13. ABSTRACT *(maximum 200 words)*

At the center of software reuse is the search and retrieval of software components from large software libraries. Recent research has illuminated a promising approach called *multi-level filtering* that breaks the problem up into a series of increasingly stringent filters that move along a continuum of high-recall, low-precision syntactic techniques towards the more computationally expensive, high-precision semantic techniques.

In multi-level filtering, syntactic matching is decomposed into two phases: profile filtering and signature matching. This thesis presents improvements to the resolution of syntactic profiles where the intent is to increase precision without a loss in recall during profile filtering. Large integer representation of profiles and profile lookup tables lead to an optimal time-and-space solution to profile representation. Finally, a new approach to signature matching is proposed that provides early pruning of the search-space in an effort to cut down the time it takes to find valid signature maps.

The resulting software is mature enough for future integration with the other elements of multi-level filtering as well as inclusion in a CASE tool such as CAPS.

ABSTRACT

At the center of software reuse is the search and retrieval of software components from large software libraries. Recent research has illuminated a promising approach called *multi-level filtering* that breaks the problem up into a series of increasingly stringent filters that move along a continuum of high-recall, low-precision syntactic techniques towards the more computationally expensive, high-precision semantic techniques.

In multi-level filtering, syntactic matching is decomposed into two phases: profile filtering and signature matching. This thesis presents improvements to the resolution of syntactic profiles where the intent is to increase precision without a loss in recall during profile filtering. Large integer representation of profiles and profile lookup tables lead to an optimal time-and-space solution to profile representation. Finally, a new approach to signature matching is proposed that provides early pruning of the search-space in an effort to cut down the time it takes to find valid signature maps.

The resulting software is mature enough for future integration with the other elements of multi-level filtering as well as inclusion in a CASE tool such as CAPS.

TABLE OF CONTENTS

I.   INTRODUCTION

Effective software reuse becomes increasingly more important as the cost and complexity of software development escalates. At the center of the issue is the search and retrieval of software components from large software libraries. When enterprises that encourage the creation of reusable software components succeed in their efforts they are often met with the discouraging reality that large software bases are difficult to *use*. Issues such as query formulation, component storage, component retrieval, and presentation of query results must all be addressed with the same technology/usability tradeoffs that accompany most tools. Searching and retrieving components in large software bases has typically been plagued by poor recall and precision, slow algorithms, and demanding query requirements.

In an effort to address such shortcomings, the literature has shed light on numerous techniques for searching and retrieving components in large software bases but they usually fall short due to their narrow approaches. A promising new hybrid approach called *multi-level filtering* combines many of the traditional aspects of search and retrieval, such as keyword matching, syntactic matching, and semantic matching. The method breaks the problem up into a series of increasingly stringent filters that move along a continuum of high-recall, low-precision syntactic techniques towards the more computationally expensive, high-precision semantic techniques. This thesis is focused on improving the syntactic matching filters used early in the process of multi-level filtering.

To begin, section II reviews the relevant literature leading up to multi-level filtering. Section III more specifically discusses the architecture of multi-level filtering, including the decomposition of syntactic matching into its two phases of profile filtering and signature matching. Section IV presents improvements to the resolution of syntactic profiles[1] that can increase precision without a loss in recall during profile filtering. Also presented are improvements to the internal representation of syntactic profiles that lead to an optimal time-and-space solution to profile representation. Section V outlines improvements to signature matching that provide early pruning of the search-space in an

---

[1] Unique to the multi-level filtering method, a *syntactic profile* is a normalized representation of a software component's syntactic properties. A more detailed definition is found in section IV.

effort to cut down the time it takes to find valid signature maps. Section VI discusses the effectiveness of the improvements through a series of experiments. Section VII draws some conclusions and suggests areas for future research. The last sub-section in sections IV and V contain a detailed design of the improvements and the appendix contains the source code representing the design's implementation. The resulting software is mature enough for future integration with the other elements of multi-level filtering as well as inclusion in a CASE tool such as CAPS.

II. BACKGROUND

A sampling of previous work in software component search and retrieval is presented in this section to provide some background and basis for the ideas proposed in this thesis.

A. KEYWORD MATCHING

The classical and somewhat popular approach to software search and retrieval has been the employment of keyword matching. Components are assigned keywords that describe their attributes and functionality. Queries are specified with keywords and a simple search through the software base for components with matching keywords returns the candidate set of components. Such an approach breaks down, however, as the size of the software base increases. A large set of keywords can cause loss of recall and small sets of keywords can cause loss of precision.

[11] improves on the classical keyword technique by utilizing a faceted approach that better structures the terms used for classifying the components. Terms chosen from a set of facets are used to categorize all the components. This facilitates a closer fit of terms and reduces the problem of deciding the best keyword to use from a fixed set of standard keywords.

Among the problems with keyword-based approaches is the inherent requirement of a well-versed librarian. The infamous garbage-in/garbage-out principle certainly applies to the software base population activity. If the librarian does not have appropriate domain knowledge for each component admitted into the software base then the keywords will not be chosen correctly and penalties in recall and precision during search and retrieval will ensue.

A long overdue use of keyword matching is to apply it along side other techniques. The multi-level filtering method in [9] is an example of such a hybrid approach. The results of keyword matching are summarized in a computed keyword ratio that can be used to determine if a candidate should be forwarded to the next filter. If

3

problems with recall and precision emerge, the keyword filter threshold can be adjusted or the keyword filter can be deactivated altogether.

B.   SYNTACTIC MATCHING

Syntactic matching has been proposed as an effective method for quickly ruling out components that cannot match the query [13]. The process can be successfully automated when syntactic normalizing procedures are applied. Syntactic normalization procedures come in many forms [2][6][13] but perhaps the most promising approach proposed recently is the application of syntactic profiles [9]. This approach is discussed and improved upon in section IV of this thesis.

The presence of subtypes in queries and components has often plagued syntactic matching by imposing penalties in recall. For example, if the query is an operation that takes a *positive* as an input and the operation components in the software base only contain *integer* inputs then the query will fail even though positives are legitimate subtypes of integers. Such a shortcoming is addressed in [2] and further refined in [9].

C.   SEMANTIC MATCHING

A major shortcoming of syntactic matching is its inability to retrieve components based on their behavior. If syntactic matching were the sole approach to search and retrieval a query for a square-root function would indeed return a square-root function but, to the user's dismay, most of the other math functions in the software base would be returned as well! Recent efforts have attempted to address this shortcoming through various approaches to semantic matching. Specification-based approaches found in [6] and [8] require the user to form queries as behavioral specifications but haven't been met with great success due to the difficulty of forming correct specifications.

The approach of using algebraic specifications [13] for encoding a component's behavior has led to promising results for successfully automating semantic matching [9]. A set of ground equations describing the component's behavior can be specified

algebraically using algebraic specification languages such as OBJ3 [3] and included with the component. The terms in the equations can be applied from left to right to simplify them to their canonical form where they can then be easily compared to a query's set of ground equations. Algebraic specifications, however, are not much of an improvement with regards to ease of use. Specification languages such as OBJ3 have to be absorbed by the librarian and the user and the domain of the component needs to be understood. A librarian will be met with a cumbersome task when preparing an entire software base for this type of semantic matching [10].

D.   MULTI-LEVEL FILTERING

Multi-level filtering [9] is an approach that integrates keyword, syntactic, and semantic matching. It is attractive because it applies a series of increasingly stringent filters that move along a continuum of high-recall, low-precision syntactic techniques towards the more computationally expensive, high-precision semantic techniques. The purpose of the work described in this thesis is to improve upon the syntactic matching processes of multi-level filtering. Hence, a discussion regarding the specifics of the multi-level filtering approach will be postponed to their relevant sections of this document.

E.   SOFTWARE BASE DESIGN AND POPULATION

Populating the software base usually involves annotating the components with additional information to facilitate search and retrieval. In every approach cited above this is the case. PSDL [5] has been shown to be an effective language for representing components independently of their native language [10]. In addition to its real-time specification support, PSDL supports operations (including generic operations), abstract data types (including generic types), state machines, and the common predefined types found in most popular programming languages. Thus PSDL is more than sufficient for representing the syntactical properties of queries and reusable components in a software

5

base. PSDL also provides a placeholder for axioms to provide semantic information for the component. Algebraically specified ground equations in the form of OBJ3, for instance, can be placed in this section of the PSDL file.

CAPS [7], a CASE tool for rapid prototyping of embedded hard real-time systems, represents great strides in integrating modern software engineering technologies. The system includes a graphical editor, an execution support system, an evolution control system, automated real-time schedulers, automated integration of Ada modules, and placeholders for making use of a software base. Its initial software base [10] includes reusable components from the Booch library. The components include syntactic specifications in PSDL and semantic specifications in OBJ3 thereby providing a good test suite for multi-level filtering and the ideas proposed in this thesis.

III. MULTI-LEVEL FILTERING ARCHITECTURE

The model of multi-level filtering is illustrated in Figure 1. The entire process can be generalized into two main activities: syntactic matching and semantic matching. Syntactic matching quickly filters out candidates based on syntactic properties to eliminate as many candidates as possible that must undergo the computationally expensive semantic matching. Clearly it is advantageous to filter out large numbers of candidates early to minimize the use of the more laborious filters later in the process. At any stage of the process the user should be able to set the thresholds that determine the constraints within which a candidate may pass. Furthermore, the user should be able to browse the set of candidates from the prior filters and have the option of manually filtering the results that are passed to the next filter.
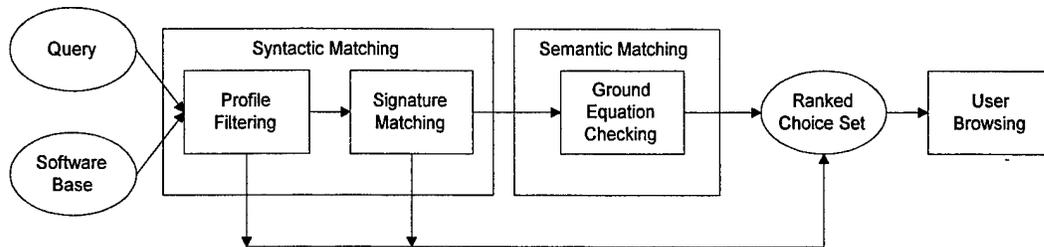

Figure 1: Multi-level Filtering Model

This thesis focuses on improving syntactic matching by making improvements to profile filtering and signature matching. Section IV discusses improvements to profile filtering and section V discusses improvements to signature matching. In addition to the presentation of theoretical improvements, each section also covers a detailed design and implementation for realizing a software module that can be practically used within the entire context of multi-level filtering and ultimately in CAPS.

7

IV. PROFILE FILTERING

A. CURRENT STATE OF THE ART

In [9] a component's syntactic properties are represented as a *Component Profile*. A component profile is the multiset of *Operation Profiles* for all the operations in a component. An operation profile is a sequence of integers each representing a unique syntactic property[2] of an operation. Definition 4 in [9] defines an operation profile as:

1. The first integer is the total number of occurrences of sorts.
2. If the total number of sort groups, N, is greater than 0, then the second to $(1 + N)^{th}$ integers are the cardinalities of the sort groups, in descending order.
3. The $(2+N)^{th}$ integer is the cardinality of the unrelated sort group.
4. The $(3+N)^{th}$ integer is:

    0 if the value sort is different from any of the argument sorts; and

    1 if the value sort belongs to some sort group.

By computing the component profiles for each reusable component in the software base, components can be placed into partitions where each partition is identified by the component profile of the components it contains. An ordering of these partitions can then be obtained to organize the software base into a haase-diagram for facilitated traversal during a process [9] defines as *Profile Filtering*.

Profile filtering is a process in which components in the software base can be easily ruled out based on whether their syntactic profiles match the query's syntactic profile. This is a high-speed (relative to signature and semantic matching) process where the goal is to increase precision in a typically high-recall/low-precision stage of retrieval.

---

[2] These properties have been referred to as profile *components* but we will use the term *property* rather than *component* to eliminate an overloading of the term *component* which we have been using to refer to a reusable component such as a type.

9

B. PROFILE IMPROVEMENTS

One way to increase precision in [9]'s approach to profile filtering is to make improvements to the definition of an operation profile. Two categories of improvement that can be easily quantified are *Resolution* and *Space-and-Time*.

1. Resolution

The point of increasing the resolution of syntactic profiles is to better distinguish between syntactically similar software components. In terms of [9]'s architecture this would result in an increase in the number of partitions in the software base. In terms of [9]'s profile filtering process this would mean an increase in the number of nodes in the haase-diagram that maps the software base's organization.

Gains in resolution can be obtained two ways:

1. Add more properties to the profile.
2. Use properties that can be measured with more possible values.

In keeping with the spirit of syntactic normalization, however, one has to be careful to define measurements that will not be affected by the permutation of the arguments or by any renaming of the types.

[1] inspired several resolution improvements to profiles that can prove quite useful in partitioning the software base more effectively. The first improvement follows the second resolution-gain technique described above and the other improvements subscribe to the first technique.

a. *Value Sort Frequency*

Item 4 of [9]'s operation profile definition has two possible values, 0 or 1, indicating if the value sort[3] is in the same sort group as other arguments in the operation or if it is a member of the unrelated sort group. The resolution of this particular property can be increased by modifying its definition to be the number of occurrences of the value sort in the operation's signature. Table 1 illustrates this improvement:

Table 1

Component Operations	Old	New
add: id set → set	1	2
union: set set → set	1	3
member: id set → bool	0	1
choose: set → id	0	1

The increase in resolution is well illustrated with the operations *add* and *union*. When using the old definition we notice that *add* and *union* have the same value for the value-sort property. When using the new definition we see that *add* and *union* each have different measurements for this property. Such a difference guarantees that *add* and *union* will have different profiles and therefore contributes to an increased resolution of the software base.

b. *Type Sort Frequency*

A majority of the reusable components the author has come across have been abstract data types. In most cases these types refer to themselves in the operations they define. For instance, in Table 1 the component is a *set* and one will notice the operations refer to *set* frequently. The frequency of such self-references can be measured and can contribute to the component's profile. Table 2 illustrates the additional property:

---

[3] The term *value sort* is used by [9] to refer to the type of the output argument of an operation. In this thesis the terms *value* and *output* are used interchangeably but an effort to use *value* when referring to concepts in [9] will be made.

11

Table 2

Component Operations	Old	New
add: id bag → bag	n/a	2
merge: bag bag → bag	n/a	3
equal: bag bag → bool	n/a	2
equal_with_set: bag set → bool	n/a	1
member: id bag → bool	n/a	1
freq: id bag → natural	n/a	1

The new property measures the number of times *bag* is referred to in the operation's signature. Notice that equal and equal_with_set are assigned different values for this new property. In the old profile definition, these two operations would have the same profile. Again, we have an improvement in resolution.

c.   *Predefined Sort Frequencies*

The final resolution improvement to introduce involves representing the sizes of the various sort groups for the predefined[4] types. [9] and [2] both note that during signature matching the predefined types can only map to predefined types of the same sort group.[5] Given this requirement, it would be beneficial to filter out components during profile filtering that would violate such a requirement. Hence we can add an integer for each predefined sort group that would reflect the size of that sort group in the operation's signature. In Table 3, five predefined sort groups are recognized in the following order: boolean, character, string, integer, and real.

