GRANT NUMBER DAMD17-94-J-4340

TITLE: Genetic Counseling Using BRCA1-Linked Markers

PRINCIPAL INVESTIGATOR: Henry T. Lynch, M.D.

CONTRACTING ORGANIZATION: Creighton University School of Medicine Omaha, Nebraska 68178

REPORT DATE: September 1996

TYPE OF REPORT: Annual

PREPARED FOR: Commander U.S. Army Medical Research and Materiel Command Fort Detrick, Frederick, Maryland 21702-5012

DISTRIBUTION STATEMENT: Approved for public release; distribution unlimited

The views, opinions and/or findings contained in this report are those of the author(s) and should not be construed as an official Department of the Army position, policy or decision unless so designated by other documentation.

INTRODUCTION

Molecular genetic research became highly pertinent to hereditary breast cancer (HBC) when Hall et al [1] described families with early-onset familial aggregations of breast cancer that were linked to the D17S74 locus on the long arm of chromosome 17. The gene is now referred to as BRCA1. Following this report, Narod et al [2] studied five large hereditary breast/ovarian cancer (HBOC) families from the Creighton HBC resource and found three of them to be positive for linkage to this BRCA1 locus. BRCA1 is a large gene which contains twenty-two coding exons distributed over approximately 100kb of genomic DNA. It produces a protein of 1863 Shattuck-Eidens et al [3] found that 86% of the 37 amino acids. different BRCA1 mutations which have been identified were either frameshifts, nonsense mutations, or splice mutations. These presumably lead to premature truncation of the BRCA1 protein.

A second susceptibility gene, BRCA2, was mapped to chromosome 13 in 1994 [4] and was identified in 1995 [5]. The majority of families with cases of male breast cancer appear to be associated with BRCA2. BRCA2 confers a high risk of breast cancer, and a low risk of ovarian cancer (\approx 10-20%).

These molecular genetic advances have provided a unique opportunity to counsel hereditary breast cancer family members, and to offer members the opportunity to be gene tested once they understand the positive as well as negative aspects of knowing their gene status.

<u>5</u>

Follow-up genetic counseling is essential.

Goals and Objectives

۰.

The initial goal of our study supported by the Department of Defense was to evaluate the impact of genetic counseling in HBC and HBOC families where BRCA1 had been identified. With the identification of BRCA2, we are now also including families with this mutation from our resource. This study is designed to demonstrate the feasibility of genetic counseling for HBC and HBOC, and to evaluate the impact of counseling on psychological state and medical behavior. The study is also designed to examine predictors of adverse consequences that could evolve from genetic testing. This information may then enable physicians and genetic counselors to anticipate and prevent problems in individual patients.

BODY

Progress to date in our study of genetic counseling based on BRCA1 and BRCA2 linked markers has been extremely well-targeted and productive. The schematic for this study is shown in the Figure.

The search for germline mutations is performed in collaboration with Steven Narod, M.D., of Women's College Hospital, Toronto, Canada, and Gilbert Lenoir, Ph.D., D.V.M., in Lyon, France.

Eligible members of BRCA1 and BRCA2-linked families receive an

<u>6</u>

introductory letter, followed by a baseline, structured telephone interview administered by a trained interviewer at Georgetown University under the direction of Caryn Lerman, Ph.D., a clinical psychologist/geneticist at Georgetown University, Washington, D.C. About four weeks later, these individuals have an opportunity to attend an education session, referred to as a Family Information Service (FIS) at which time information about gene linkage, hereditary breast cancer and surveillance measures are again reinforced <u>prior</u> to individual counseling and disclosure of genetic test results for breast-ovarian cancer susceptibility.

All genetic counseling and testing is provided by, and/or supervised by Dr. Lynch and his colleagues. Structured telephone interviews are conducted from Georgetown University at one-, six-, and twelve-months following genetic counseling to evaluate the impact of disclosure of genetic information.

<u>Results</u>

Since the initiation of this study, 14 BRCA1 families and 2 BRCA2 families have been counseled and 246 family members have been advised of their individual gene status (Table 1). Preliminary results were presented at the meetings of the American Society of Clinical Oncology, Philadelphia, PA, May, 1996, and a report has been published [6]. (Appendix). A manuscript has also been submitted to <u>Cancer</u> describing our genetic counseling experience with the 14 BRCA1 families.

<u>7</u>

An additional 27 families (245 individuals sampled) have had a mutation identified and will be counseled. Twenty-three families (148 individuals sampled) are still being evaluated. Thirty-one families (405 individuals sampled) do not, to date, have an identifiable mutation on either the BRCA1 or BRCA2 genes.

Table 2 describes the demographic characteristics of the fourteen BRCA1 families who received education at family information sessions (FIS) and/or underwent DNA testing and genetic counseling. Initially, as part of our formal linkage analysis, informative married-in spouses of family members in the direct lineage underwent DNA testing. This accounts for the fact that the total number of family members was 3,678, of whom 2,549 were direct blood line relatives.

Table 3 describes cancer of all anatomic sites in concert with those individuals who are gene positive, inclusive of obligate gene carriers, versus those who are gene negative or wherein the gene status is unknown. As expected, the overwhelming majority of these patients had carcinoma of the breast and/or ovary occurring in the gene positive/obligate gene carrier individuals.

There was a slight excess of colorectal cancer among the gene positive/obligate gene carrier class (7 cases) versus the individuals in the gene negative category. However, the gene status was unknown for eight individuals, therefore, the interpretation of whether colorectal cancer occurs in excess in the

<u>8</u>

14 BRCA1 families remains elusive [7].

The issue of prostate cancer has similar limitations. Two individuals were gene positive/obligate gene status, while two were gene negative, and seven were gene status unknown. The same concern applies to malignant melanoma where three patients were gene positive/obligate gene carrier status, three were BRCA1 negative, and two were gene status unknown. Interestingly, a sarcoma occurred in two gene positive, but none in gene negative patients, but again the numbers are too small for interpretation. The remainder of the cancer sites were not informative with respect to their BRCA1 status, but the data is presented here because of the need to publish findings pertaining to cancer of <u>all</u> anatomic sites among individuals from BRCA1 families wherein germline testing has been performed.

