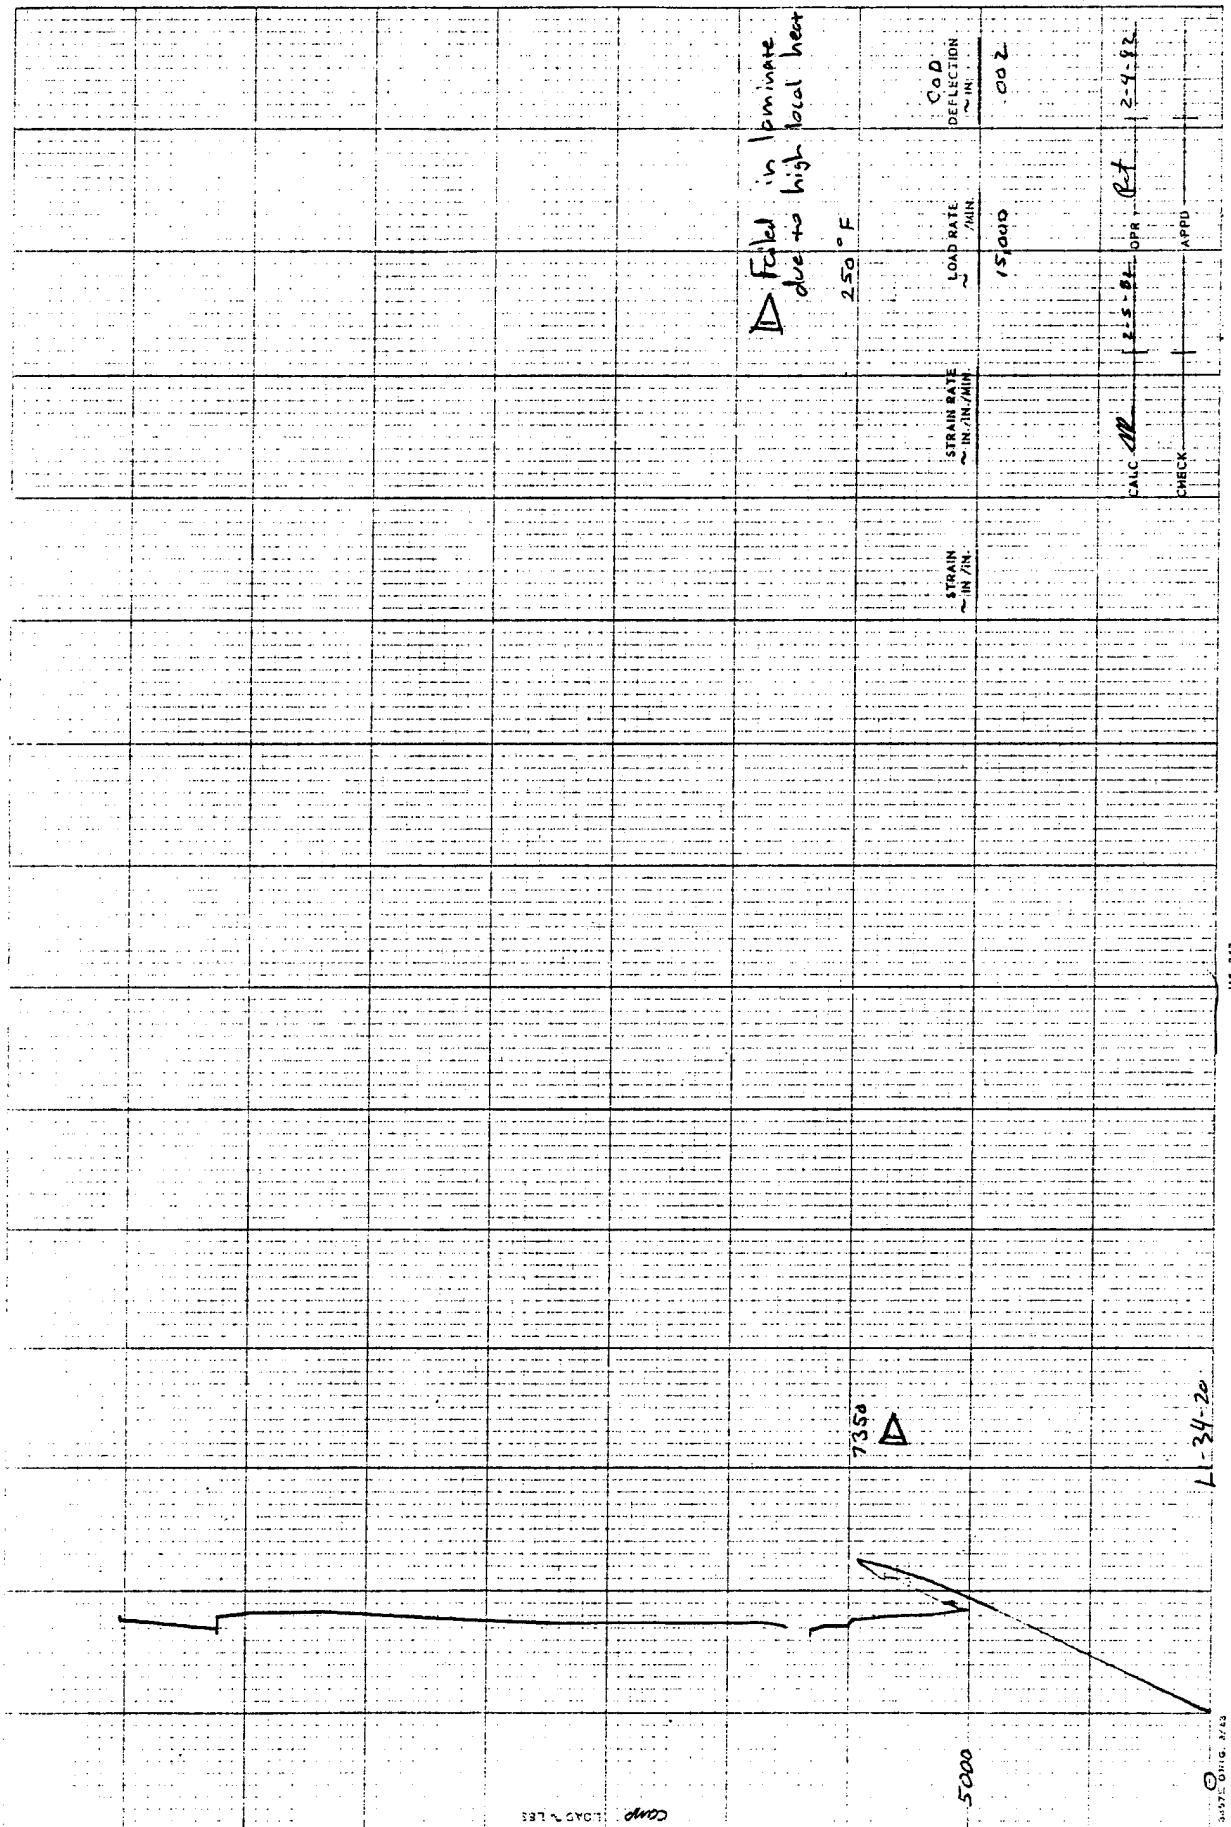

Key points marked on the graph:

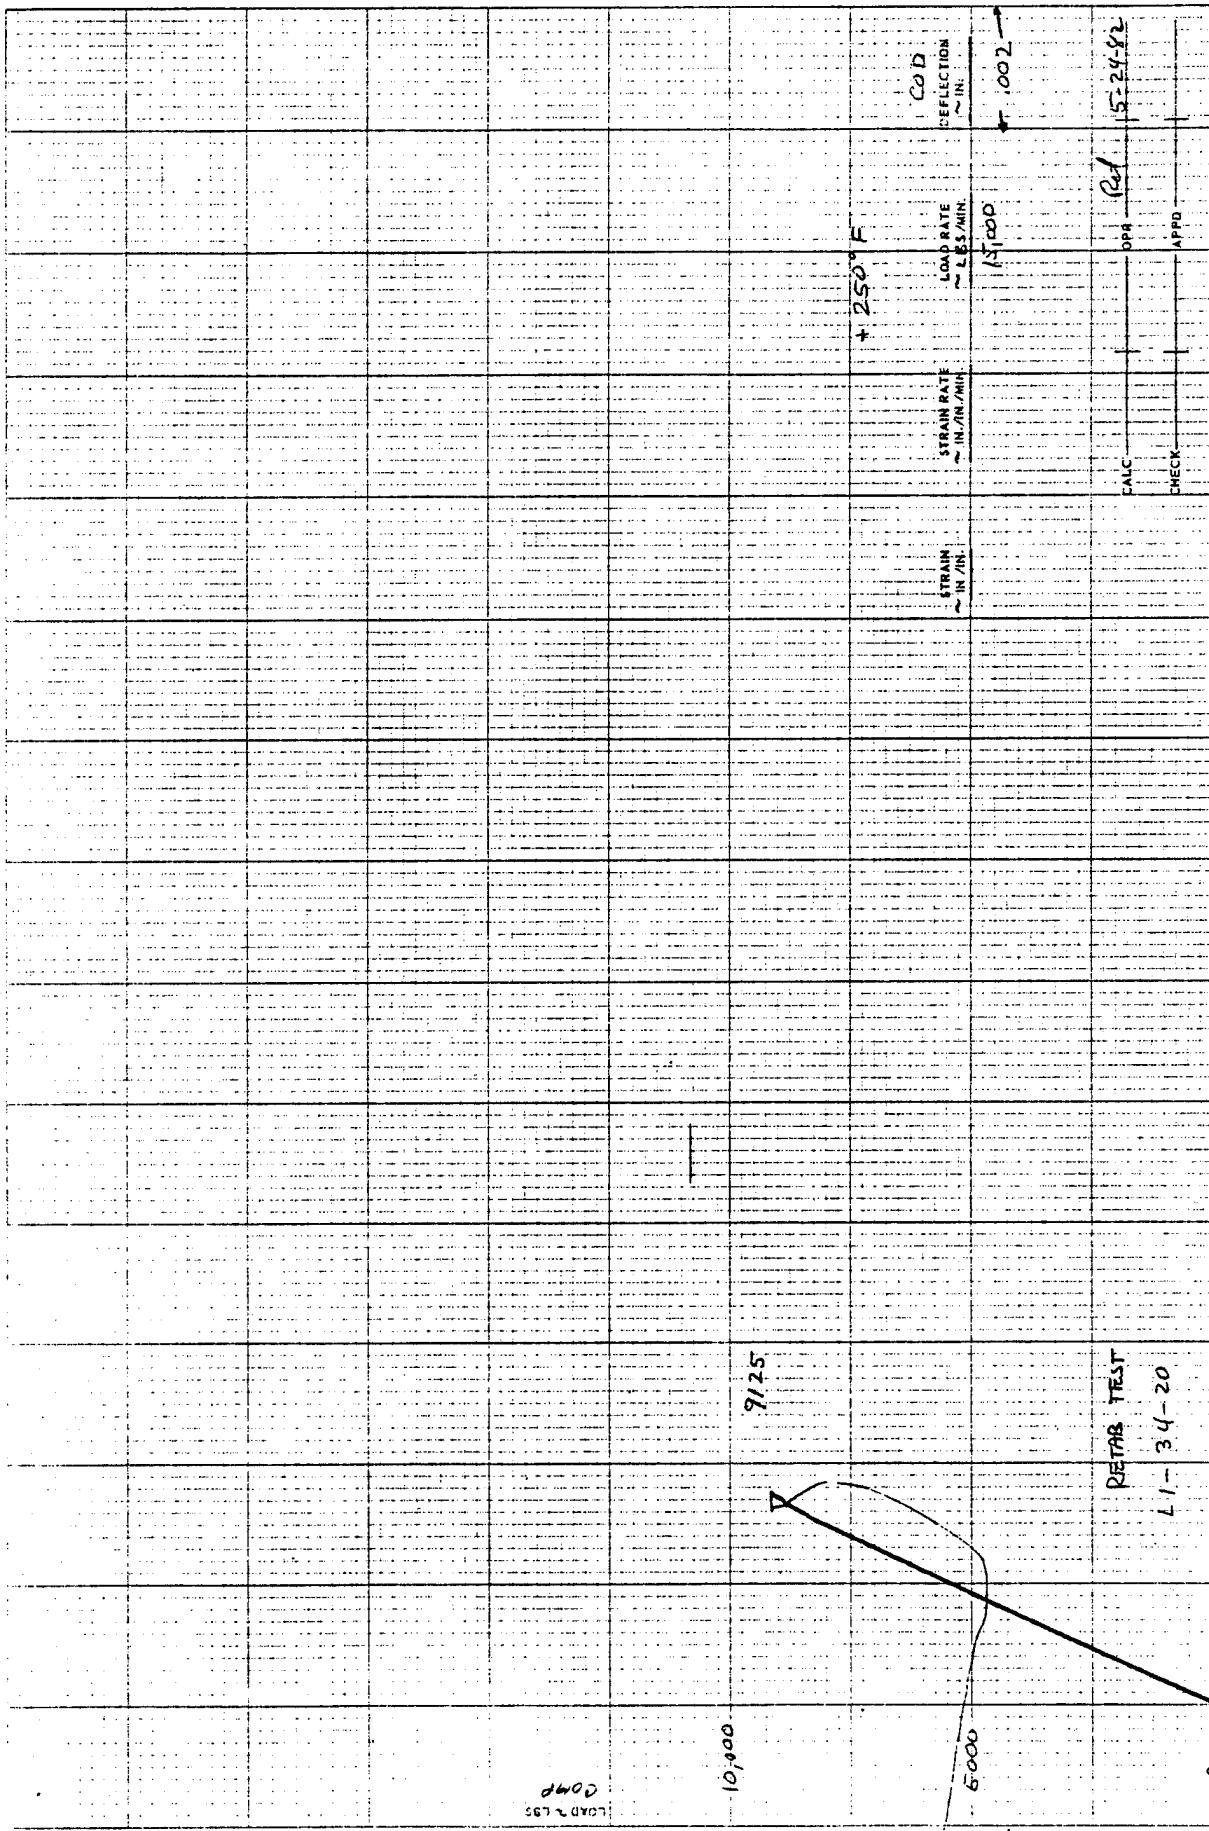

- Strain Rate = 11.875
- Load Rate = 5000

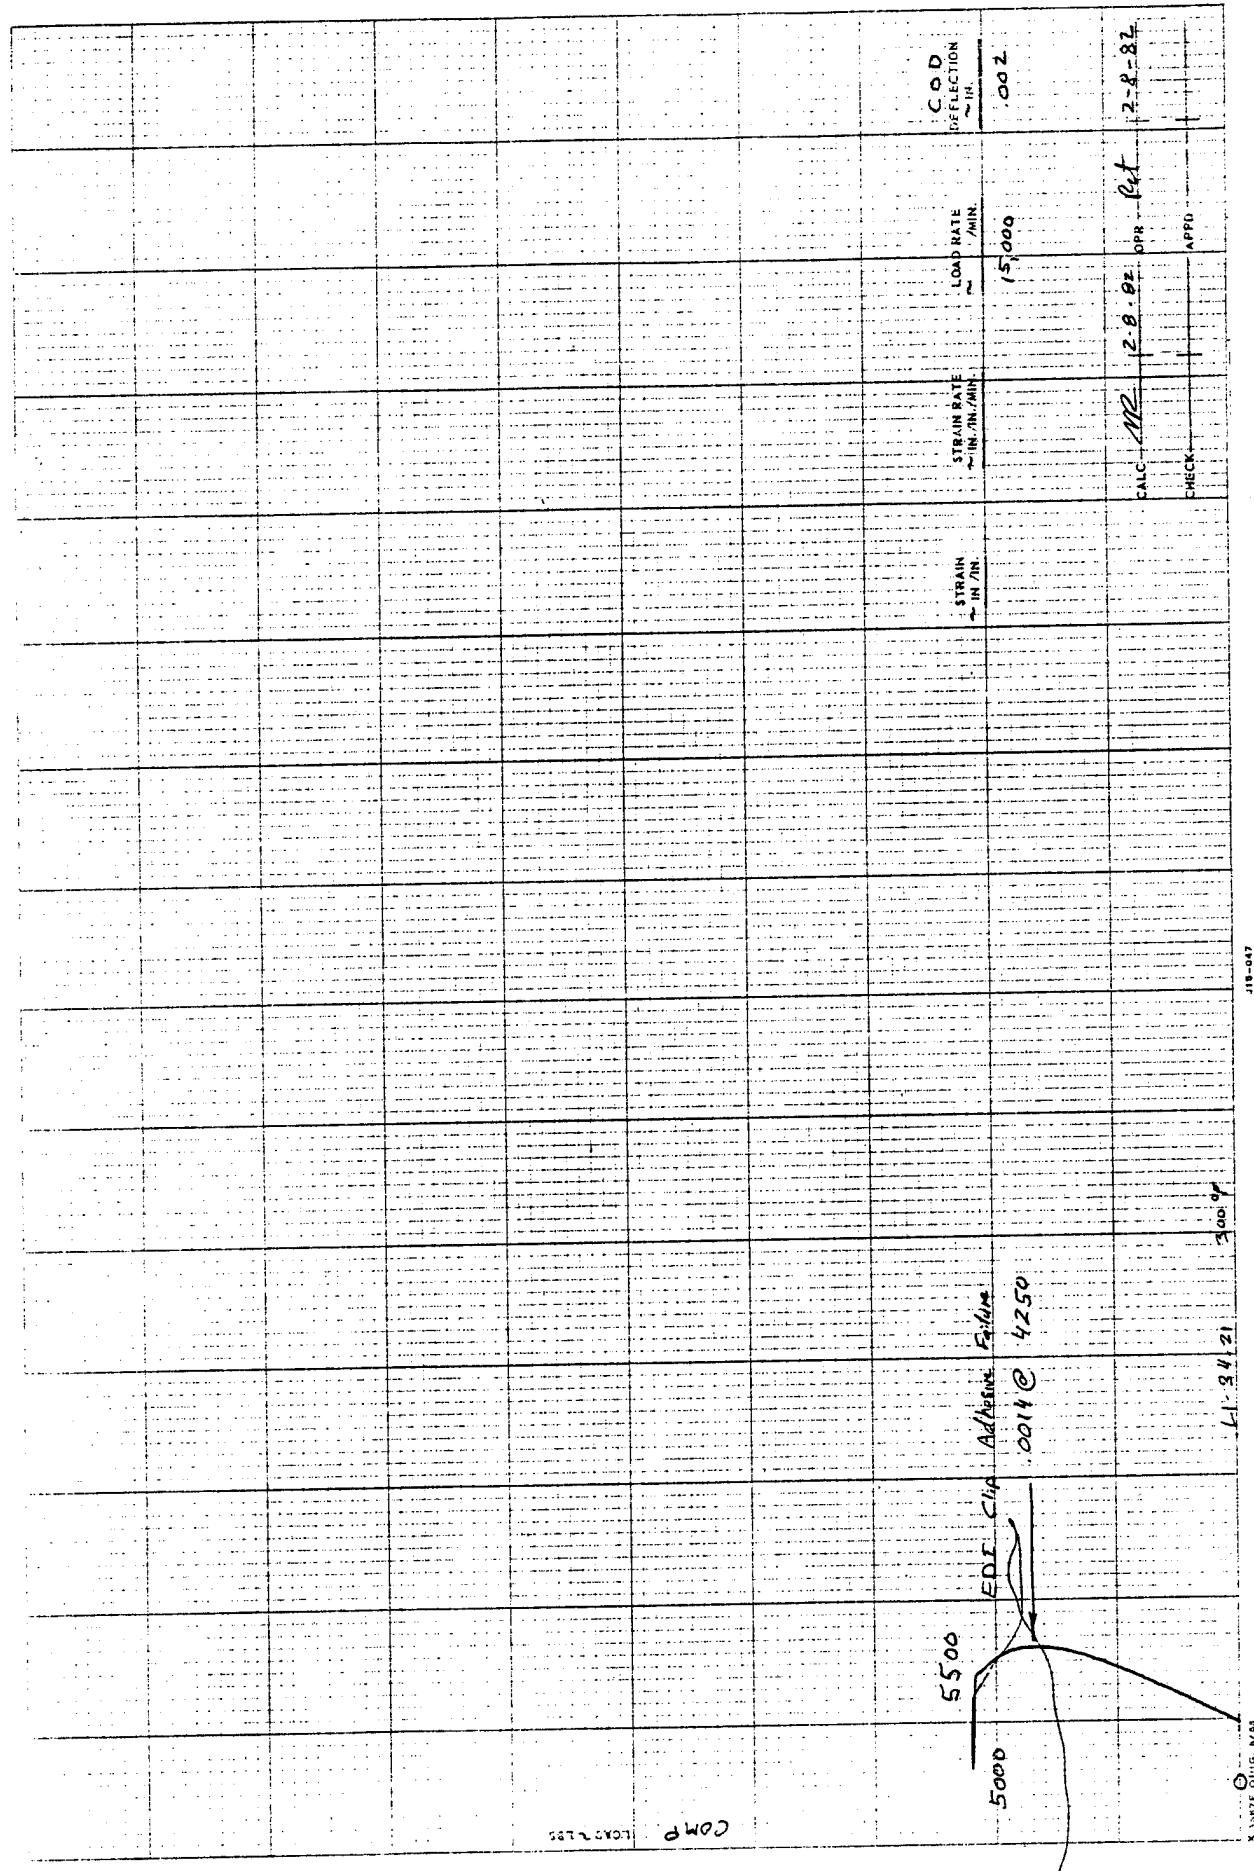

Approximate data points from the graph:

| Strain Rate (IN/IN/MIN) | Load Rate (IN/IN/MIN) |
|-------------------------|-----------------------|

| 16. Abstract<br><br>This report presents the results of a program with the objective to experimentally investigate the effects of moisture and temperature on the fatigue and fracture response of composite laminates under compression loads. The structural laminates investigated were a typical angle ply laminate and a typical turbine-engine fan blade laminate. Defects investigated were: full- and half-penetration slits and impact delaminations. Results are presented showing the effects of moisture on the fracture and fatigue strength at room temperature 394K (250°F) and 422K (300°F). Static test results are presented that show the effects of defect size and type on the compression-fracture strength under moisture and thermal environments. The cyclic test results compare the fatigue lives and residual-compression strength under compression only and under tension-compression fatigue loading. |  | 13.