Table 3

Component Operations	Old	New
add: id bag → bag	n/a	00000
merge: bag bag → bag	n/a	00000
member: id bag → bool	n/a	10000
freq: id bag → natural	n/a	00010

The operations *member* and *freq* are good examples of the increased resolution this improvement provides. The old profile definition would assign these two

---

[4] [9] refers to predefined types as *basic* types. The two terms are used interchangeably in this thesis.
[5] [2] further restricts this statement with rules regarding subtype matching within the sort group. This is addressed in the section on Signature Matching where the discussion is more applicable.

operations the same profile. The enhancement assigns different profiles thereby increasing the resolution and eliminating the signature-matching algorithm from trying to map incompatible predefined types.

2. Time-and-Space

Software bases can become enormous rather quickly. A large enterprise's software base can contain thousands of reusable components. Representing such a large software base in the architecture proposed by [9] can tax the resources of the enterprise's computer/s responsible for maintaining and searching the software base. To this end, the representation of syntactic profiles is an issue worth special attention since thousands of components can actually translate into tens of thousands of operations!

[9] suggests the operation profile be represented as a sequence of integers. This requires a sequence abstract data type with standard operations defined such as equality and less-than (for sorting). Numerous instantiations of such an abstract data type could require a substantial amount of memory. Two possible suggestions for making time-and-space improvements to syntactic profile representation are explained below.

a. Large Integer Representation

A representation that would take up less space would be a large integer of something like 64 bits. Each digit in the integer would represent each integer in the profile. Besides space, speed issues regarding the testing for equality and less-than would be greatly sped up because the default operations for the integer would apply, thereby eliminating the need for putting a user-defined function on the stack each time these common operations are called.

The biggest disadvantage to this approach should be evident: such a representation would limit the number of sort occurrences in the signature to nine. A function with ten sort occurrences is rather rare, however. One could use two digits for each property thereby potentially relaxing the restriction to 99 sort occurrences, which is definitely enough. Two digits per property, however, would require a much larger integer

13

than one that could be represented with 64 bits and it is questionable if any high-level language can efficiently represent greater-than-64-bit integers any more efficiently than a smart implementation of a sequence.

b. Profile Lookup Table

A component profile is traditionally thought of as a sequence of operation profiles. In other words, it is a sequence of sequences of integers. Given thousands of components, this can take up a lot of space and can tax the component profile equality operations. Especially wasteful is the fact that the number of unique operation profiles is much smaller than the actual number of components in the software base.

A promising approach for improving the time-and-space issues of component profiles is the employment of a profile lookup table. To eliminate the redundancy of integer sequences that represent operation profiles throughout the software base, this table would map a unique integer to each unique operation profile used in the software base. A component profile can then be represented as sequence of these unique integers rather than a sequence of integer sequences. Below is an example to illustrate the concept:

Table 4: Profile Lookup Table

Lookup ID	Operation Profile
1	[2,1,2,1,0,0,0,0,0]
2	[3,1,3,1,0,0,0,1,0]
3	[3,1,3,1,1,0,0,0,0]
4	[3,2,1,2,0,0,0,0,0,2]
5	[3,3,0,3,0,0,0,0,0,3]

Table 5: Set

Component Operations	Operation Profiles	Lookup ID
add: id set → set	[3,2,1,2,0,0,0,0,0,2]	4
union: set set → set	[3,3,0,3,0,0,0,0,0,3]	5
member: id set → bool	[3,1,3,1,1,0,0,0,0]	3
choose: set → id	[2,1,2,1,0,0,0,0,0]	1

14

Table 6: Bag

Component Operations	Operation Profiles	Lookup ID
add: id bag → bag	[3,2,1,2,0,0,0,0,0,2]	4
merge: bag bag → bag	[3,3,0,3,0,0,0,0,0,3]	5
member: id bag → bool	[3,1,3,1,1,0,0,0,0]	3
freq: id bag → natural	[3,1,3,1,0,0,0,1,0]	2

Table 4 depicts the profile lookup table after the *set* and *bag* components from Table 5 and Table 6 have been loaded. The first thing to note from this example is the redundancy in operation profiles between *set* and *bag*. Three out of the five unique operation profiles in the lookup table are shared between *set* and *bag*. The second thing to note is the huge space savings gained for a component profile. Without the lookup table the *set's* component profile would be [[3,2,1,2,0,0,0,0,0,2], [3,3,0,3,0,0,0,0,0,3], [3,1,3,1,1,0,0,0,0], [2,1,2,1,0,0,0,0,0]]. By using the lookup table *set's* component profile can be represented as [4,5,3,1].[6] Given thousands of components the amount of space saved is significant. Furthermore, the amount of time saved checking for component profile equality can be substantial since the number of actual integer comparisons is cut drastically.

The profile lookup table represents an optimal time-and-space solution to profile filtering. During profile filtering, the actual profiles themselves are irrelevant. What is relevant is whether two profiles are the same. The profile lookup table ensures that each profile is represented by a unique identifier. Since this identifier can be represented by an integer we have an optimal time-and-space solution to profile representation.

C.   DESIGN AND IMPLEMENTATION

The software used in [9] is not very conducive to reusability and extendibility and therefore is difficult to use for testing the improvements in syntactic matching outlined in this thesis. Furthermore, it is desirable to have a software module that is practical for inclusion in CAPS. To this end, a significant amount of design and implementation is

necessary. This section details the various data types and implementation strategies used to implement a practical system to test the improvements proposed in this thesis with the understanding that such a system should ultimately integrate with other elements of multi-level filtering and CAPS in the large.

1.   Component Types

[13] proposed components ultimately be stored in an object-oriented database to easily associate the various elements of a software component required for search and retrieval. This idea is highly appropriate for a production quality implementation of a software base but given the lack of engineering resources at this stage of the research such an idea has not yet come to fruition. The CAPS software base is currently composed of a set of files for each component where each file for the component represents a different element of the component that is useful for reuse [10]. Specifically this includes the component's native language (e.g. Ada) specification, native language body, PSDL specification, and OBJ3 specification.

The first task, then, is to organize these files into an intelligent scheme to support the goals of this thesis and the short-term goals of the CAPS project. The organization proposed here is to create a directory for each component that contains all of its files. Figure 2 illustrates examples of these directories.

```
/CAPS/sb/set/          /CAPS/sb/map/
   set.psdl               map.psdl
   set_s.a                map_s.a
   set_b.a                map_b.a
   set.obj3               map.obj3
```
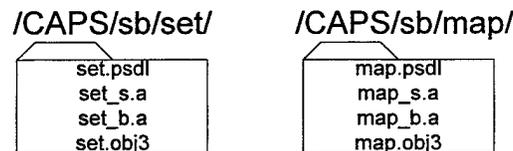

Figure 2: Sample Directories for a Software Base

A header file is used to identify all of the components that comprise the software base. An example of such a header file is shown in Figure 3. Notice that a unique integer is

---

[6] The component profile in this example is not ordered but could be for improved signature matching. A discussion of this can be found in section V.B.1.

16

assigned to each component. This ID will be used to identify the component in the data structures that internally represent the software base because it is easier to manipulate and it saves space. A nice feature the header file provides is the ability to represent a distributed software base due to the use of a networked file system. Notice components 1100 and 1400 are components that actually exist on remote machines.
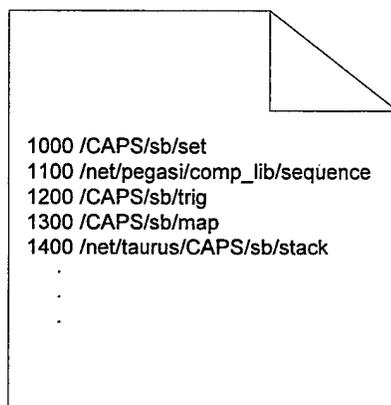

```
1000 /CAPS/sb/set
1100 /net/pegasi/comp_lib/sequence
1200 /CAPS/sb/trig
1300 /CAPS/sb/map
1400 /net/taurus/CAPS/sb/stack
    .
    .
    .
```

Figure 3: Sample Header File for a Software Base

Now that we have a way of representing the components in secondary storage we need a way of representing them internally. Figure 4 shows the objects used to represent components in memory using Rational's Unified Method [12].
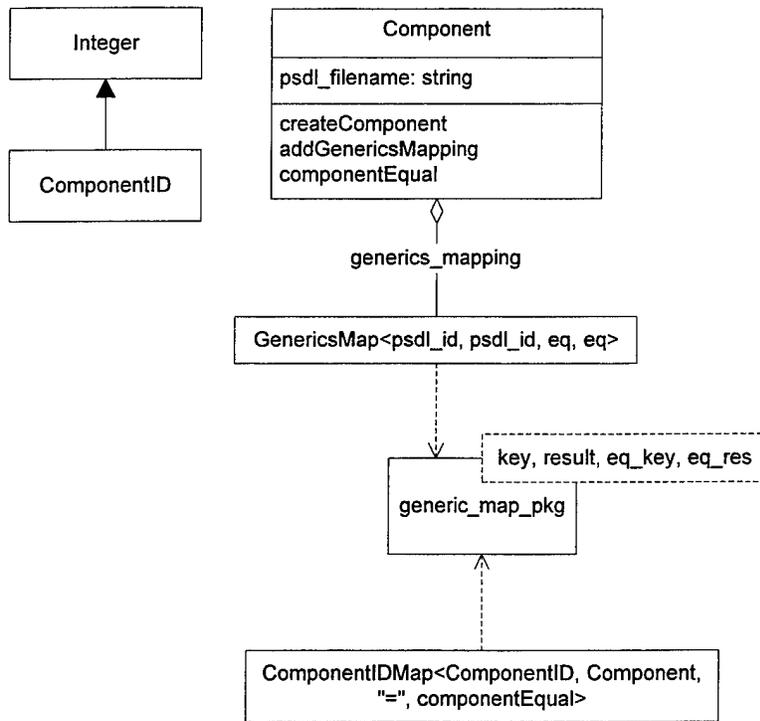

Figure 4: Component Types

The ComponentIDMap maps the ComponentID to a Component. The ComponentID is the unique integer read in from the software base's header file. The Component contains the filename of the component's PSDL specification and an association to an instance of a GenericsMap. A GenericsMap maps the generic parameter identifiers in generic components to actual type names. This needs some explanation.

Suppose we have the following PSDL specification for the generic component Stack:

```
TYPE Stack                          OPERATOR Pop
SPECIFICATION                       SPECIFICATION
  GENERIC                             INPUT
    Item : PRIVATE_TYPE                 The_Stack : Stack
                                      OUTPUT
OPERATOR Push                           The_Stack : Stack
  SPECIFICATION                       EXCEPTIONS
    INPUT                               Overflow, Underflow
      The_Item : Item,              END
      On_The_Stack : Stack
    OUTPUT
      On_The_Stack : Stack
    EXCEPTIONS
      Overflow, Underflow
END
```

18

```
OPERATOR Depth_Of                          OPERATOR Is_Empty
  SPECIFICATION                              SPECIFICATION
    INPUT                                      INPUT
      The_Stack : Stack                          The_Stack : Stack
    OUTPUT                                     OUTPUT
      Result : Natural                           Result : Boolean
    EXCEPTIONS                                 EXCEPTIONS
      Overflow, Underflow                        Overflow, Underflow
  END                                        END

                                           END
```

This component has one generic parameter named *Item* and makes reference to three different types: *Stack*, *Natural*, and *Boolean*. Instantiating Item to the different types used in the component can potentially yield a different component profile for each instantiation. This could place the various instantiations into different partitions. Hence, each generic component must undergo the generic instantiation process to obtain the various generic parameter mappings. Each instantiation is stored internally as a separate component with its unique generic mapping. The ComponentID for each instantiation is based on the base ID from the header file. For example, if the header file assigns the ID 1200 for the stack component listed above then the ComponentID entries in the ComponentIDMap would be 1201, 1202, 1203, and 1204. Table 7 illustrates this mapping.

Table 7

ComponentID	Component	Component.generic_mapping
1201	Stack	Item → Stack
1202	Stack	Item → Natural
1203	Stack	Item → Boolean
1204	Stack	Item → Item

Notice there is a fourth entry for mapping Item to itself. This is a simple way of representing the possibility that the generic parameter does not map to any of the types used in the component. Another important point to note is the ids in the header file need to be spaced sufficiently to give the generic instantiation algorithm room for the automatic generation of unique ids for a given component. The software base used to test the ideas in this thesis was given a spacing of 100 between component ids, which provided sufficient room for generic instantiation.

19

One final point to note regarding generic parameter instantiation is a single generic component can end up being instantiated into numerous components through the generic parameter instantiation process. This is especially true for components with more than one generic parameter because the cross-product of the generic parameters and the normal types in the component must be computed to exhaust all the possible combinations. Measurements regarding the instantiation of generic components are presented in section VI.A.

2. Profile Types

The natural design for profiles and component profiles is to use sequences. A Profile would be implemented as a sequence of integers and a ComponentProfile would be implemented as a sequence of Profiles. This approach is depicted in Figure 5.
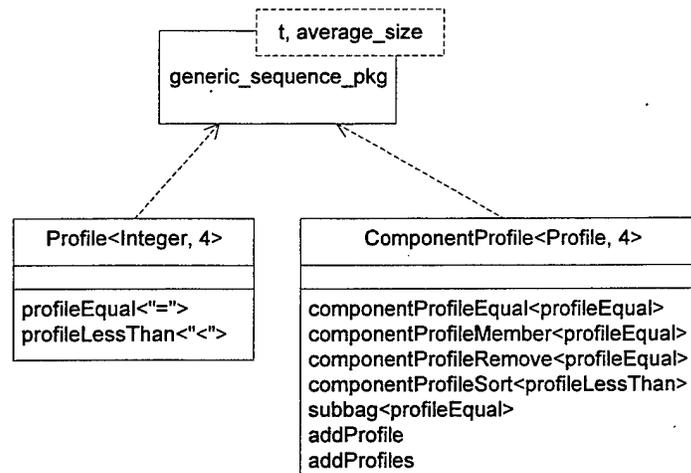

Figure 5: Profile Data Types

The method *profileLessThan* provides a means of ordering the Profiles lexicographically in the ComponentProfile. The advantages of such an ordering are detailed in section V.B.1. The method *subbag* is a multiset subset operation that can be used to order the partitions in the haase diagram since the partitions are keyed using ComponentProfiles. The design and implementation of the haase diagram is discussed in section IV.C.3.