The reasons cited by family members <u>at baseline</u> telephone interview for wanting <u>BRCA1</u> testing and for not wanting testing were evaluated. The most widely cited reasons for wanting testing were to learn about one's children's risks and to increase use of screening tests. Of interest, almost one-half of individuals surveyed reported childbearing decisions as a "very important" reason for wanting <u>BRCA1</u> testing. This is surprising, since reproductive decision making generally is not a focus in genetic counseling for cancer susceptibility. Overall, fewer individuals reported strong reasons for not having testing. This is consistent

<u>9</u>

with the high level of acceptance of testing in this population. However, concerns about the effect of testing on one's family and worries about losing health insurance were cited most frequently as barriers to receiving <u>BRCA1</u> test results.

Table 4 shows the demographic characteristics of the 181 blood line relatives from the 14 BRCA1 families who were counseled, tested, and received results of their individual DNA testing.

We examined whether persons who came forward for BRCA1 testing had different sociodemographic backgrounds than those who declined, a finding which was supported by our data. Individuals who decided to be tested were predominantly female, under age 50, had at least a high school education, and had health insurance. Thus, <u>BRCA1</u> test decliners were mostly males over age 50 who had not completed high school and had no health insurance. In a logistic regression model, the following factors were significant independent predictors of acceptance of testing: gender (OR=3.8, CI=1.8-8.1), age (OR=2.9, CI=1.3-6.2), education (OR=3.4, CI=1.1-11.2), and health insurance status (OR=5.1, CI=1.5-17.0). Thus, females were almost four times more likely than males to request testing; individuals under age 50 were $3\frac{1}{2}$ times more likely than those over age 50; and individuals with health insurance were about five times more likely than those who did not have insurance [6].

Table 5 provides information about emotional responses among

<u>10</u>

individuals who received their BRCA1 result. Not unexpectedly, those receiving BRCA1 positive information had more emotional responses of sadness when compared to the relief obtained among those who received BRCA1 negative information.

Short-term Impact of BRCA1 Testing on Depressive Symptoms. The psychological and behavioral impacts of <u>BRCA1</u> testing are being evaluated using validated psychometric tools that are administered during baseline and follow-up telephone interviews. These interviews are conducted with individuals who test positive, negative, and with those who decline testing. Outcomes of interest in this study include perceptions of risk, depression, functional health status, screening behaviors, and medical and reproductive decision-making.

Depression symptoms reported at baseline by individuals in these HBOC families do not differ from general population norms for depression using the Center for Epidemiologic Studies Scale [8]. This is somewhat surprising in light of previous studies showing elevated distress levels in women at risk for breast cancer [9,10]. It is possible that members of hereditary breast cancer families develop stronger coping mechanisms as a result of repeated experiences of having relatives diagnosed with cancer.

Following disclosure of <u>BRCA1</u> status, carriers show a slight elevation in depressive symptoms over time (about .10 standard

<u>11</u>

deviations), while noncarriers show a slight decline in depression (about .25 standard deviations). These changes in depression in carriers and noncarriers are not statistically or clinically significant.

Tables 6 and 7 depict our interpretation of the attitudes about surveillance and prophylactic surgery among BRCA1 positive versus BRCA1 negative patients. As expected, a significantly larger number of individuals in the BRCA1 positive category (32%) had already manifested carcinoma of the breast and had undergone mastectomies when compared to those who were BRCA1 negative (where only 6% had already manifested carcinoma of the breast) (p= .001). Thirty-two percent of patients in the BRCA1 positive category and 22% in the BRCA1 negative category had considered prophylactic mastectomy prior to receiving their results. In contrast, 35% in the BRCA1 positive status category contemplated prophylactic mastectomy after receiving their results, but none of the negative women continued to consider this option (p= .012).

It was of interest that 73% of BRCA1 positive individuals had considered prophylactic oophorectomy <u>prior</u> to receiving their results, and 40% of those who were negative for BRCA1 had considered prophylactic oophorectomy prior to receiving their results (p= .002). However, after receiving findings that their status was positive for BRCA1, 76% considered prophylactic oophorectomy, while none in the negative BRCA1 category considered

<u>12</u>

prophylactic oophorectomy (p= .001).

Insurance Issues

· · .

About one-fourth of the individuals in both BRCA1 positive and BRCA1 negative categories were concerned about their potential for insurance discrimination. In a sample of 88 individuals tested for BRCA1 mutations, 4 of them indicated problems in obtaining or maintaining insurance; however, in each of these cases the difficulties predated receipt of test results. Four out of 38 individuals who tested positive indicated changes their in insurance since testing; however, these changes were unrelated to genetic testing [6]. Our preliminary data indicate that insurance concerns may have an effect on decisions to receive BRCA1 testing and on medical decision-making. For example, 18% of mutation carriers indicated that insurance concerns affected their decisions Thus, it is critical that about receiving prophylactic surgery. the potential for insurance discrimination be addressed during the pre-test education session.

CONCLUSION

While these preliminary results are encouraging, caution must be taken in generalizing to all individuals who may participate in <u>BRCA1</u> testing. Individuals in this study received extensive education and counseling as part of their involvement in prior linkage studies. The psychological effects of <u>BRCA1</u> testing may differ for individuals who are less aware of their personal risk

<u>13</u>

and who receive test results outside of a controlled research setting. In addition, patients' scores on the depression measure at one-month follow-up show large standard deviations. This suggests that there is substantial variability within the groups of carriers and noncarriers in their responses to testing. This supports the clinical observation that individuals vary widely in how they respond psychologically to genetic information. Once sufficient numbers of individuals have been accrued to this trial, it will be important to identify and characterize the subset of participants who may experience adverse effects following receipt of positive or negative results of <u>BRCA1</u> testing in all areas that are being evaluted in our study.

