### ABSTRACT

Single and multi-dimensional fiber grating strain sensors have been embedded into a composite pressure vessel and used to determine the presence of damage associated with a cut tow and a Teflon tape defect.

### MULTI-AXIS FIBER GRATING STRAIN SENSORS

Figure 1(a) illustrates a multi-axis grating written onto polarization preserving fiber, which is subject to uniform transverse loading. In this case, the two spectral reflection peaks, corresponding to the effective fiber gratings along each birefringent (polarization) axis, will move apart or together uniformly providing a means to measure transverse strain.<sup>1,2,3</sup> In the case where load along the transverse axis is not uniform, as shown in Figure 1(b), the peak associated with the nonuniform transverse load will split.<sup>1</sup> The transverse strain gradient can be measured quantitatively by the spectral separation between the peaks. The portion of the grating under a fixed transverse load is reflected in the amplitude of the peak. For example, in Figure 1(a) the transverse load along the vertical axis is uniform. There are only two spectral peaks as a result, and their spectral separation defines the transverse load. In the case of Figure 1(b), the transverse load has two values along the vertical axis, each along approximately one half of the fiber grating length. In this case, the spectral peak corresponding to the vertical axis splits. The spectral shift between these subpeaks determines the transverse load gradient. As an example, a shift of 0.1 nm would correspond to approximately 300 microstrain. The amplitudes of the two split peaks are approximately equal indicating that each of the two distinct transverse load regions are approximately equal (the amplitude of the fiber grating spectral peak indicates the fraction of the fiber grating under that load). The response of the fiber to transverse strain is approximately 1/3 of that

of axial strain along the length of the fiber. As a specific example at 1300 nm, a spectral shift of 0.01 nm along the fiber axis corresponds to 10 microstrain. A peak-to-peak separation of 0.01 nm due to nonuniform transverse strain corresponds to approximately 30 microstrain for 125 micron diameter bow-tie polarization preserving fiber. These properties may be used effectively to measure the extent and location of damage in a composite pressure vessel.

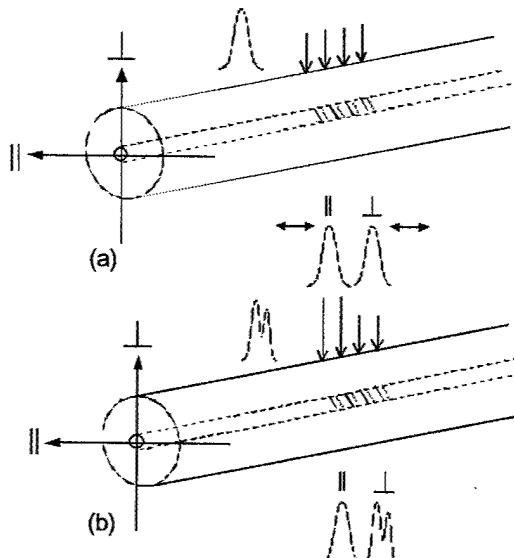

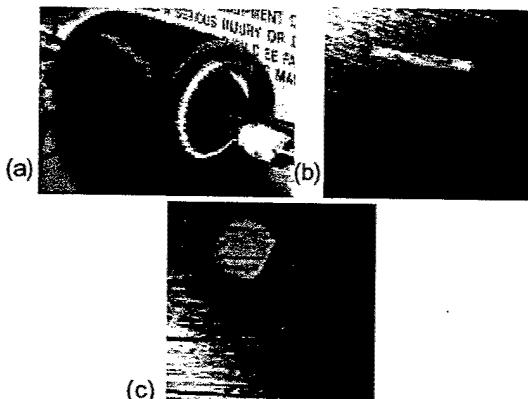

Figure 1. The Effect of Strain on a Multi-Axis Fiber Grating (a) When a multi-axis fiber grating sensor is subject to uniform transverse loading two spectral reflections result whose spectral separation is a measure of transverse strain. (b) When transverse strain across the fiber is not uniform along one of the birefringent (polarization) axes, the peak associated with that axis splits, providing a means to measure transverse strain gradients effectively and quantitatively.