Section IV.B.2 introduced time-and-space improvements to the design in Figure 5. These improvements are represented in Figure 6.
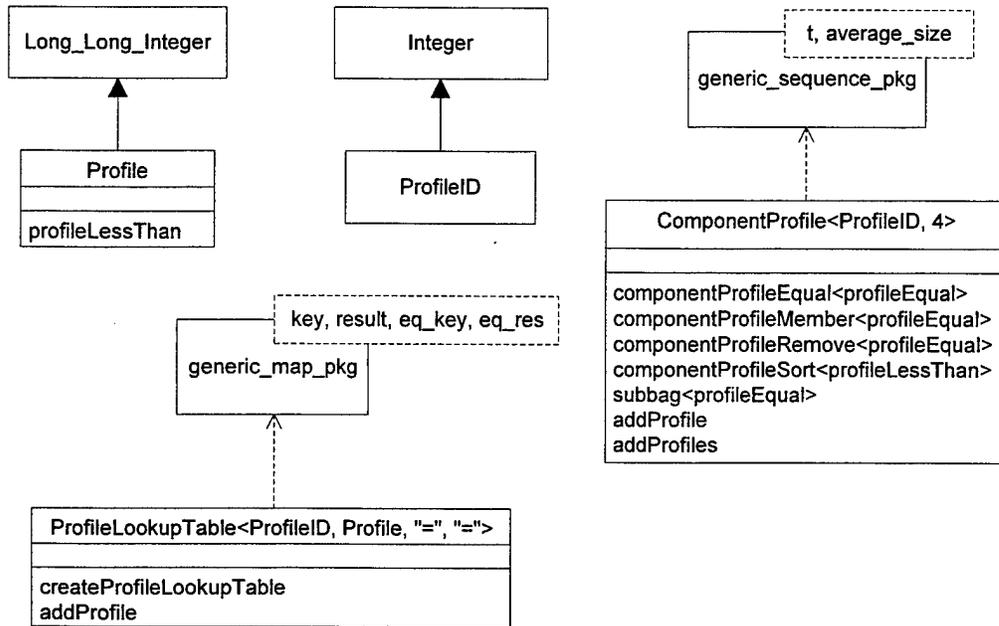

Figure 6: Time-and-Space Improvements for Profile Types

This shows all of the improvements used together but it is possible through the use of abstract data types to mix and match the designs. For example, if one wanted to be able to handle operations with more than nine arguments (see section IV.B.2.a) then Profile could be implemented as a sequence of integers rather than the Long_Long_Integer and still be able to take advantage of the ProfileLookupTable.

3. **Haase Diagram Types**

The haase diagram can be constructed using the objects in Figure 7.

21
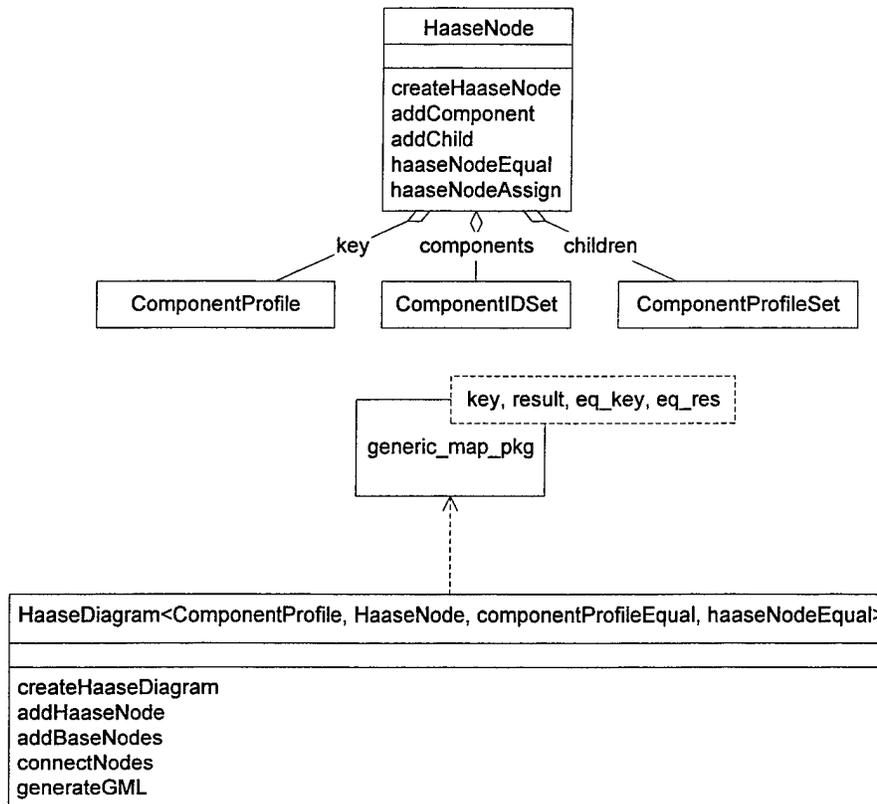

Figure 7: Haase Diagram Data Types

A HaaseNode is a partition that is keyed by a ComponentProfile. The node contains components that have the same ComponentProfile as the key. Notice the components are a set of ComponentIDs rather than Components to save space. When access to the actual component is necessary the ComponentID can be used to fetch the component from the ComponentIDMap as described in section IV.C.1. The HaaseNode is related to other nodes (or partitions) through its *children* association. This association is implemented as a set of ComponentProfiles, which are the *keys* to the next partitions in the ordering. Relating nodes in this way allows the use of a map to represent the entire haase diagram. Direct access to partitions can be obtained by fetching with a ComponentProfile key.

Constructing the haase diagram is a three step process.

Step 1: for each component check if a node exists with that component's CompoentProfile. If it does then put that component in that node (add it to the node's *components* association). Otherwise add a

22

new node with the component's ComponentProfile as the key and put the component in it.

Step 2: for each Profile in each HaaseNode's key add a node to represent a base node. This is accomplished by calling *addBaseNodes* on the populated HaaseDiagram from step 1.

Step 3: connect the nodes (set the *children* association for each node) based on the following invariant from [9]: n2 is n1's child if and only if *subbag(n1.key, n2.key)* and there is no node n3 such that *subbag(n1.key, n3.key)* and *subbag(n3.key, n2.key)*. This is accomplished by calling *connectNodes* on the populated HaaseDiagram from step 2.

4. Candidate Types

Candidates are the "currency" passed between the various stages of the multi-level filtering process. Figure 8 shows these data types.
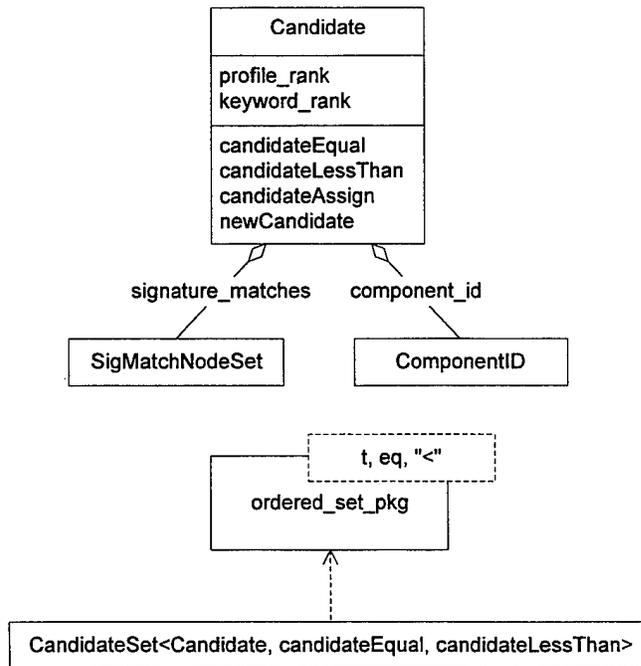

Figure 8: Candidate Data Types

A Candidate is a component with a ranking. The component is identified through the ComponentID association. The ranking is a combination of the results of profile filtering, keyword filtering, and signature matching. [9] calls this combination the *KPS* value. Each candidate can have multiple signature matches, each with a different signature rank, so an association to a SigMatchNodeSet is present (see section V.C). Notice the CandidateSet is an *ordered* set. The ordering is provided through the candidateLessThan method which uses the KPS value to determine the ordering.

5.   **Software Base Types**

The software base ties everything together. The *software_base* object and the functional summary of its methods are shown in Figure 9. The *initialize* method is responsible for parsing the header file, loading the components' PSDL specifications, generating the generics mappings for the generic components, computing the profiles, and populating the haase diagram and component id map. The software base also provides some methods for gathering statistics, including a method to generate a GML [4] file to graphically depict the haase diagram. Finally, the software base contains methods for profile filtering and signature matching.

24
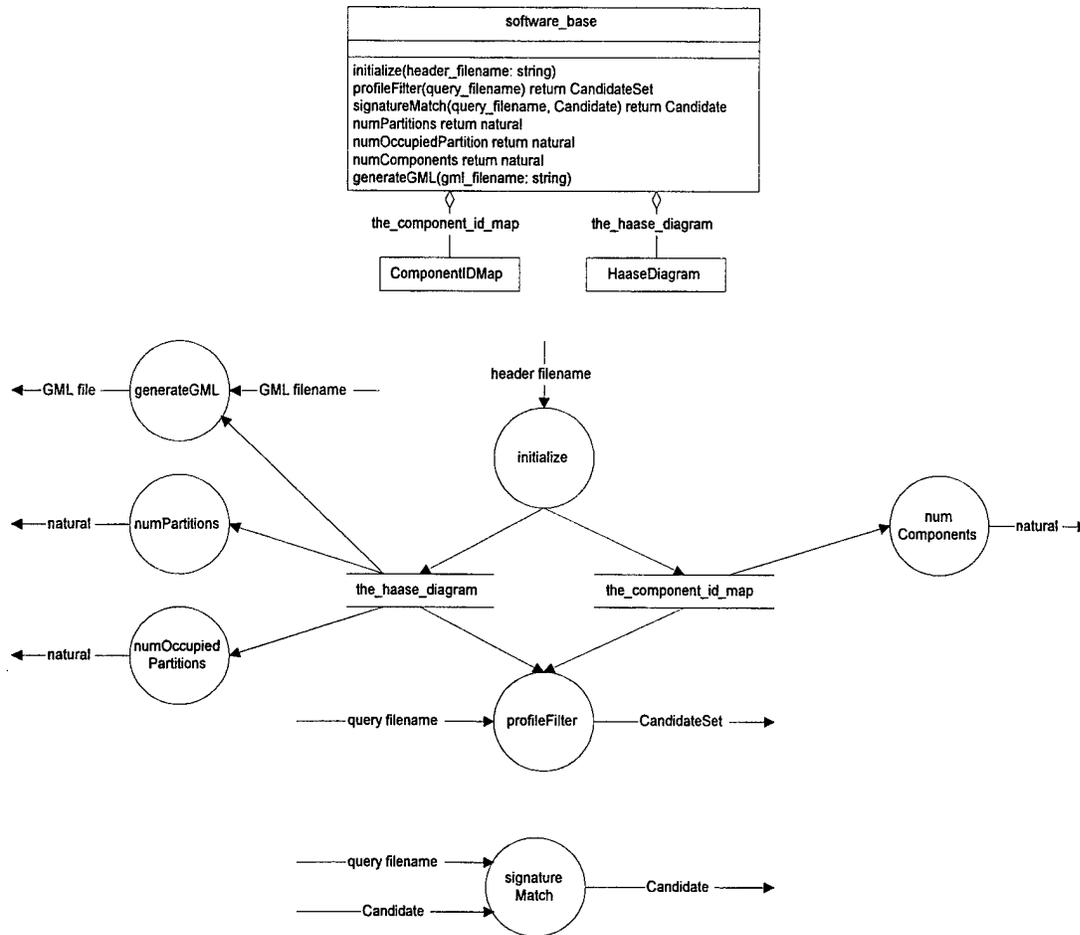

Figure 9: Software Base Types and Functions

6. Profile Filtering Strategy

We now have an infrastructure with which to experiment and conduct profile filtering and have laid the groundwork for a signature matching implementation which is presented in section V.C. The profile filtering strategy laid out in [9] can now be applied to this design and is encapsulated in the method *profileFilter*. A high level expansion of the profileFilter method in the software base is shown in Figure 10.
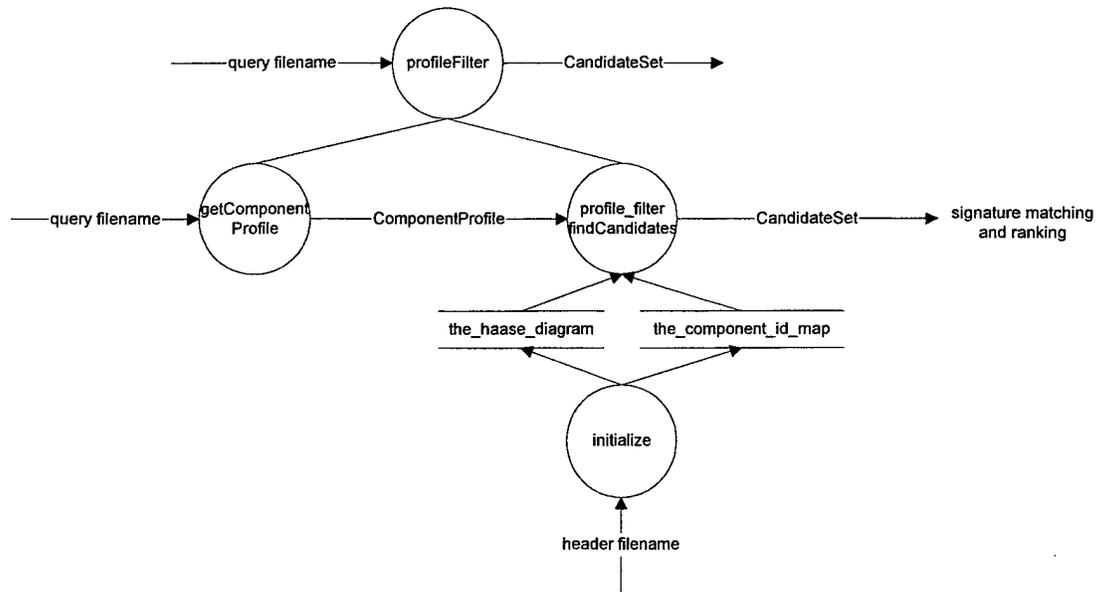

Figure 10: Decomposition of profileFilter

profileFilter decomposes into two main functions: *getComponentProfile* and *findCandidates*. getComponentProfile reads a PSDL specified query, computes its ComponentProfile and passes it to findCandidates where the actual profile filtering takes place. The decomposition of getComponentProfile is shown in Figure 11. getComponentProfile has been designed to take a GenericsMap if the component it is processing is generic. To process queries, which are assumed to NOT be generic however[7], the GenericsMap passed in to getComponentProfile can just be empty.

---

[7] [9] cites the handling of generic queries as a topic of future research.