BRCA1 Testing in Families With Hereditary Breast-Ovarian Cancer

A Prospective Study of Patient Decision Making and Outcomes

Caryn Lerman, PhD; Steven Narod, MD, FRCPC; Kevin Schulman, MD; Chanita Hughes, MS; Andres Gomez-Caminero, MPH; George Bonney, PhD; Karen Gold, PhD; Bruce Trock, PhD; David Main, MS; Jane Lynch, RN; Cecil Fulmore, MS; Carrie Snyder, RN; Stephen J. Lemon, MD, MPH; Theresa Conway, RN; Patricia Tonin, PhD; Gilbert Lenoir, DVM; Henry Lynch, MD

Objectives.—To identify predictors of utilization of breast-ovarian cancer susceptibility (*BRCA1* gene) testing and to evaluate outcomes of participation in a testing program.

Design.—Prospective cohort study with baseline interview assessment of predictor variables (eg, sociodemographic factors, knowledge about hereditary cancer and genetic testing, perceptions of testing benefits, limitations, and risks). *BRCA1* test results were offered after an education and counseling session in a research setting. Outcome variables (including depression, functional health status, and prophylactic surgery plans [follow-up only]) were assessed at baseline and 1-month follow-up interviews.

Participants.—Adult male and female members (n=279) of families with *BRCA1*-linked hereditary breast-ovarian cancer (HBOC).

Results.—Of subjects who completed a baseline interview (n=192), 60% requested *BRCA1* test results (43% of all study subjects requested results). Requests for results were more frequent for persons with health insurance (odds ratio [OR], 3.74; 95% confidence interval [CI], 2.06-6.80); more first-degree relatives affected with breast cancer (OR, 1.59; 95% CI, 1.16-2.16); more knowledge about *BRCA1* testing (OR, 1.85; 95% CI, 1.36-2.50); and indicating that test benefits are important (OR, 1.45; 95% CI, 1.13-1.86). At follow-up, noncarriers of *BRCA1* mutations showed statistically significant reductions in depressive symptoms and functional impairment compared with carriers and nontested individuals. Individuals identified as mutation carriers did not exhibit increases in depression and functional impairment. Among unaffected women with no prior prophylactic surgery, 17% of carriers (2/12) intended to have mastectomies and 33% (4/12) to have oophorectomies.

Conclusions.—Only a subset of HBOC family members are likely to request *BRCA1* testing when available. Rates of test use may be higher in persons of a higher socioeconomic status and those with more relatives affected with breast cancer. For some high-risk individuals who receive test results in a research setting that includes counseling, there may be psychological benefits. More research is needed to assess the generalizability of these results and evaluate the long-term consequences of *BRCA1* testing.

(JAMA. 1996;275:1885-1892)

Omaha, Neb (Mss Lynch, Snyder, and Conway and Drs Lemon and Lynch); Department of Human Genetics, McGill University, Montreal, Quebec (Dr Tonin); and Unit of Mechanisms of Carcinogenesis, International Agency for Research in Cancer, Lyon, France (Dr Lenoir).

Reprints: Caryn Lerman, PhD, Division of Cancer Prevention and Control, Georgetown University Medical Center, 2233 Wisconsin Ave NW, Suite 535, Washington, DC 20007. THE ISOLATION of the BRCA1 gene offers an unprecedented opportunity for high-risk members of families with hereditary breast-ovarian cancer (HBOC) to learn whether they carry a cancerpredisposing mutation.¹ Females found to carry a mutation in BRCA1 have an 80% to 90% lifetime risk of breast cancer, a 40% to 65% lifetime risk of ovarian cancer, and an increased risk of colon cancer.^{2,3} Male mutation carriers are at increased risk for prostate and colon cancer and can also transmit breast-ovarian cancer susceptibility to their daughters.³ Early identification of BRCA1 mutation carriers within HBOC families can allow for targeted surveillance and management strategies.4-6

For editorial comment see p 1928.

At present, little is known about whether high-risk patients from HBOC families will want to know their mutation status or how they will make decisions about undergoing BRCA1 testing. Preliminary reports indicate that there is strong interest in BRCA1 testing, both in the general population and in highrisk families.⁷⁻¹⁰ However, past experiences with Huntington disease (HD gene) and cystic fibrosis (CF gene) have shown that usage rates of genetic tests may be substantially lower than anticipated based on stated intentions to receive a hypothetical genetic test.¹¹⁻¹⁴ For example, prior to the initiation of testing for the *HD* gene, two thirds of at-risk individuals expressed strong interest in testing.^{15,16} Following the introduction of predictive testing programs, fewer than 15% of those who initially expressed interest participated.¹¹

From the Department of Medicine, Lombardi Cancer Center, Georgetown University Medical Center, Washington, DC (Drs Lerman, Schulman, Gomez-Caminero, Gold, and Trock, Ms Hughes, and Messrs Main and Fulmore); Department of Medicine, Women's College Hospital, Toronto, Ontario (Dr Narod); Division of Population Science, Fox Chase Cancer Center, Philadelphia, Pa (Dr Bonney); Department of Preventive Medicine and Public Health, Creighton University Medical Center,

In deciding whether to have BRCA1 testing, patients must weigh complex information about the potential benefits of testing against the limitations and possible risks of this new technology. These limitations and risks include uncertainties inherent in cancer risk figures,² the absence of proven strategies for preventing cancer in carriers (including surgical prophylaxis),17 the risk of genetic discrimination in employment or in obtaining or maintaining insurance,¹⁸ and the potential for negative psychological consequences of learning one's genetic status.^{6,19,20} Models of consumer health behavior^{21,22} can be used to understand better the ways that patients will process this complex information in deciding whether to be tested for BRCA1 mutations. These frameworks predict that patients would acquire knowledge about the inheritance of breast-ovarian cancer susceptibility and about the test itself. This knowledge would then shape their perceptions of the benefits, limitations, and risks of being tested. Perceptions of the importance of the benefits of BRCA1 testing would be expected to facilitate test use, while concerns about the limitations and risks should hinder use of this test.