26
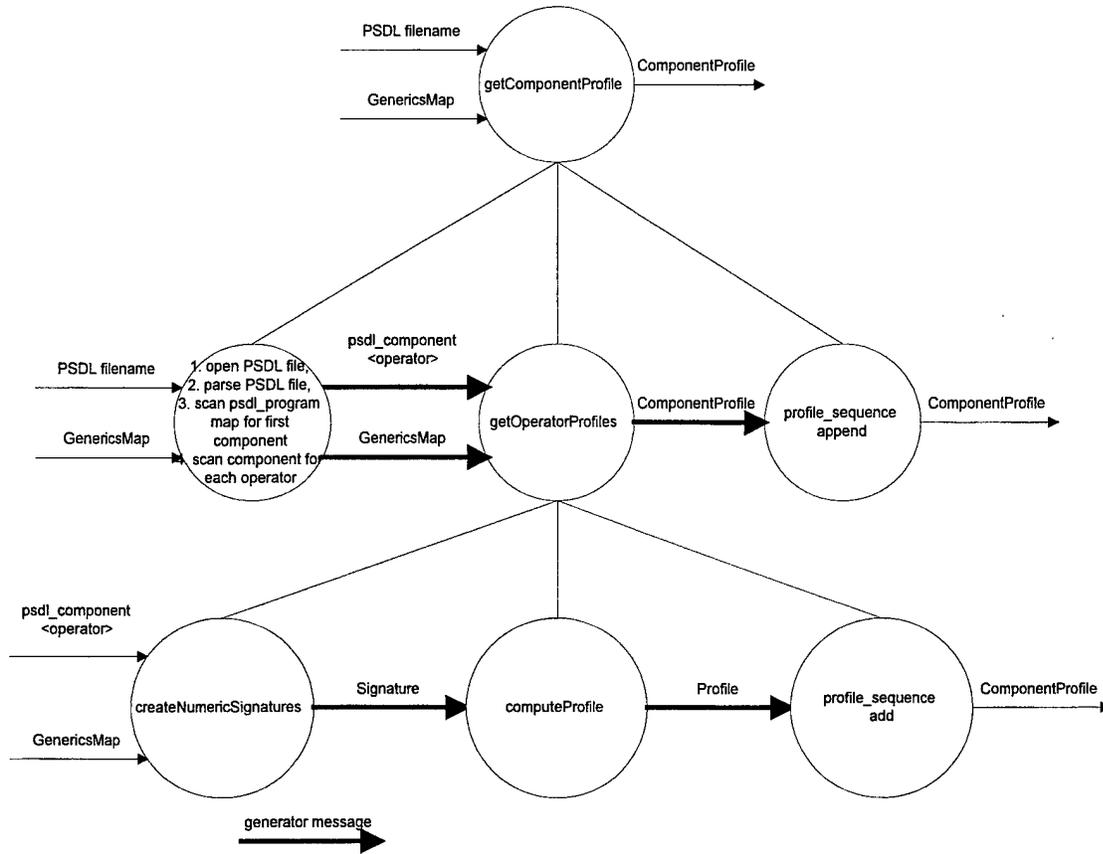

Figure 11: Decomposition of getComponentProfile

The algorithm to compute profiles was given as a class project in [1]. The approach taken by the author's group was to have the algorithm use a language independent (including independence from PSDL) signature for greater reuse potential with other specification languages. The resulting signature, which is referred to as a *numeric signature*, is represented as an array of integers where each unique integer represents a different sort group and each entry in the array indicates to which sort group each argument belongs. Negative integers were used for generic sort groups and the array was terminated with a 0. For example, given *id* from the component listed in Table 6 was a generic parameter, the numeric signatures for each operation would be generated as listed in Table 8.

Table 8: Numeric Signatures for Bag

Component Operations	Numeric Signature
add: id bag → bag	[-1,1,1,0]
merge: bag bag → bag	[1,1,1,0]
member: id bag → bool	[-1,1,2,0]
freq: id bag → natural	[-1,1,2,0]

This format works fine for the profile definition in [9] and even for the value sort frequency improvement presented in section IV.B.1. The problem with this format arises when adding the other profile improvements that are concerned with measuring the frequency of predefined and user-defined sorts. The integers in the numeric signature do not carry with them sort identity. Hence the numeric signature was modified to contain these two profile improvement properties directly. The first integer after the original terminating 0 represents the type sort frequency and the remaining integers represent the frequency of the predefined sort groups. Also, the createNumericSignatures method was modified to take a GenericsMap to create a numeric signature with the generic parameters instantiated and therefore remove any negative integers representing generic parameters. The improvements are represented in Table 9 and assume *id* is mapped to a boolean.

Table 9: Improved Numeric Signatures

Component Operations	Numeric Signature
add: id bag → bag	[1,2,2,0,2,0,0,0,0,0]
merge: bag bag → bag	[1,1,1,0,3,0,0,0,0,0]
member: id bag → bool	[1,2,1,0,1,2,0,0,0,0]
freq: id bag → natural	[1,2,3,0,1,0,0,0,1,0]

With these improvements to the numeric signatures we can now develop an algorithm to compute profiles for generic components with all the improvements presented in this thesis from a language independent format. This algorithm is represented by the function *computeProfile* and its source code can be found in the appendix.

V. SIGNATURE MATCHING

A. CURRENT STATE OF THE ART

[9] proposes a strategy for signature matching that involves the discovery of *Partial Signature Maps*. A partial signature map maps operations and sorts from the query to operations and sorts in the candidate. The signature maps are called partial because it is possible that not all of the query's operations can be mapped to operations in the candidate component. A signature map that successfully maps all of the query's operations is considered a *Full Signature Map*.

In [9] syntactic profiles play an important role in signature matching. Their use in profile filtering eliminate syntactically incompatible components from being passed on to signature matching, but most importantly they provide a quick test for determining which operations in the query and the candidate have the potential for matching. Simply stated, signature matching is only performed on operations that have equal operation profiles.

B. IMPROVEMENTS

Signature matching becomes expensive as the sizes of the query and the candidate grow. More specifically, the number of possible operation pairings grows exponentially as the number of syntactically compatible operations (operations with equal syntactic profiles) increases. To compound the problem, the number of possible sort matches for each pairing grows exponentially as the number sort occurrences increases. These combinatorial explosions can result in large search spaces. Table 10 illustrates the problem:

29

Table 10

Query	Operation Profiles	Component
Q1: E A D → B	[4,1,4,0,0,0,0,0,0]	C1: V W Y → Z
Q2: A B C D → F	[5,1,5,0,0,0,0,0,0]	C2: J K L M → Y
Q3: D B C A → E	[5,1,5,0,0,0,0,0,0]	C3: W X Y Z → T
	[5,1,5,0,0,0,0,0,0]	C4: W X Y Z → S

The query operation Q1 can only match to C1 because C1 is the only operation in the component that contains a compatible operation profile. Q2, however, can match to C2, C3 and C4. Furthermore C3 can also match to C2, C3, and C4. Before sort matching occurs we already have many possible combinations of operation parings to test. The problem really explodes as the sorts for each of these possible pairings undergo the matching process. For the Q2/C2 pairing, A can match to J, K, L or M. For each of these possibilities B must then be matched to the remaining types in C2. This continues until all the possibilities are permuted for the Q2/C2 pairing. And this is just for the Q2/C2 pairing!

Below are several improvements that can be made to combat the combinatorial explosion problems associated with matching large components.

1. Operation Ordering

[9] suggests ordering the operations in the query and components by their syntactic profiles as a possible improvement to signature matching. This would allow the signature matching algorithm to sequentially step through the operations for matching and reduce the number of combinations to be considered.

The signature matching algorithm presented in this thesis uses the concept of operation ordering to help constrain the search by matching *smaller* operations before larger operations. By ordering profiles lexicographically, the smallest operations would be the operations with profiles that come first in the ordering. For example, in Table 10 Q1 is smaller than Q2 because it contains less sort occurrences. This is indicated by the first property in the profile and therefore Q1's profile is ordered before Q2. Given this ordering, we can intelligently match the sorts for smaller operations before matching the

30

sorts for larger operations. This is advantageous because smaller operations constrain the number of matching possibilities and therefore can contribute to a quick reduction of the search space. This is explored in greater detail in the section on design and implementation for signature matching.

Additional techniques for reducing the search space that are not dependant on operation orderings are considered next.

2. Match Outputs

When a query operation is mapped to a candidate operation we can immediately attempt to map the value sorts of the operations because all operations are normalized to the point of having a single output [9][10]. This reduces the search space in two ways. First, if either of the value sorts is already mapped (because of a previous operation mapping) then it is possible the operations cannot be mapped. This would be based simply on the fact that the value parameters are already mapped to *different* sorts. Table 11 illustrates this concept:

Table 11

Query	Operation Profiles	Component
Q1: E A D → B	[4,1,4,0,0,0,0,0,0]	C1: V W Y → Z
Q2: A B C D → B	[5,1,5,0,0,0,0,0]	C2: J K L M → Y
Q3: D B C A → E	[5,1,5,0,0,0,0,0]	C3: W X Y Z → T
	[5,1,5,0,0,0,0,0]	C4: W X Y Z → S

Suppose we map Q1 to C1. This would mean B would have to map to Z. Now we move to Q2. Suppose we attempt to map Q2 to C2. This would mean B would have to map to Y but this is illegal because B was already mapped to Z! Thus we can immediately prune this branch of the search space and try to map Q2 to C3, which coincidentally will not work either. Hence we have a way of quickly eliminating possible operation mappings before moving on to the potentially more expensive task of mapping the input sorts.

The second way this technique reduces the search space is by constraining the number of input sorts that have to be matched in an operation. As we saw from the

31

example Table 10 illustrated, the search space grows exponentially as the number of unmapped sorts for an operation grows. Using Table 10 again, if we map Q1 to C1 and Q2 to C2 then by applying the technique of immediately matching the output sort, we would have B mapped to Z and F mapped to Y. The fact that B is mapped means that we can eliminate B from the set of unmapped sorts in Q2 when performing sort matching for the Q2/C2 pair. This means only three of the four input sorts would have to be permuted to discover a sort mapping. It turns out that in this particular case, however, since B is mapped to Z, Z, or some supertype of Z, would have to be present in C2's set of input sorts but it is not, therefore we can eliminate the Q2/C2 pairing immediately and prune this branch from the search space.

3.   Match Predefined Types

[9] and [2] both allude to the fact that basic types must be preserved in the partial signature map. Such a rule well serves the quest for reducing the signature matching search space by establishing more constraints that can be applied early in the process. For example, the previous section described how the output parameters could be matched immediately following an operation mapping to determine if such a pairing was worth exploring further. Incompatibilities were not caught, however, until at least two operations had been proposed for matching. By applying the constraints that predefined types impose, we have an opportunity to short circuit the branch even earlier. Consider Table 11 for example. If B is an integer, then Z must belong to the integer sort group such that Z is a subtype of B.[8] If Z does not meet this criteria than the branch can be pruned immediately and Q1 and C1 will never be considered for matching. If Z did pass such constraints then Q2 and C2 can be considered for matching, thereby subjecting Y to the same constraints that Z was required to pass.

The preservation rules of predefined types can also be used to reduce the number of unmapped input sorts to permute. All of the query's predefined sorts can be tested for

---

[8] [2] explicitly declares subtype matching rules for input and output parameters. Such rules and their applicability to the method of signature matching described in this thesis are addressed in section V.C.3.

compatibility with the candidate before the permutation process begins. If they all have matches then they can all be removed from the query's set of input parameters, leaving just the unmapped user-defined types for permutation. Clearly this can have profound effects on the number of permutations required to evaluate and therefore pare the search space down significantly.

C. DESIGN AND IMPLEMENTATION

This section is divided into two subsections. The first subsection introduces the objects used to implement the signature matching algorithms and the second subsection discusses the signature matching approach in terms of the objects defined in the first subsection.

1. Signature Matching Types

In order to better illustrate the signature matching strategy proposed in this thesis we must first examine the data types used to carry out the strategy. Figure 12 depicts the signature matching objects.
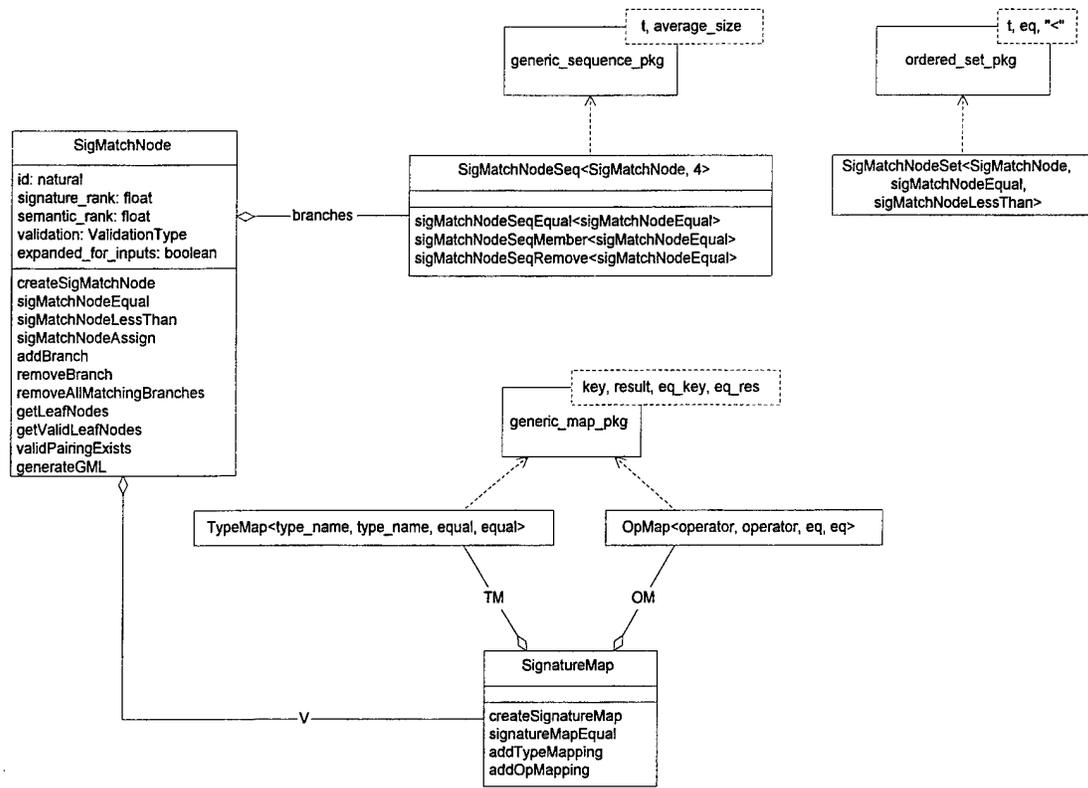

Figure 12: Signature Matching Types

The first object of interest is the *SignatureMap*. This is used to store the operation and type mappings between a query and a candidate and follows [9]'s definition of a partial signature map.

At the crux of the design is the *SigMatchNode*. This data type is used to represent solutions in the signature matching search space by being represented as a node in a tree data structure. The node stores the signature and semantic ranks of the solution (the SignatureMap V) it represents and maintains validation and expansion information for search space maintenance. Since this object is used to form a tree, a handle to a single SigMatchNode can be used to contain the entire search space. When the signature matching process is finished, all the leaves of this tree can be considered valid solutions and therefore can be "clipped" from the tree and returned as the set of solutions. The *getLeafNodes* method is the leaf "clipper" in this case.