For individuals who decide to have a BRCA1 test, adverse psychological consequences are considered to be a potential risk.²⁰ This concern is based on anecdotal reports of participants in genetic linkage studies^{6,19} and on the results of studies of women's anticipated emotional reactions to a hypothetical BRCA1 test.^{8,9} As yet, however, there are no published empirical accounts of the effects of BRCA1 testing on participants' psychological and functional health status. The importance of conducting a systematic evaluation of genetic testing outcomes was underscored by a major prospective study of genetic testing for Huntington disease.23 In contrast to the serious adverse psychological effects of genetic testing for Huntington disease that had been anticipated based on anecdotal reports,²⁴ the prospective study found that testing had long-term psychological benefits-both for carriers and for noncarriers of HD gene mutations.

To fill the gap in our knowledge of patient decision making and the outcomes of *BRCA1* testing, we conducted a prospective observational study of 279 members of *BRCA1*-linked HBOC families. This study had 3 principal goals: (1) to examine predictors of decisions to receive *BRCA1* test results, including sociodemographic factors, knowledge, and perceptions of the benefits, limitations, and risks of testing; (2) to evaluate the effects of *BRCA1* testing on psychological and functional health status; and (3) to evaluate how testing influences participants' medical decisions. At present, it is recommended that BRCA1 testing be provided only to members of high-risk families in the context of research protocols.^{25,26} By identifying factors associated with actual utilization in these studies, we can estimate the magnitude of the demand for BRCA1 testing and identify the characteristics of those who are likely to request such testing. In addition, a better understanding of patient decision making is necessary to guide the development of educational materials and informed consent protocols for BRCA1 testing. Finally, to the extent that we can delineate the psychosocial effects of BRCA1 testing, we will be better able to provide counseling and to attend to participants' psychosocial and medical needs.

METHODS

Study Population

Eligible subjects included 279 women and men, aged 18 years and older, who are members of 13 extended HBOC families from a registry maintained by the Creighton University Hereditary Cancer Institute. These families were enrolled into a prospective observational study during the period from July 1994 through November 1995. These families were selected from the registry because the BRCA1 mutations (and in 1 family, a multipoint lod score of 6.2) had previously been identified.27 The study sample included unaffected at-risk family members (without cancer at present) as well as family members affected with cancer. Affected family members were included because, in some cases, cancers were sporadic and not due to inherited susceptibility. The 38 affected individuals included 21 women with breast cancer, 4 women with ovarian cancer, 3 women with breast and ovarian cancer, 2 men with prostate cancer, and 8 patients with other cancers. Subjects were considered ineligible for this study if they had a psychiatric or cognitive disorder which precluded informed consent (1 mentally retarded subject was excluded based on this criterion).

The families under investigation had participated in prior genetic studies.^{28,29} As part of these prior studies, family members had received written educational materials about the genetics and natural history of HBOC, although none had received the results of *BRCA1* testing prior to the current research project.

Procedures

All study procedures had been approved by the Creighton University Institutional Review Board. Eligible male and female members of these extended families received an introductory letter explaining the prospective study and inviting them to participate. Individuals who did not wish to be contacted for the interview returned a self-addressed stamped postcard to the investigator (these individuals were still offered BRCA1 testing and their decisions were recorded). Those who did not decline to be interviewed were contacted within 2 weeks to obtain oral consent for the baseline telephone interview. It was stressed that agreeing to the baseline interview did not obligate them to participate in the education session or to receive their BRCA1 test results. A professional interviewer from Lombardi Cancer Center conducted a 40-minute structured telephone interview 1 to 2 months prior to the education session and the offer of BRCA1 test results. Measures included sociodemographic characteristics; medical history; baseline levels of knowledge; baseline perceptions of the benefits, limitations, and risks of BRCA1 testing; and depression and functional health status (see description of measures below).

All family members were subsequently invited to attend an education session on BRCA1 testing. These 1- to 2-hour sessions were conducted on a family-by-family basis through a series of trips to a geographic area central to most family members. Individuals who were unable to attend the education session for their family were given the option of traveling to Creighton University (funds were available through the research grant to support this travel) or to receive the education by telephone. An oncologist/geneticist (H.T.L.) conducted all education sessions following a semistructured protocol. After written informed consent was obtained, the following topics were addressed: (a) inheritance of breastovarian cancer susceptibility; (b) cancer risks associated with BRCA1 mutations, including breast, ovarian, colon, and prostate cancer; (c) genetic linkage studies, gene identification, and tests for mutation status; (d) benefits of genetic testing, including the potential for early detection and reduction of uncertainty; (e) limitations of genetic testing, including incomplete penetrance (not all mutation carriers get cancer) and etiologic heterogeneity (noncarriers can still get cancer); (f) risks of genetic testing, including the potential for loss of insurance or employment and adverse psychosocial consequences for oneself and one's family; (g) options for prevention and surveillance and their limitations (including the possibility of peritoneal cystadenocarcinomatosis of the ovary); and (h) assurance of confidentiality of test results and related information.