Finally, the *SigMatchNodeSet* is used to store the set of SigMatchNodes that will be placed in the Candidate (section IV.C.4) object. Notice first that this collection is a set

34

so that duplicate solution nodes can be easily eliminated and second that this set is ordered. The ordering is defined by the signature rank until semantic matching is performed. Once semantic matching has taken place, the semantic rank takes precedence.

2. Signature Matching Strategy

A high-level view of the signature matching strategy is depicted in Figure 13.
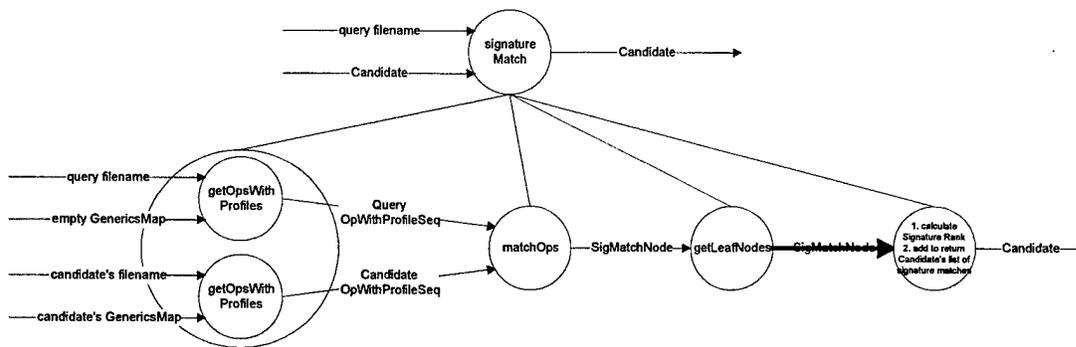

Figure 13: High-level View of Signature Matching

This illustration shows the context in which the core signature matching function, *matchOps*, operates. Once profile filtering is complete, each candidate with a profile rank above a certain threshold is passed to *signatureMatch* along with the original query. signatureMatch then outputs the same candidate passed in but with its set of SigMatchNodes populated.

signatureMatch decomposes into four major steps. The first step calculates the profiles for the operations in the query and the candidate and returns them in the form of *OpWithProfile* sequences. An OpWithProfile, depicted in Figure 14, is simply an association between an operator and its profile. An *OpWithProfileSeq* is a sequence of OpWithProfiles ordered by the lexicographic ordering on profiles used in *opWithProfileLessThan*. The advantages of such an ordering were detailed in section V.B.1. The query's and candidate's OpWithProfileSeq is then passed to matchOps where the actual signature matching takes place. matchOps passes the root SigMatchNode of

35

the entire signature matching search space for the particular query and candidate to getLeafNodes where the valid signature match solutions represented in the leaves of the search space are extracted into a set of SigMatchNodes. Finally, the signature rank for each SigMatchNode in the set is computed and the set is then assigned to the Candidate.
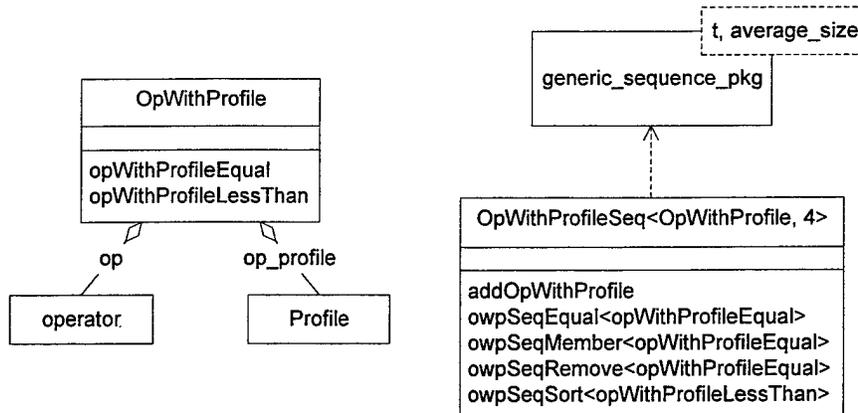

Figure 14: OpWithProfile Data Types

The core signature matching routine is matchOps. Ada-like pseudo-code for matchOps is listed below:

```
procedure match_ops(query: in OpWithProfileSeq, candidate: in OpWithProfileSeq,
        root_sn: in out SigMatchNode) is
    temp_sn, return_val: SigMatchNode;
    temp_query, temp_candidate: OpWithProfileSeq;
    q_op, c_op: OpWithProfile;
begin
    return_val := root_sn;

    --
    -- depth-first-search into possible operation pairings
    --
    temp_query := query;
    temp_candidate := candidate;
    foreach OpWithProfile q_op in query loop
        foreach OpWithProfile c_op in candidate
                where q_op.op_profile = c_op.op_profile loop
            temp_sn := root_sn;
            op_map_pkg.bind(q_op.op, c_op.op, temp_sn.V.OM);
            if not validPairingExists(temp_sn.V.OM, return_val) then
                if match_outputs(temp_sn) then
                    if match_basics(get_basics(q_op.inputs),
                            get_basics(c_op.inputs)) then
                        temp_query := temp_query - q_op;
                        temp_candidate := temp_candidate - c_op;
                        match_ops(temp_query, temp_candidate, temp_sn);
                        addBranch(temp_sn, return_val);
                    end if;
                end if;
            end if;
        end loop;
    end loop;
```

36

```
--
-- depth-first-search into possible input pairings
-- prune until all leaves are valid solutions
--
pruned := true;
while pruned loop
    pruned := false;
    root_sn := return_val;
    foreach leafnode leaf_sn in root_sn loop
        if leaf_sn.validation = UNKNOWN then
            if not match_inputs(leaf_sn) then
                leaf_sn.validation := INVALID;
            elsif not verify_subtypes(leaf_sn) then
                leaf_sn.validation := INVALID;
            else
                if length(leaf_sn.branches) = 0 then
                    leaf_sn.validation := VALID;
                else
                    leaf_sn.expanded_for_inputs := true;
                end if;
            end if;
            if leaf_sn.validation = INVALID then
                removeAllMatchingBranches(leaf_sn, return_val);
                pruned := true;
            end if;
        end if;
    end loop;
end loop;

    root_sn := return_val;
end match_ops;
```

There are two main sections to this procedure. The first is a depth-first search into the space of all compatible operation pairs and the second is a combined matching of input sorts and retraction of invalid nodes. The first section steps through each operation in the query, trying to match it to an operation in the candidate. This is done by invoking the following three steps in order: first verifying that the profiles are equal, second verifying if the outputs match (see section V.B.2) and third verifying that the predefined types can match (see section V.B.3). If any of these three steps fail, the operation pairing is not considered and the remaining tests are immediately short-circuited to reduce time. If the three steps succeed then the pairing is added as a branch to the root SigMatchNode passed in to matchOps and matchOps is recursively called again with the same query and candidate OpWithProfileSeqs with the operations just paired removed. Figure 15 illustrates the search space for possible operation pairings for the query and component in Table 10. The highlighted path is the path searched before moving on to the second part of matchOps that involves matching the input sorts and performing any possible retractions of invalid nodes. The rest of the space is depicted here to illustrate the nature of the search space but at this point only the highlighted nodes have been instantiated.
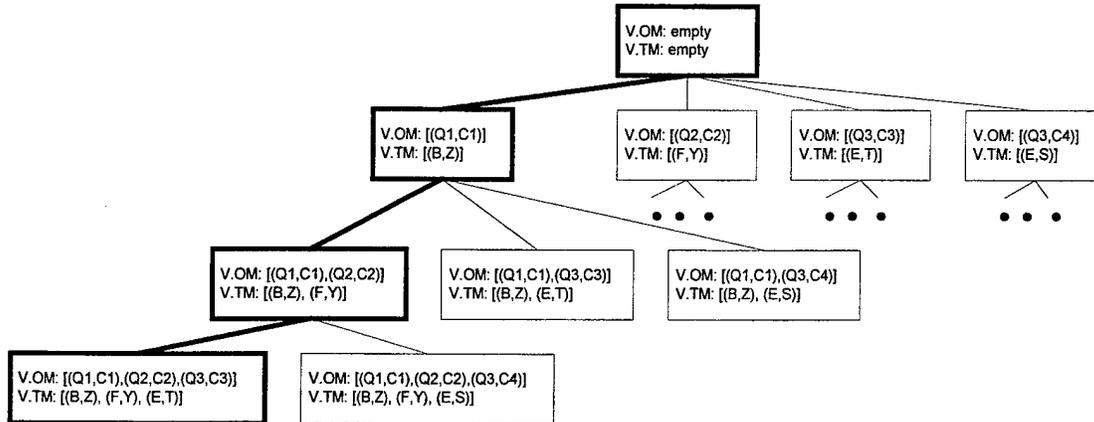

Figure 15: Example Search Space for Compatible Operations

Now that we have searched to the bottom of this particular path we can now begin expanding the search space for matching the inputs for the various operations paired in the node. Ada-like psuedo-code is listed below for this phase of signature matching.

```
--
-- Function: match_inputs
--
function match_inputs(root_sn: in out SolutionNode) return boolean is

    function match(q_inputs: in TypeSequence; c_inputs: in TypeSequence;
            root_sn: in out SolutionNode) return boolean is
    begin
        -- recursive stopping case
        if size(q_inputs) = 0 then
            return;
        end if;

        return_val := root_sn;

        new_q_inputs := q_inputs;
        new_c_inputs := c_inputs;

        -- verify mapped inputs in q_inputs are legally mapped
        -- and set new_q_inputs and new_c_inputs to only
        -- the unmapped inputs
        foreach input_type qi in q_inputs loop
            if type_map_pkg.member(qi, root_sn.V.TM) then
                ci := type_map_pkg.fetch(root_sn.V.TM, qi);
                -- if the current input type is already mapped
                -- then make sure it is mapped to an existing type
                -- in the candidate's input.
                if not type_sequence_pkg.member(ci, c_inputs) then
                    return false;
                end if;
                new_q_inputs := new_q_inputs - qi;
                new_c_inputs := new_c_inputs - ci;
            end if;
        end loop;

        qi := q_inputs[1];
        foreach input_type ci in c_inputs loop
            temp_sn := root_sn;
            temp_sn.expanded_for_inputs := false;
```

38

```
            type_map_pkg.bind(qi, ci, temp_sn.V.TM);
            if not match(new_q_inputs-qi, new_c_inputs-ci, temp_sn) then
                return false;
            end if;
            addBranch(temp_sn, return_val);
        end loop;

        root_sn := return_val;
        return true;
    end match;

begin
    foreach op_mapping om in root_sn.V.OM loop
        -- remove the input types that have already been mapped
        q_inputs := om.key.inputs - type_map_pkg.map_domain(root_sn.V.TM);
        c_inputs := om.result.inputs - type_map_pkg.map_range(root_sn.V.TM);

        -- if the number of remaining input types for the query and
        -- the candidate are unequal than the operations cannot match
        if type_sequence_pkg.length(q_inputs) /=
                type_sequence_pkg.length(c_inputs) then
            return false;
        end if;

        -- if the node has already been expanded before to try and match
        -- the inputs and it still has unmapped input types then return
        -- false so we won't try again
        if root_sn.expanded_for_inputs then
            return size(q_inputs) = 0;
        else
            return match(get_basics(q_inputs), get_basics(c_inputs), root_sn);
        end if;
    end loop;
end match_inputs;
```

This function first removes any sorts from the set of inputs that have already been mapped. At this point in our example, this would mean removing any input sorts that were the same as the output sorts since the output sorts have been mapped. If this results in an uneven number of unmapped sorts between the query and the candidate then we can immediately stop and return false since there cannot be a match. Next, if this node has already been expanded in the past and it ultimately led to an invalid node then we do not want to expand this node again since we know where it leads. Finally, if we make it through these preliminary checks then we can pass the node on to the recursive function *match* that will expand the node into all the possible input sort pairings to be investigated. If there are no legal possibilities, match will return false and cause match_inputs to return false, signaling match_ops to flag this node as invalid.

Going back to our example, the node for which we are currently trying to match inputs cannot be expanded because Q1's first input sort, E, is already mapped to T but there is no T in the input sorts for C1! The test for making sure the number of unmapped input sorts in the query is equal to the number of unmapped input sorts for the candidate

will fail and cause match_inputs to return false. Looking back at match_ops, this will cause the node to be pruned and match_ops will pop back to its previous instantiation on the stack and search the next possibility in the search space. The tree at this point is shown in Figure 16.
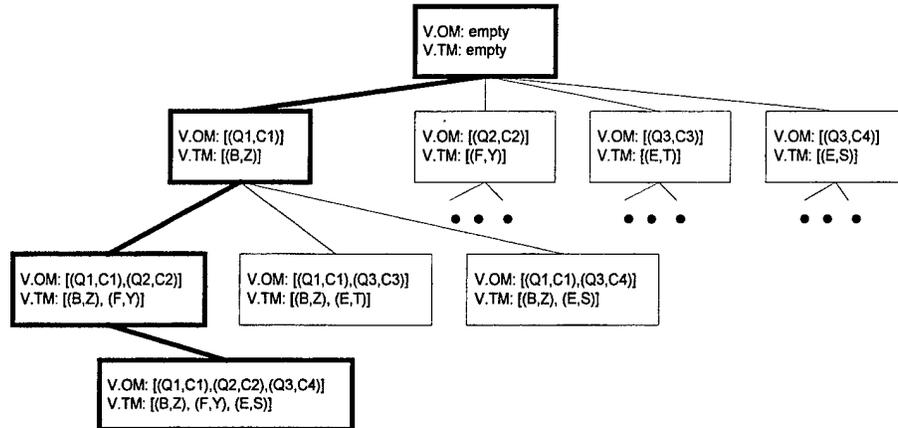

Figure 16: Search Space after First Pruning

The current node will be pruned for the same reasons the first node was pruned: E is already mapped to a sort that does not exist in the candidate's input sorts. So again, another node is pruned, match_ops pops back up and we are now left with the tree in Figure 17.
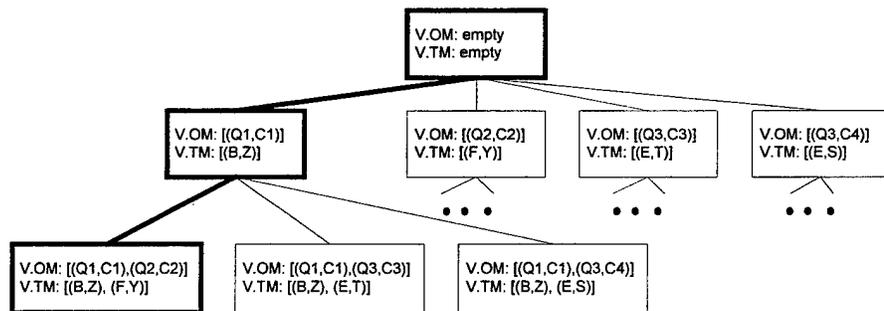