After the education session, participants were given the option of receiving their BRCA1 test results. To increase access to the counseling, test results were made available on the same day as the education session. This was possible because linkage results and mutational status had been determined as part of prior genetic studies and subsequently confirmed in an independent laboratory. Individuals had been informed in the introductory letter that results would be available. However, they were also informed that they could elect to receive their results at any time after receipt of pretest education. Because testing was conducted in the context of a research protocol, all testing and counseling were free of charge. In accordance with current guidelines,²⁵ all individuals who wished to receive their test results provided additional written informed consent.

511 -

Individuals who elected to receive their BRCA1 test results participated in an individual counseling session with a physician/geneticist (H.T.L., S.N., or S.J.L.). The following topics were addressed according to a standardized counseling protocol: (a) patient expectations about the test result, (b) the test result and associated cancer risks for the individual and his or her offspring, (c) available options for surveillance and prevention and the associated limitations and risks, (d) the patient's plans for communicating his or her test results to others, (e) assertion of confidentiality of all test results and related information, and (f) supportive counseling as needed. All study subjects were recontacted for a telephone interview assessment of depression, functional health status, and medical decision making 1 month later.

Predictors of Utilization

All predictor variables were assessed at baseline, prior to the education session and the offer of receipt of *BRCA1* test results.

Sociodemographic and Clinical Variables.—Sex, age, education level, marital status, employment status, health insurance status, clinical status (affected vs unaffected), and number of first-degree relatives affected with breast or ovarian cancer were assessed.

Knowledge About Inherited Breast Cancer and *BRCA1* Testing.—An 11item true-false measure was used to assess knowledge of inheritance of breastovarian cancer susceptibility and genetic testing. This measure has high internal consistency (coefficient $\alpha = .74$). It includes items used in a core instrument developed for use by the National Center for Human Genome Research (NCHGR) Cancer Studies Consortium.

Perceptions of the Importance of the Benefits, Limitations, and Risks of BRCA1 Testing .--- A 12-item measure, developed and validated in previous research,^{8,9} was used to assess attitudes about BRCA1 testing. Subjects were offered a series of items enumerating potential benefits, limitations, and risks of BRCA1 testing and were asked to indicate whether each was "not at all important," "somewhat important," or "very important" in their decision to have a BRCA1 test. Principal components factor analysis indicated that this measure consists of 2 independent factors with a nonsignificant negative correlation. These 2 factors, labeled "perceptions of benefits" (pros) and "perceptions of limitations/risks" (cons) are highly internally consistent (coefficient $\alpha = .83$ and .81, respectively).

Outcome Variables

BRCA1 Testing Decisions.—All subjects (including interview respondents and nonrespondents) were classified as either requesters or decliners of *BRCA1* testing. Requesters were those who received their *BRCA1* test results within the time frame of this study. Decliners were those who indicated that they did not wish to know their *BRCA1* mutation status at the present time. Status (request vs decline) was confirmed during the 1-month follow-up phone contacts.

Depression Symptoms.—The Center for Epidemiologic Studies Depression (CES-D) Scale was administered during the baseline and 1-month follow-up telephone interviews to assess depressive symptomatology. This scale has adequate test-retest reliability (r=0.57 for 2-8 weeks) and has been shown to correlate with clinical ratings of the severity of depression.³⁰ The Cronbach coefficient α in our sample was .91. Possible scores on this measure range from 0 to 60, with higher scores reflecting more depressive symptoms.

Functional Health Status.-Functional health status was assessed during the baseline and 1-month follow-up telephone interviews using 2 targeted scales from the Medical Outcomes Study (MOS).^{31,32} The 4-item role functioning scale of the MOS was used as a measure of impairment in daily activities³¹ (Cronbach coefficient $\alpha = .75$). Scores on this measure range from 0 to 4. The 4-item sexual functioning scale was used because of the potential implications of BRCA1 testing for reproductive and sexual functioning³² (Cronbach coefficient $\alpha = .84$). Scores on this measure range from 4 to 16. Both of these measures were scored such that higher scores reflected greater impairment in functioning.

Medical Decision Making.—During the 1-month follow-up interview, 2 individual items were administered to assess the impact of receipt of *BRCA1* test results on decisions about prophylactic mastectomy and prophylactic oophorectomy.

Statistical Analysis

Descriptive statistics were used to determine the rates of participation and to characterize the study population in terms of knowledge of *BRCA1* testing and perceptions of the importance of the benefits, limitations, and risks of testing. Variables associated with *BRCA1* testing decisions were analyzed using χ^2 tests and t tests and by multivariate logistic regression models. Since members within a given family may have had correlated outcomes,^{33,34} we used logistic regression analysis with general estimating equations³⁵ to account for intrafamily clustering.

The second stage of analysis focused on evaluating the psychosocial effects of BRCA1 testing at 1-month follow-up. To identify possible baseline confounder variables, associations between study group (carrier, noncarrier, or decliner) and sociodemographic variables were assessed using χ^2 tests. Variables having significant associations with the study group were examined for their effects on 3 outcome variables (depressive symptoms, role impairment, and sexual impairment) using t tests and 1-way analyses of variance (ANOVAs). Next, 1-way ANOVAs were performed to test for differences between carriers, noncarriers, and decliners in terms of baseline psychological and functional status, as well as changes from baseline to 1-month follow-up. Linear regression analysis with general estimating equations³⁵ was used to examine changes in functioning while controlling for baseline levels, other potential confounder variables, and correlated responses within families. These analyses of the effects of testing were conducted for all study participants and then repeated excluding affected participants. Finally, effects of BRCA1 testing on medical decision making in carriers and noncarriers were examined using an extension of the Fisher exact test.³⁶

RESULTS

Response Rate to Baseline and Follow-up Interviews

As shown in Figure 1, of the 279 eligible men and women, 192 (69%) completed the baseline telephone interview, and 87 (31%) refused. Compared to interview respondents, nonrespondents were more likely to be male (χ^2 =15.1;

P < .001) and to have had a prior diagnosis of cancer (χ^2 =4.4; P=.03), but did not differ significantly in age. The vast majority of interview nonrespondents (81/87) also declined BRCA1 test results when offered. Among the 192 individuals who completed the baseline interview, 140 (73%) were recontacted and completed the 1-month follow-up interview; the remaining subjects could not be reached after multiple attempts. Individuals lost to follow-up (n=52) were significantly more likely to have declined BRCA1 testing (n=33) (χ^2 =16.2; P<.001), to be male (n=26) (χ^2 =9.6; P=.002), to lack health insurance (n=9) (χ^2 = 10.6; P=.001), and to be unaffected (n=47) $(\chi^2=4.6; P=.03)$. Individuals lost to followup were similar to remaining subjects with respect to any other demographic or clinical variables or in terms of the primary outcomes of depression and functional health status.

Sociodemographic Factors, Knowledge of *BRCA1* Testing, and Perceptions of the Importance of the Benefits and Limitations or Risks of Testing

The average (SD) age of interview respondents was 43 (14) years. All respondents were white, 67% were female, and 77% were married. Most (90%) had completed high school and most (93%) had health insurance.

Responses to the baseline knowledge

1888 JAMA, June 26, 1996—Vol 275, No. 24

measure are shown in Table 1. Scores on this measure ranged from 0 to 11, with an average (SD) score of 5.97 (2.91). Thus, on average, subjects gave correct responses to about 55% of the items. The percentage of subjects responding correctly to individual knowledge items ranged from 10% to 75%.

As shown in Table 2, the benefit of BRCA1 testing rated as most important was "to learn about my children's risks" (rated by 96% of participants as somewhat or very important). The most important perceived limitation or risk of testing was "test results might not be accurate" (rated by 40% of participants as somewhat or very important). The possibility of losing health insurance was rated as a somewhat or very important limitation or risk of testing by 34% of the sample. Interestingly, individuals with and without health insurance endorsed this item at the same rate. Scores for the perception of benefits scale and the perception of limitations or risks scale ranged from 6 to 18, with average (SD) scores of 15.30 (2.78) and 8.47 (2.48), respectively. Overall, individuals rated the benefits of testing as significantly more important than the limitations or risks of testing ($t_{190}=2.71$; P=.007).

Utilization of BRCA1 Testing

The rates of participation and *BRCA1* testing decisions are shown in Figure 1. Among all family members offered the opportunity to receive their BRCA1 test results (n=279), 43% requested their test results (n=121), and 57% declined (n=158). The rate of requests for testing was higher when the denominator included only those individuals who participated in the baseline interview (n=192). In this sample of respondents, 116 individuals (60%) opted to receive pretest education and all but 1 of these decided to obtain the results of testing. The results presented below compare baseline interview respondents who elected to receive *BRCA1* test results (n=115; 60%) with those who declined (n=77; 40%). Of those who received the test results, 46% (n=53) were mutation carriers and 54% (n=62) were noncar-

riers. Information on specific mutations has been previously reported.²⁷

Predictors of Utilization of BRCA1 Testing

The results of the bivariate analyses of BRCA1 testing decisions are shown in Table 3. BRCA1 test use was associated with female sex, having a high school education or beyond, and having health insurance. Having a greater number of firstdegree relatives with breast cancer was positively related to test use, while the number of relatives with ovarian cancer was not. There was a marginal association (P=.053) between test use and clinical status (affected vs unaffected). Marital status and employment were unrelated to BRCA1 testing. Baseline knowledge about BRCA1 testing $(t_{190}=4.46; P<.001)$ and perceived importance of the benefits of testing $(t_{190}=2.76; P=.006)$ both related strongly to test use, while the perceived importance of the limitations or risks of testing was not.

To identify factors having independent associations with BRCA1 testing decisions, predictor variables with P < .10associations in bivariate analyses were tested in logistic regression models (Table 4). Significant independent predictors of test use in this model included the number of first-degree relatives with breast cancer (OR, 1.59; 95% confidence interval [CI], 1.16-2.16) and having health insurance (OR, 3.74; 95% CI, 2.06-6.80). Knowledge of BRCA1 testing and perceived importance of the benefits of testing both exhibited independent positive associations with BRCA1 test use (OR, 1.85; 95% CI, 1.36-2.50 and OR, 1.45; 95% CI, 1.13-1.86, respectively). Odds ratios for these continuous measures were based on a 1 SD difference in scale scores. Thus, individuals who scored 1 SD above the mean on either knowledge of BRCA1 testing or the perceived benefits of testing were 1.5 to 2times more likely to use BRCA1 testing than individuals scoring at the mean. 2 X X #

†Odds ratios reflect the increase in odds associated with each additional first-degree relative.

‡Odds ratios reflect the increase in odds associated with 1 SD increase in the continuous measure.

Education level and sex did not enter this adjusted model, despite significant bivariate associations with *BRCA1* test use. This may be due to multicollinearity with the knowledge variable. The model was repeated excluding affected subjects and the results were similar.

Psychosocial Outcomes of *BRCA1* Testing

To identify potential baseline confounder variables, we compared the 3 study groups (carriers, noncarriers, and decliners) with respect to sociodemographic and clinical variables. Only 2 variables had significant associations with the 3-level study group variable: clinical status (affected vs unaffected) $(\chi^2=31.8; P<.001)$ and number of affected first-degree relatives ($\chi^2 = 10.7$; P = .03). Not surprisingly, carriers had a significantly greater number of affected firstdegree relatives than noncarriers or decliners and were more likely to be affected themselves. However, neither of these 2 variables was associated with changes in depression, role impairment, or sexual impairment and therefore would not be likely confounder variables. Nonetheless, because of the increased relevance of BRCA1 testing for unaffected individuals, we conducted 2 sets of outcome analyses: 1 set of analyses for all subjects and 1 set for unaffected individuals only. The latter set of analyses also served to control for heterogeneity that potentially could mask meaningful between-group differences in psychosocial outcomes.