Figure 17: Search Space after Second Pruning

Now we have a node that will pass all the preliminary steps and successfully expand for all the possible input pairings. Given the relatively large number of

40

unmapped inputs in Q1 and Q2, the expansion is quite significant. Figure 18 shows part of this expansion.
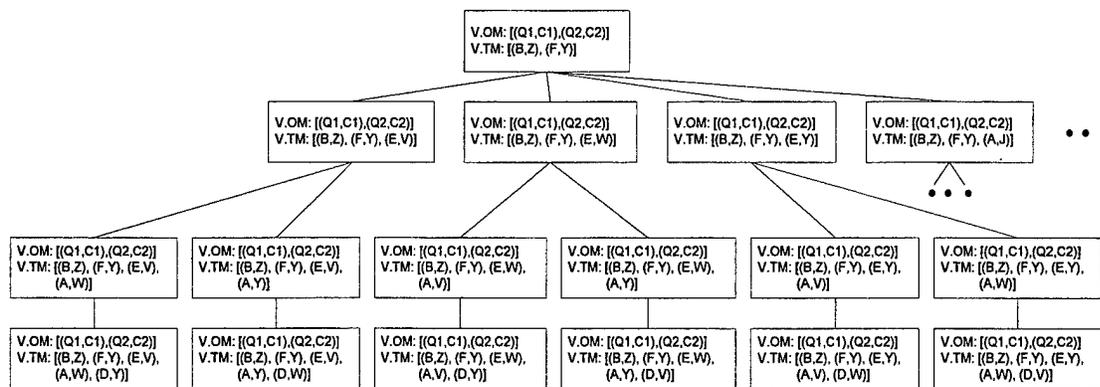

Figure 18: Input Sort Matching Expansion

The figure effectively illustrates the combinatorial explosion associated with large numbers of unmapped inputs and underscores the need for the improvements cited in section V.B. Figure 18 only shows the expansion for the first pairing Q1/C1 and *one* node for the pairing Q2/C2. Q2/C2 is expanded in the same way Q1/C1 is expanded but is not shown here due to space limitations. The entire expansion is ultimately returned back to match_ops where the valid leaves will continue to go through the match_inputs expansion. In this case all the leaves shown in Figure 18 will have to be expanded further to add any more mappings Q2/C2 brings on top of the Q1/C1 mappings. Similarly this would be done for Q1/C1 on top of the Q2/C2 mappings in the portion of the tree not shown. The expansion/prune loop in match_ops continues until there are no more leaves to expand and all of the existing leaves are valid.

A legitimate concern might arise from the example thus far regarding the fact that Q1/C1 and Q2/C2 are expanded twice, but in different order. This must take place because it is possible to have different input sort mappings depending on which order the operations are expanded in. For instance, notice in the first node representing Q2/C2's input matching (whose expansion is not shown further in Figure 18 due to space) that A is mapped to J. In the Q1/C1 expansions A is never mapped to J. This possibility would

41

never be explored in this part of the search space if the different ordering of pairing expansions were not represented.

3.   Subtype Matching

In section V.C.2 we see that match_ops tests if the predefined types in the operations for an operation pairing can be legally matched. The Ada-like pseudo-code for determining this legality for the input types is listed below.

```
function match_basics(q_basics: in out TypeSequence; c_basics: in out TypeSequence)
      return boolean is
begin
    -- cannot match if query has different number of basics than the
    -- candidate
    if size(q_basics) /= size(c_basics) then
       return false;
    end if;

    --
    -- Basic types: either they must match exactly
    -- or the query's input type must be a
    -- subtype of the component's input type.
    --

    --
    -- filter out the basics that match exactly
    --
    new_q_basics := q_basics;
    new_c_basics := c_basics;
    foreach input_type qi in q_basics loop
        foreach input_type ci in c_basics loop
            if equal(qi, ci) then
                new_q_basics := new_q_basics - qi;
                new_c_basics := new_c_basics - ci;
                break; -- out of inner foreach loop
            end if;
        end loop;
    end loop;
    q_basics := new_q_basics;
    c_basics := new_c_basics;

    --
    -- Filter out the remaining basics that can match to supertypes.
    -- This is done by temporally mapping each query input types to a
    -- supertype in the candidate that is closest in the partial ordering.
    --
    foreach input_type qi in q_basics loop
        foreach input_type ci in c_basics loop
            if subtype_of(qi, ci) then
                found_ci2 := false;
                foreach input_type ci2 in new_c_basics loop
                    if not found_ci2 and subtype_of(qi, ci2) and not equal(ci, ci2)
                             and subtype_of(ci2, ci) then
                        found_ci2 := true;
                    end if;
                end loop;
                if not found_ci2 then
                    new_q_basics := new_q_basics - qi;
                    new_c_basics := new_c_basics - ci;
                end if;
            end if;
        end loop;
```

42

```
        end loop;

        --
        -- if there are any basics left over than match is not possible
        -- since basics cannot be matched to non-basics
        --
        return type_sequence_pkg.length(new_q_basics) = 0;
    end match_basics;
```

Of particular note is the portion of the function that is responsible for subtype matching. Without subtype matching the operation pairing would fail if there were predefined types left over after all the predefined types that can find exact matches were mapped. With subtype matching, however, the possibilities of mapping the remaining predefined types are explored.

[2] defines subtype matching rules for mapping the input and output types of an operation. These rules are summarized below:

1. an input type of a query must be a subtype of the input type in the candidate to which it is mapped
2. an output type of a query must be supertype of the output type in the candidate to which it is mapped

These rules are followed in the pseudo-code above. An interesting case arises when there is more than one supertype available in the candidate. In such a case the algorithm above will choose the supertype closest in the partial ordering for that particular sort group. For instance, if we are trying to map a positive in the query and the candidate has a natural and an integer still unmapped, then the natural is selected over the integer because the positive is closer to the natural in the partial ordering of the integer sort group. This has the advantage that the less refined sorts remain available in the candidate for potential mappings with less refined sorts in the query.

[9] extends [2]'s rules by maintaining subtype consistency throughout the partial signature map. For example, suppose we are trying to match Q1 and C1 from Table 10 and we map E to V and A to W. The subtype rules in [9] state that if E is a subtype of A then V must be a subtype of W, otherwise the mapping is invalid. The test of such consistency in the approach outlined in this thesis is made by the call to *verify_subtypes*

43

in match_ops. If the test fails for all the mapped sorts in the node then the node is considered invalid and pruned.

VI. EXPERIMENTATION

To test the effectiveness of the syntactic matching improvements presented in this thesis the CAPS software base [10] was selected as well as the following four queries:

Query: Stack

```
TYPE Stack                              SPECIFICATION

The queries are instantiations of generic components from the software base to ensure interesting matching activity. An attempt was made to instantiate the generic parameters differently in order to facilitate observation of the different manifestations of improvement in this thesis. For instance, the *stack* and *queue* query use predefined types for the generic parameters, whereas the *set* and *map* queries do not. As a result, the sensitivity to improvements involving predefined types will be different amongst the queries.

A.   GENERIC COMPONENT INSTANTIATION

The CAPS software base contained 80 components, most of which are generic abstract data types. After instantiating all of the generic components with all possible

combinations (see section IV.C) the number of searchable components increased to 566. This is a substantial increase and demonstrates the need for quick filters early in the search process.

B.   PROFILE FILTERING

1.   Software Base Resolution

As mentioned in section IV.B.1, increasing the resolution of profiles will increase the resolution of the software base by requiring more non-empty partitions (haase-nodes) to store the components.   An increased partition count means there will be fewer components sharing partitions and therefore contributes to an increase in precision without a loss in recall during profile filtering. A simple metric for determining the effectiveness of the resolution improvements is the number of partitions necessary to store all the components in the software base. The more partitions, the more effective the profile resolution improvement. Figure 19 illustrates the effectiveness of the resolution improvements outlined in this thesis on the CAPS software base. The graph shows that applying all the resolution improvements yields a 65% gain in the number of partitions over no improvements at all.
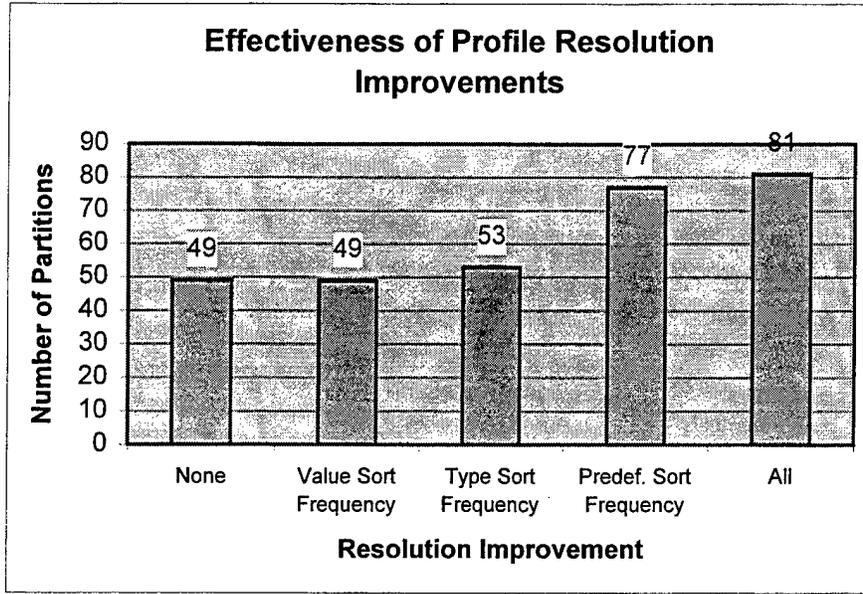

Figure 19: Effectiveness of Profile Resolution Improvements on Software Base Partitioning

By observing the effects of the different resolution improvements individually it is evident that the kind of components in the software base drive the effectiveness of the various improvements differently. For instance, in the CAPS software base the components have similar operations to one another that do not vary in the frequency of the value sort. Thus the value sort frequency improvement has no effect. The components do, however, make reference to various predefined types thereby causing the substantial increase in partitions. If the CAPS software base did not use predefined types at all, however, then such an improvement would obviously have no effect.

2.   Profile Filtering Performance

Increasing the resolution of the profiles should cause an increase in precision without a recall penalty. Hence, we want to see a reduction in the number of components returned at high profile rank thresholds. Such behavior is exactly what we see in the graphs illustrated in Figure 20 through Figure 23. For each query a substantially greater number of components are filtered out at high profile rank thresholds when all of the profile improvements are employed then when none of the improvements are employed.

The effectiveness of each profile improvement individually is again dependent upon the properties of the query and the components in software base. As we saw in Figure 19, the CAPS software base is rather sensitive to the predefined sort frequency improvement. As expected, this sensitivity is evident during profile filtering. For example, when the profile rank threshold is set at 1 (requiring a 100% match) the predefined sort frequency causes the number of recalled components to be drastically reduced.
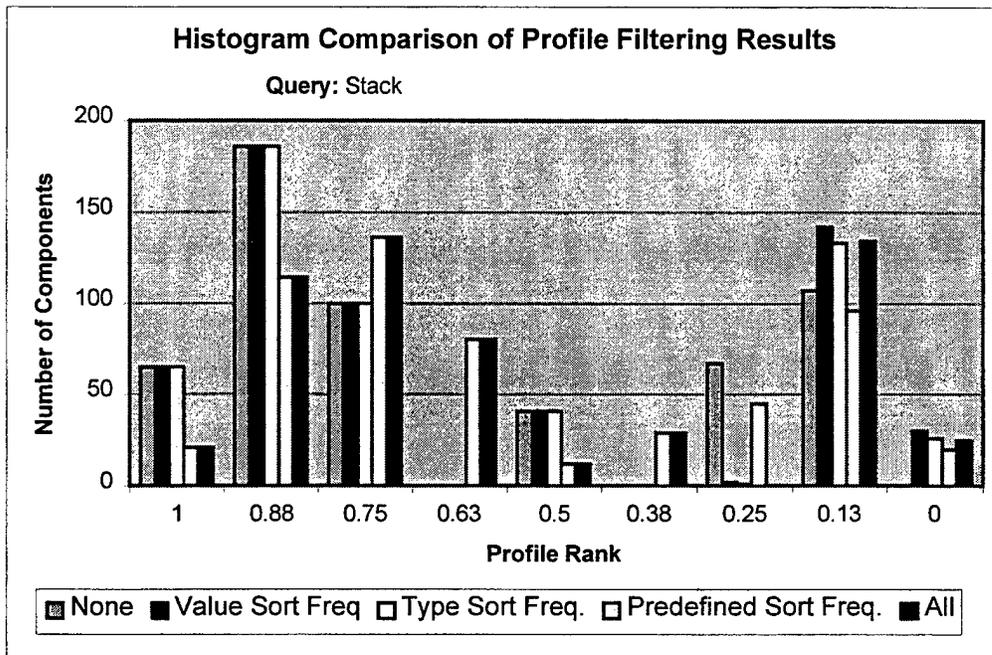

Figure 20: Histogram Comparison of Profile Filtering Results with Stack Query
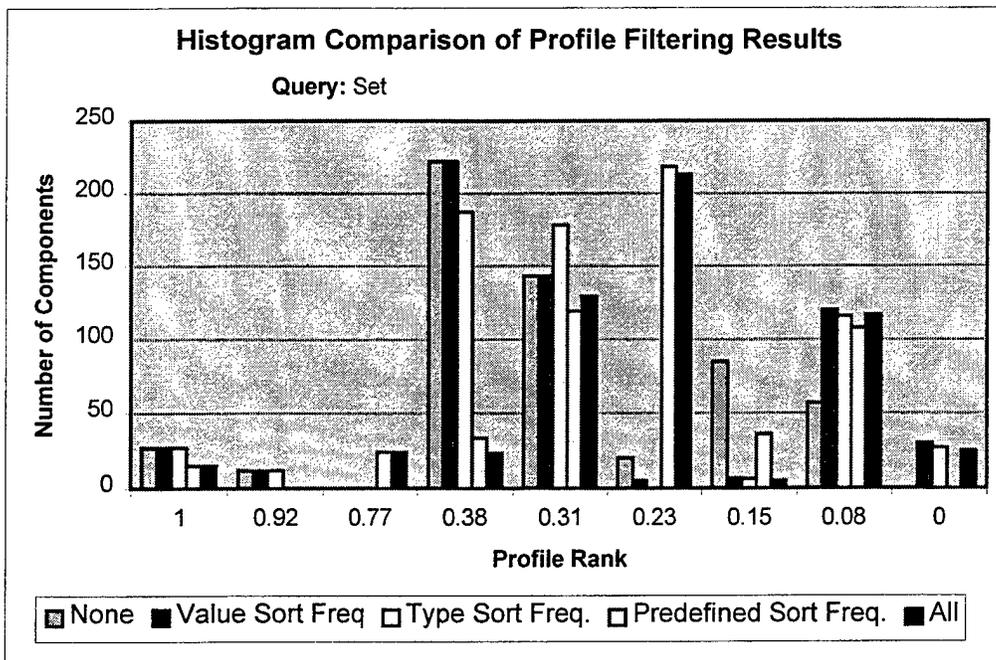

Figure 21: Histogram Comparison of Profile Filtering Results with Set Query
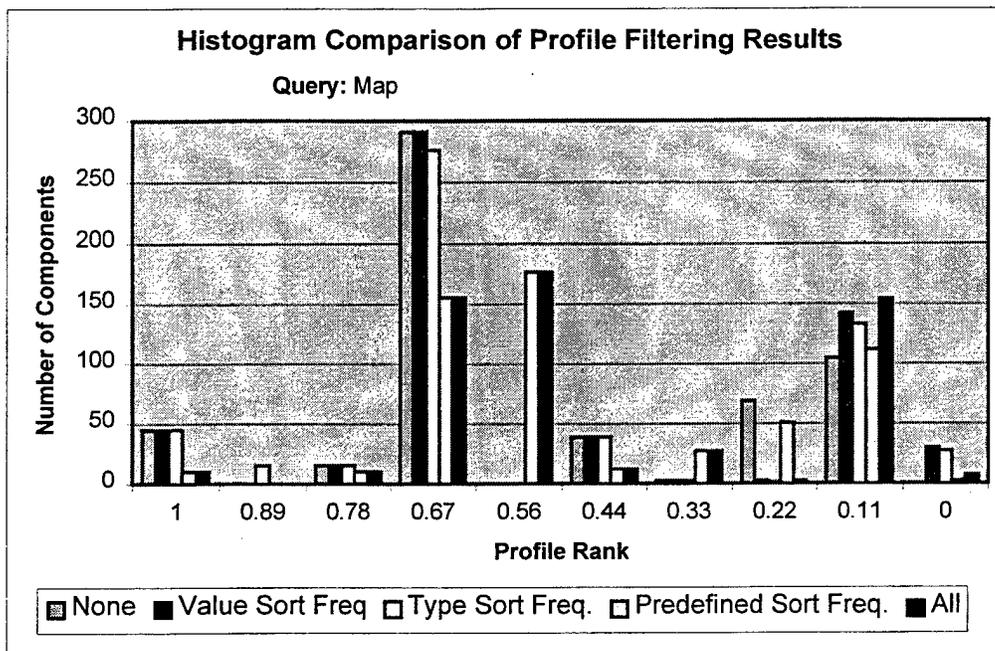

Figure 22: Histogram Comparison of Profile Filtering Results with Map Query
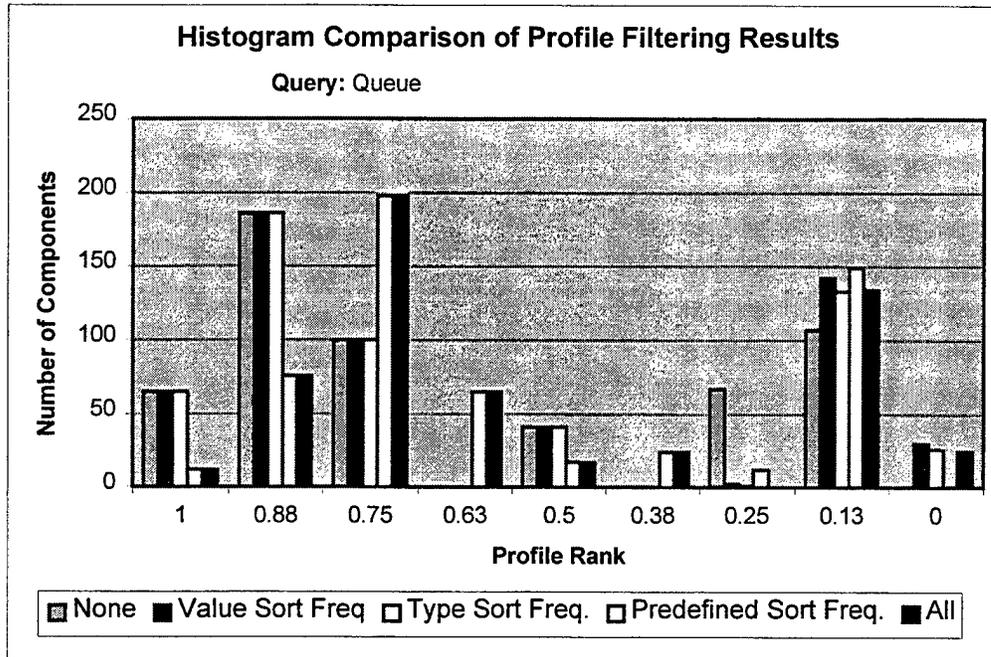

Figure 23: Histogram Comparison of Profile Filtering Results with Queue Query

Figure 24 through Figure 27 present a different perspective on the effectiveness of the resolution improvements during profile filtering. These graphs maintain a running sum of the number of recalled components throughout the continuum of profile rank thresholds. They show us that at a profile rank threshold of .65 (65% of the operations in the query must be in the component) the improvements lose their advantage. In other words, if the user sets the profile rank threshold above .65, the resolution improvements presented in this thesis will have a significantly positive effect on increasing precision.

C.   SIGNATURE MATCHING

This thesis has presented improvements to signature matching both indirectly through improvements to profile resolution and directly through early pruning of the search space.   This section illustrates the effectiveness of these improvements respectively.

1.   Effectiveness of Profile Improvements on Signature Matching

Determining the effects profile resolution improvements have on signature matching is difficult because the traditional rankings that order the outcome of profile filtering and signature matching are not orthogonal.   Furthermore, it is difficult to compare the effects the individual profile resolution improvements have on signature matching because they will cause the profile filtering process to potentially return different sets of components to pass on to signature matching. Finally, different queries can cause behavior that is difficult to correlate. To this end, a concise quantification of the effectiveness profile improvements have on signature matching will not be made in this thesis. Rather, informal comments can be made regarding the results of the signature matching process for the four queries and the various resolution improvements in Figure 28 through Figure 31. These graphs compare the effects the different profile resolution improvements have on signature matching by showing distributions of the number of valid partial signature maps for each signature rank. The signature matching was performed on a randomly selected component that had a profile rank of 1 (100% of the query's operations had compatible operation profiles in the component), meaning a signature rank of 1 was possible.

To begin, Figure 28 shows that when all of the profile resolution improvements are active, a valid signature map where 88% of the *stack* query's operations are mapped can be obtained. For the particular candidate chosen, this is not possible when no improvements are active.
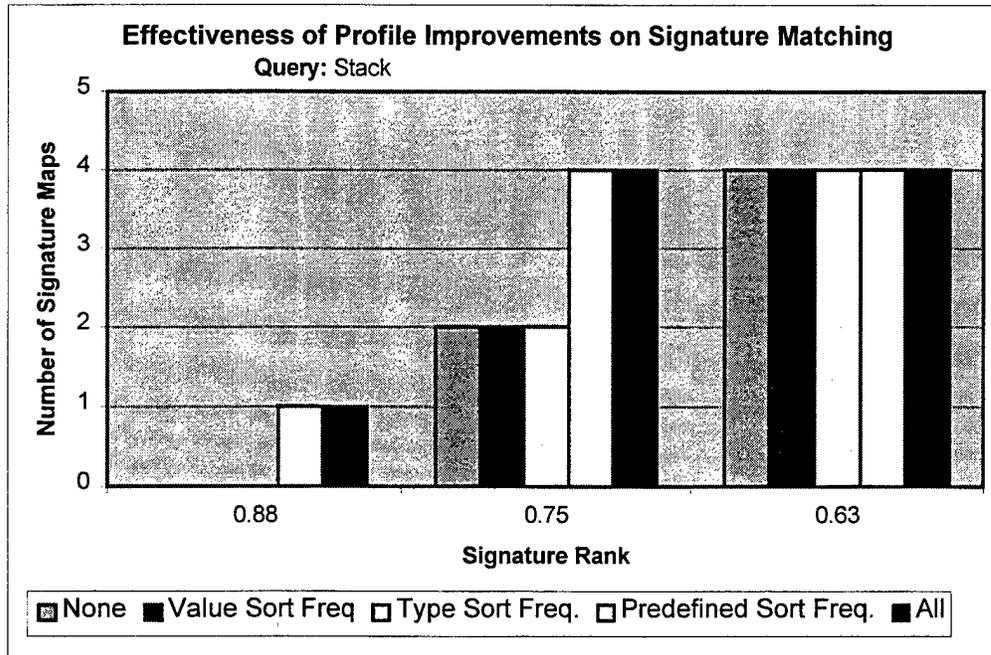

Figure 28: Effectiveness of Profile Improvements on Signature Matching with Stack Query

In Figure 29 two main characteristics are visible. First, the number of valid signature maps that are generated is substantially more than with the other queries. This is due to the fact that the *set* query has many operations that are compatible with the candidate from the software base. As described in section V.B, the possible permutations grow exponentially as the number of operations with compatible operation profiles grows. The second characteristic to notice is the lack of performance from the predefined sort frequency improvement. Throughout the distribution it returns the same number of maps as the version without improvements. This can be attributed to the lack of predefined types in the inputs of the operation signatures, causing the predefined sort frequency improvement to make only a small precision improvement over no resolution improvements for a profile rank of 1 (see Figure 25). The same candidate happened to be chosen for both cases and hence the same signature matching results ensued.
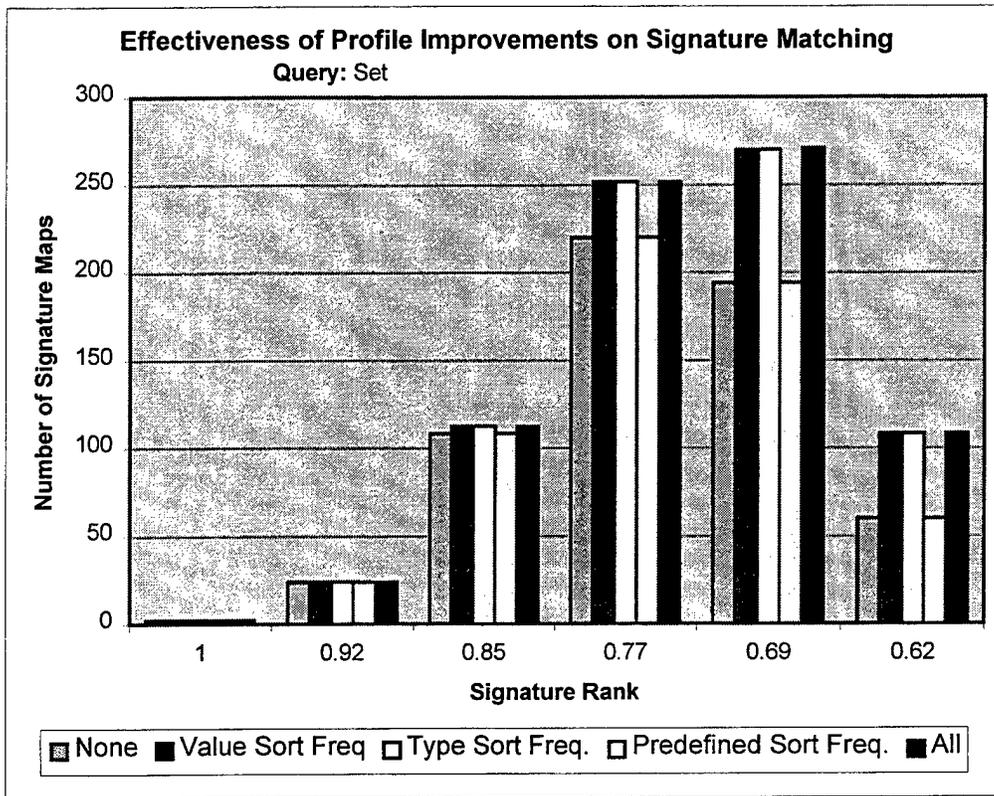

Figure 29: Effectiveness of Profile Improvements on Signature Matching with Set Query

Figure 30 and Figure 31 both have examples of 100% success in syntactic matching. The profile resolution improvements do not make any difference in these examples, however, primarily because the combination of the query and software base caused the random selection of the candidate to select the same candidate.
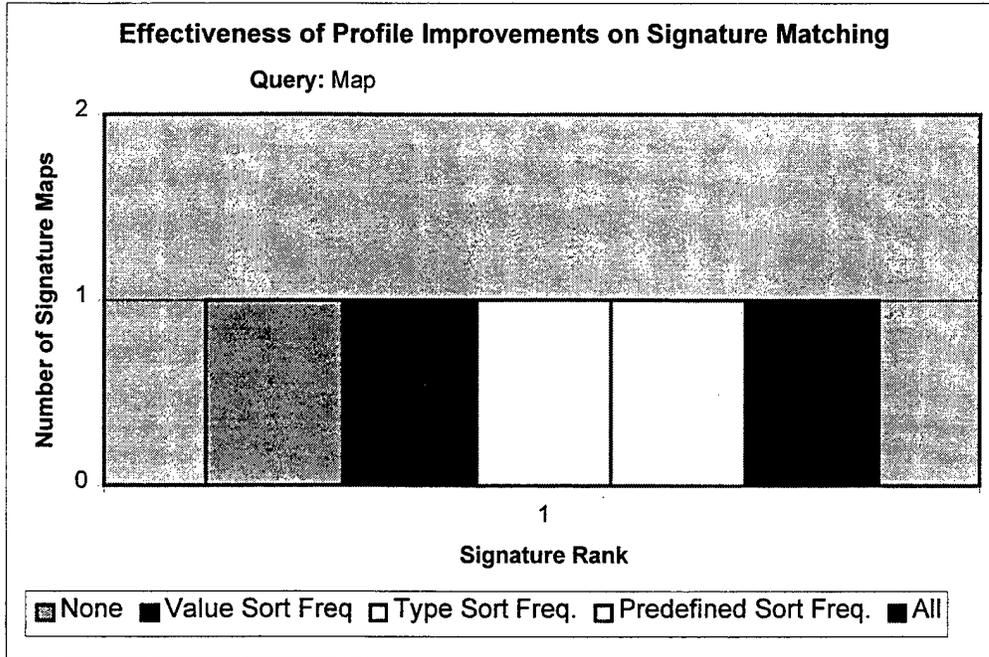

Figure 30: Effectiveness of Profile Improvements on Signature Matching with Map Query
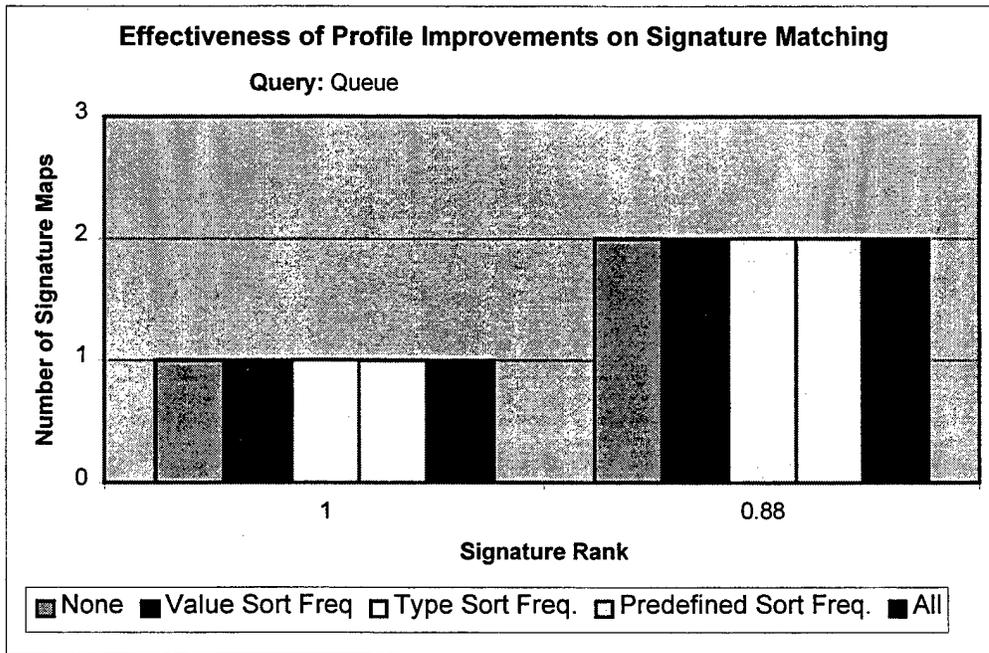

Figure 31: Effectiveness of Profile Improvements on Signature Matching with Queue Query

2.   Signature Matching Algorithm Performance

The signature matching improvements presented in section V.B can be observed by counting the number of nodes that pass and fail the early tests for output matching and predefined type matching. Of particular interest is the number of failed nodes. Failed nodes represent nodes that are pruned. Clearly, the more nodes pruned the better. Such a measurement shows off the signature matching improvements presented in this thesis. The graphs in Figure 32 through Figure 35 show pass/fail node measurements for each query and compare between the various profile resolution improvements.
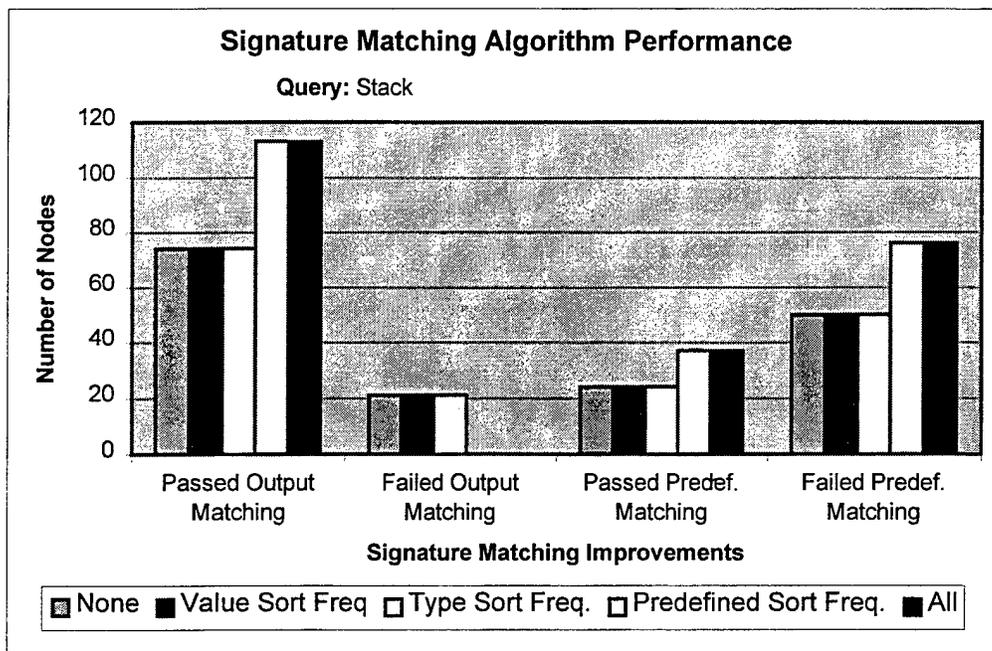

Figure 32: Signature Matching Algorithm Performance with Stack Query
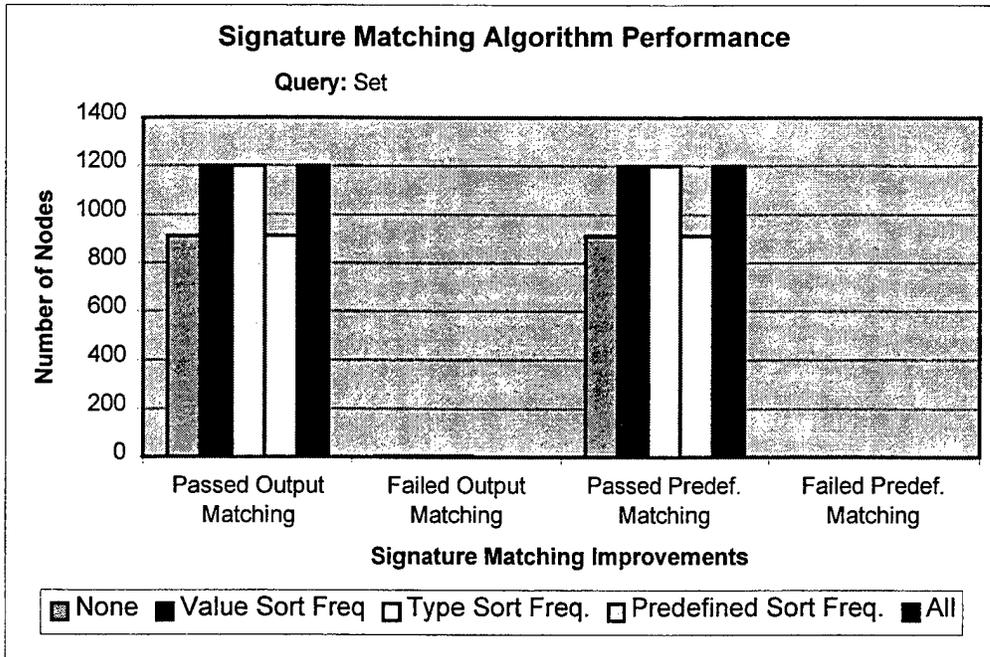

Figure 33: Signature Matching Algorithm Performance with Set Query
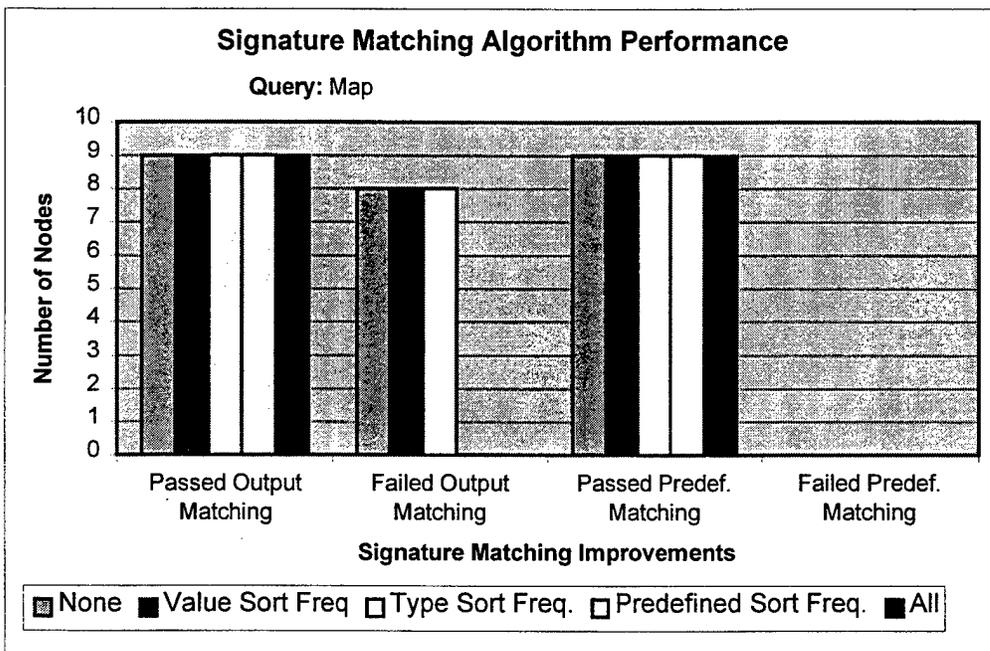

Figure 34: Signature Matching Algorithm Performance with Map Query

61
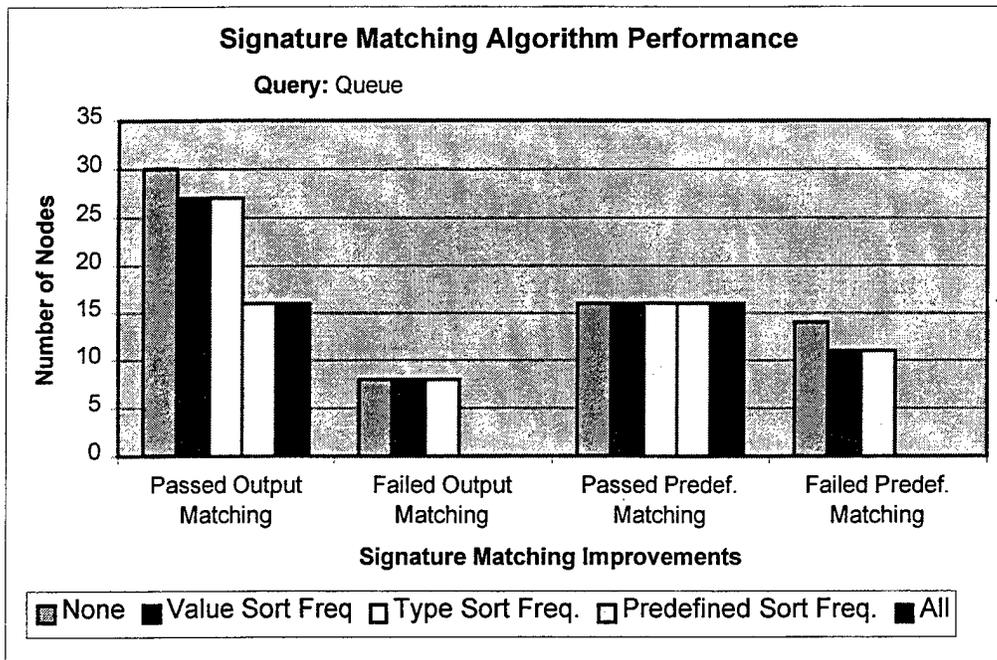

Figure 35: Signature Matching Algorithm Performance with Queue Query

Observing the number of failed nodes, however, does not consider the notion that the profile resolution improvements implicitly "prune" during the profile matching process. For example, the predefined sort frequency profile improvement, in many cases, can beat the predefined-matching signature matching improvement to the punch because it causes less operation pairs to be generated for operations with predefined types (operation pairs are generated when an operation in the query has an equal profile with an operation in the candidate). Hence, to merely look for a large number of failed nodes does not properly measure the full effectiveness of the complete syntactic filtering improvements outlined in this thesis because of the lack of orthogonality between profile filtering and signature matching.

VII. CONCLUSION AND FUTURE RESEARCH

A.   ACCOMPLISHMENTS

This thesis has presented improvements to profile filtering and signature matching that help multi-level filtering achieve its goal of reducing large amounts of candidate components early in the process. More specifically, the resolution improvements to syntactic profiles enable the profile filtering process to significantly cut down the number of components passed on to the more computationally intensive signature matching process. Furthermore, we have seen that large-integer representations of syntactic profiles and exclusive use of a profile lookup table can lead to an optimal time-and-space implementation.

The improvements to signature matching included techniques for pruning the search-space of signature maps in an effort to find valid mappings quicker and with less computational resources. Initial experiments have backed up the theoretical instinct that the signature matching improvements are sensitive to the profile resolution improvements.

Finally, a detailed design and implementation of a syntactic matching software module that includes the improvements proposed in this thesis has been developed. The software has been written in Ada 95 and is mature enough for future inclusion with the other elements of multi-level filtering and CASE tools such as CAPS.

B.   FUTURE RESEARCH

Future research should include more experiments with different software bases to better measure the effectiveness of the profile resolution improvements. Additionally, more data could be collected to better assess the effect profile resolution improvements have on signature matching.

The implementation facilitated the collection of statistics for generic component expansion. More software bases with generic components should be experimented with

to gain more insight into the bloat generic components so quickly create. Further research into generic queries would also be insightful. The algorithms that instantiated generic components for search and retrieval preparation can also be used to instantiate a generic query. A study in using concurrent search and retrieval processes for each instantiation would certainly prove interesting.

Finally, research into effective graphical user interfaces for the user is needed. The multi-level filtering concept is natural for supporting incremental updates of query results, much like a web-browser incrementally updates information from a web-page. As the efficient front-end filters finish they provide early results that can be output to the user quickly. The user can then either select from these results or let the search process continue refining them. Either way, the user is given quick feedback that is important for user acceptance.

profile_calc.ads