The psychological and functional health status outcomes by study group (carrier, noncarrier, and decliner) are shown in Table 5. The study groups had similar baseline levels of depression and sexual impairment, but differed at baseline with respect to role impairment; ie, noncarriers had higher baseline levels of role impairment $(F_{2,137}=3.59; P=.03)$. Baseline levels for all measures were within the normal ranges.³⁰⁻³² In the analysis of all subjects, significant between-group differences in changes from baseline to 1-month posttesting were observed for role impairment ($F_{2,137}=8.61$; P<.001). Nonsignificant between-group differences in change scores were observed for depression $(F_{2,137}=2.83; P=.06)$ and sexual impairment ($F_{2,116}=2.39$; P=.10). Among unaffected subjects, significant betweengroup differences in change scores were observed for depression $(F_{2.104}=3.00;$ P=.05) and role impairment ($F_{2.104}=7.39$; P=.001). A nonsignificant between-group difference in change scores was observed for sexual impairment ($F_{2,83}=2.68; P=.07$). As shown in Table 5, noncarriers and carriers in unaffected subjects both showed consistent reductions in all 3 measures of Table 5.--Psychological and Functional Health Status by Study Group

*The variable for depression is based on the Center for Epidemiologic Studies Depression Scale. The variables for role impairment and sexual impairment are based on scales from the Medical Outcomes Study. †Scores shown are changes from baseline to 1-month follow-up. Higher scores reflect more impairment.

These items had "not applicable" responses from 21 of the subjects.

distress and impairment (reflected in negative change scores), while decliners showed small increases or no change.

Multiple linear regression models were generated to predict changes in each of the 3 psychosocial outcome variables (depression, role impairment, and sexual impairment); these models examined the effect of study group while controlling for baseline levels of the outcome variable. In the analyses of all subjects, noncarriers exhibited significantly greater reduction in depression than both carriers and decliners ($\beta = 3.07$, $P < .001; \beta = 3.10, P < .001,$ respectively). Noncarriers also exhibited significantly greater reduction in role impairment than both carriers and decliners ($\beta = .55$, $P = .001; \beta = .60, P = .004,$ respectively). For sexual impairment, noncarriers exhibited significantly greater reductions than decliners ($\beta = 1.17$; P = .03), but did not differ from carriers. Those identified as carriers did not show increases in depression and functional impairment. When conducted with unaffected individuals only, results for depression did not change. Role impairment differed only between noncarriers and carriers, and there were no significant differences between the 3 groups of unaffected individuals in sexual impairment.

Medical Decision Making

The impact of BRCA1 testing on prophylactic surgery decisions was examined for unaffected women who received their BRCA1 test results. As shown in Table 6, 17% of carriers reported that they intended to obtain prophylactic mastectomies and 33% intended to obtain prophylactic oophorectomies. An additional 17% of carriers remained undecided. None of the noncarriers intended to have prophylactic surgery. It is notable that of 9 unaffected women who had previously opted for prophylactic

mastectomies, 5 were determined to be carriers and 4 were noncarriers of a BRCA1 mutation. Of the 15 women who had previous oophorectomies, 4 were determined to be carriers and 11 were noncarriers.

COMMENT

Forty-three percent of all individuals from HBOC families requested BRCA1 test results when offered. Among individuals who agreed to participate in a baseline telephone interview, 60% requested test results. While these rates are somewhat lower than predicted based on prior surveys of interest in BRCA1 testing in HBOC families,¹⁰ they exceed the rates of uptake for other new genetic tests such as those for the HD and CFgenes.¹¹⁻¹⁴ This is not surprising considering key differences between breast cancer and other genetic disorders. For example, unlike Huntington disease and cystic fibrosis, there are options available for potentially reducing breast cancer risk; if breast cancer is found early, treatment may be effective.

There are other possible explanations for the higher rates of BRCA1 test use in this study. First, subjects were members of a hereditary cancer registry and had provided blood samples for previous genetic studies.²⁷⁻²⁹ They were also aware that BRCA1 test results would be available on the same day as the pretest education. Utilization of carrier testing has been shown to increase when the offer of test results is immediate vs delayed.^{13,14} Second, testing was offered in the context of a research study and was therefore free of cost. The cost of commercial BRCA1 testing may range from approximately \$150 to \$1500, depending on whether the specific mutation in the family has been identified.³⁷ This cost may be a deterrent for some individuals. While some insurance companies may pay for

testing and counseling services, patients may be reluctant to request such payment because of concerns about future genetic discrimination.

The results of this study provide some insights into the characteristics of individuals likely to come forward for BRCA1 testing. In the bivariate analyses, women were about twice as likely to request test results as men. The lower rate of test use among men may be because they perceive themselves as less vulnerable to the effects of BRCA1 mutations.¹⁰ Had we included information in the initial letter to family members about prostate and colon cancer and paternal transmission of susceptibility, the rate of participation of men in the education session and subsequent testing might have increased (these issues were discussed in the education sessions). Individuals who had been affected with cancer requested test results at a higher rate than unaffected at-risk individuals. Requests for *BRCA1* test results were significantly more frequent among individuals with a greater number of relatives affected with breast cancer.

The potential for discrimination by health insurers on the basis of genetic status is considered to be one of the most serious risks of BRCA1 testing.^{18,38} Consistent with this, our results suggest that the lack of health insurance may be a significant barrier to participation in BRCA1 testing programs. Individuals who did not have health insurance were almost 4 times less likely to request BRCA1 testing than individuals with health insurance, even after adjusting for other sociodemographic factors. Moreover, 34% of individuals reported at baseline that the possibility of losing health insurance was an important risk in having BRCA1 testing. Concerns about insurance discrimination may also deter carriers of BRCA1

ı.