```
------------------------------------------------------------------------
-- Package Spec: profile_calc
--
-- This package contains functions and types that support the computation
-- of profiles from numeric representations of signatures.
--
-- Description of numeric signatures: Positive integers represent
-- instances of non-generic types in the signature.  Negative integers
-- represent instances of generic types in the signature.  Finally,
-- a 0 is used to terminate the array of integers representing the
-- signature.
--
-- Examples of numeric signatures:
-- [integer, char, float -> integer]   ==> [1,2,3,1,0]
-- [integer, generic, float -> float]  ==> [1,-1,2,3,0]
-- [generic1, generic2 -> generic2]    ==> [-1,-2,-2,0]
--
-- Profiles are sequences of integers.
--
-- Generic Types:
-- Generic types cause more than one profile to be generated for a
-- single signature.  Hence, computeArrayProfileWithGenerics returns an
-- array of ArrayProfiles, ProfileValues, bound by NumProfiles.
--
-- ArrayProfiles are terminated with PROFILE_TERMINATOR.  For example,
-- the profile [3,1,1,2] is returned as [3,1,1,2,-99].
--
-- Eventually a different method for handling generic types will be
-- employed and will likely do away with the ArrayProfile data type.

  --
  -- GenericsMap
  --
  -- Description: this is a mapping of generic type identifiers to
  -- actual types that exist in the component.  For example, if the
  -- PSDL type Stack has one generic type named Item and has methods
  -- that have parameters that use the types natural, Stack, and
  -- boolean then there would be four different instantiations of
  -- Stack in the software base representing the four possible
  -- mappings for Item:  1. Item => natural; 2. Item => Stack,
  -- 3. Item => boolean, 4. Item => Item.  Option 4 really just
  -- means that Item is mapped to a type that does not appear in the
  -- component.  Suppose Stack used two generic types.  In that case
  -- each instantiation's GenericsMap would have two entries, one
  -- for each generic type.  In such a case the number of different
  -- instantiations present in the software base grows rapidly;
  -- specifically the number would be the cross product of the number
  -- of types across each generic type.
  --