*This value was obtained using the Fisher exact test for 2×3 contingency table.

mutations from sharing their mutation status with their providers and insurers and from undergoing potentially beneficial preventive interventions.³⁹ Also, individuals who know their mutation status and deliberately withhold such information from insurance companies could risk the loss of their policy or coverage for an illness related to the mutation. Individuals who lacked health insurance may also have been deterred by the cost of subsequent medical care that might be indicated if they tested positive.

The results of this study also shed light on how patients process information in making their decisions about BRCA1 testing. Individuals with more knowledge about HBOC and genetic testing and those who rated the benefits of *BRCA1* testing as significantly more important than the limitations and risks were more likely to request BRCA1 test results. Thus, to the extent that the public is educated about BRCA1 testing and the potential benefits are emphasized, utilization of *BRCA1* testing is likely to increase. Contrary to our expectations and previous research,^{21,22} we found that the perceived importance of the limitations and risks of BRCA1 testing did not influence BRCA1 testing decisions. In addition, subjects rated the limitations and risks of BRCA1 testing as statistically significantly less important than the benefits. This is despite the fact that the limitations and risks of BRCA1 testing were emphasized in all contacts, including those prior to our assessments. Thus, it appears that BRCA1 testing decisions were influenced disproportionately by the benefits of testing, relative to the limitations and risks of testing.

Another goal of this study was to evaluate the effects of BRCA1 testing on psychological and functional health status and on patients' medical decisions. The results of these analyses do not provide evidence for serious short-term adverse effects of BRCA1 testing, at least among high-risk individuals. Carriers of BRCA1 mutations showed no increases in depressive symptoms and functional impairment by 1 month following disclosure of test results. Improvements in psychosocial functioning were statistically significant for noncarriers. Individuals who declined BRCA1 test results experienced no changes in depression or functional health status. As was found for genetic testing for Huntington disease (the HD gene),²³ learning one's BRCA1 genetic status may reduce prolonged uncertainty and thereby enhance quality of life. This may be true even when the result reveals a risk-conferring mutation.

The results of *BRCA1* testing may also be useful to carriers in decision making about prophylactic surgery. In the present study, 33% of carriers reported that they planned to obtain prophylactic oophorectomies and 18% intended to obtain prophylactic mastectomies. For members of HBOC families who do not carry a *BRCA1* mutation, receipt of a negative test result may prevent unnecessary prophylactic surgery.¹⁹

While these outcomes are encouraging, they must be considered in the proper context. First, participants in this study were members of high-risk families in a hereditary cancer registry, many of whom were involved in prior cancer genetics studies. All of these individuals were white and most had a high school education. These factors may limit the generalizability of the study findings. Second, in accordance with current guidelines,^{25,26} all testing was provided as part of a carefully monitored research protocol including pretest education and genetic counseling. Such counseling may be responsible for the psychosocial benefits observed at 1-month follow-up. Outside a controlled research environment or in the general population, the potential for adverse effects of BRCA1 testing may be greater. Third, outcome data for this study were collected 1 month after BRCA1 testing and different results may be found with longer-term follow-up. However, based on studies of Huntington disease genetic testing,²³ the psychological benefits would be expected to increase, rather than decrease, over time. Finally, the results of the present study may have been influenced by a response bias. A subset of eligible individuals (31%) elected not to participate in the baseline interview: the vast majority of these individuals also declined BRCA1 testing. The model of BRCA1 test decision making might have differed had these individuals been included in the analysis. On the other hand, individuals who withdrew from the study (most of whom declined test results) did not differ in terms of their demographic backgrounds or in psychological or functional profiles from those who remained. Therefore, significant bias in the results of the psychosocial outcomes analysis is unlikely.

Although the results of the outcome analysis provide information about overall responses to BRCA1 testing, additional studies are needed to examine individual differences among testing participants. The SDs in depressive symptoms and other outcomes suggested the presence of a moderate degree of withingroup variability. Thus, it is likely that persons with different educational backgrounds or with different psychological profiles responded differently to learning their BRCA1 mutation status.²⁰ Information about such differences would be very useful to identify individuals who are more or less vulnerable to adverse effects of *BRCA1* testing and to tailor counseling and follow-up accordingly. Future studies should also examine more subtle effects of BRCA1 testing on carriers and noncarriers, including guilt, anger, and strained family relationships.¹⁹

CONCLUSIONS

Our findings suggest that some, but not all, members of HBOC families will want to have BRCA1 testing. Rates of BRCA1 test use may be highest for individuals of a higher socioeconomic status and those who have a greater number of relatives affected with breast cancer. Individuals who lack health insurance may be deterred from *BRCA1* testing because of concerns about genetic discrimination in employment and insurance. This inequity in access to testing will be best addressed by federal legislation prohibiting insurance companies from using genetic information to establish eligibility for enrollment or continuation of insurance or to determine premium rates.40

Although the findings related to the psychosocial impact of BRCA1 testing in HBOC families are promising, the complexities of testing and counseling must be considered carefully prior to extending these services outside the context of carefully monitored research protocols.⁴¹ The high frequency of BRCA1 mutations found in women of Ashkenazi Jewish descent,^{42,43} coupled with the recent availability of commercial testing and the widespread publicity about BRCA1 testing,³⁷ may create strong pressures for physicians to offer testing. However, prior to the translation of BRCA1 technology from research to clinical practice, strategies for patient education and informed consent must be developed and tested. The results of the present study underscore the importance of conveying information, not only about the benefits of testing, but particularly about the limitations and risks of these tests. Individuals who elect to receive their test results should be counseled extensively about the implications of these results, as well as about the limitations and risks of available surgical and prevention options.¹⁷ Proper informed consent and counseling is es-