## USAGE OF MULTI-AXIS FIBER GRATING STRAIN SENSORS TO DETECT DAMAGE IN A COMPOSITE PRESSURE VESSEL

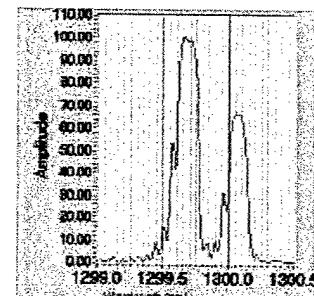

A pressure vessel was fabricated and multi-axis and single axis fiber grating strain sensors were placed to enable the detection of damage. The transverse strain axes of the multi-axis fiber grating sensors were aligned in the plane and out of the plane of the cylinder. Damage was purposefully introduced into two locations prior to cure. In the first damage area, a section of prepreg tow was cut. In the second damage area, a piece of Teflon tape was introduced. The dual-axis fiber grating sensor in the area of the cut tow was able to clearly indicate that damage occurred in the plane of the cylinder after cure. In the case of the Teflon tape, the dual-axis sensor in the vicinity did not detect damage after cure, but it was able to pick up damage after the first pressure cycle. Impacts were made on the composite pressure vessel on both the cut tow and Teflon tape damage area with resulting changes in the multi-axis strain fields that could be observed after each impact, and with additional changes induced by subsequent pressure cycling.

Figure 2(a) shows an overview of the part in the process of being fabricated. Figure 2(b) shows the placement and orientation of a single and dual-axis fiber grating strain sensor. Figure 2(c) shows the placement of a Teflon tape defect relative to the fiber grating strain sensors in this location.

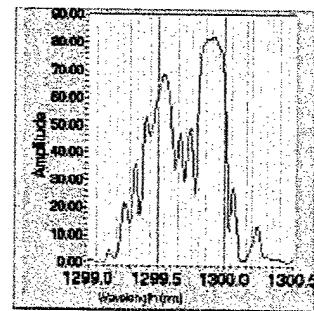

**Figure 2. Fabrication of Composite Pressure Vessel** (a) Part, (b) placement of dual-axis fiber grating strain sensor in prepreg tow on the first helical winding and a bare single axis fiber grating strain sensor orthogonal to it, (c) introduction of Teflon tape defect near the single and dual-axis fiber grating strain sensor.

Figure 3 shows the spectral profile of the dual-axis fiber grating strain sensor placed near the area of the cut tow damage site in the pressure vessel. In this case, prepreg tow alignment elements were placed on either side of the fiber grating but not over it, so the dual-axis fiber grating was integrated directly into the composite part. Before cure and completion of the composite pressure vessel, the two spectral peaks corresponding to the two transverse axes of the dual-axis fiber grating strain sensor are undistorted by transverse strain gradients. The short wavelength peak is aligned in the plane of the cylinder while the long wavelength peak is orthogonal to it. After the cure, significant transverse strain gradients appear on the short wavelength peak corresponding to transverse strain gradients in the plane of the cylinder, in the direction of the cut tow. Of the six dual-axis fiber grating strain sensors placed in the part this was the only one exhibiting this type of behavior.

**Figure 3. Aligned Dual-Axis Fiber Grating Strain Sensor Placed Bare into the Composite Pressure Vessel Near the Area of the Cut Tow Damage Site**  
(a) Before cure and (b) after cure.

Figure 4 shows a sequence illustrating transverse strain gradients on a single axis fiber grating strain sensor near the Teflon tape defect through the first pressure cycle.

**Figure 4. Sequence of Spectral Profiles**  
**Sequence of spectral profiles from single axis fiber grating strain sensor placed bare into the part approximately 2.5 cm from the Teflon tape damage site during the first pressure cycle (a) 0 psi, (b) 666 psi, (c) 1000 psi, (d) 666 psi, (e) 333 psi, and (f) return to 0 psi**

The advantage of using multi-axis sensors is that the directions of the transverse strain gradients, as well as the magnitudes are known. In the case of the damage sequence involving the cut tow of Figure 3 the known orientation of the multi-axis fiber grating sensor allows the user to understand that damage is in the plane of the cylinder of the composite pressure vessel. In addition, from Figure 3 it is apparent that out of the plane of the cylinder the spectral peak associated with that direction shows no change indicating that in this direction damage did not occur. By using arrays of multi-axis fiber grating sensors the directional information may be used to localize and characterize the extent of damage. In the case of Figure 4, the single axis fiber grating sensor located near the Teflon tape defect severe transverse strain gradients arise and the evolution of damage throughout the pressure cycle is clearly evident.

These transverse strain gradients are locked in after the cycle is complete. Because the fiber grating is single axis the direction of the damage is not known and information for both out of plane and in plane transverse, strain gradients as well as possible axial strain gradients are intermixed. When the damage sites around the cut tow area of Figure 3 and the Teflon tape area of Figure 4 are impacted the resulting damage releases the transverse strain gradients and eventually the fiber grating spectral profiles move back to their unloaded state.

## SUMMARY

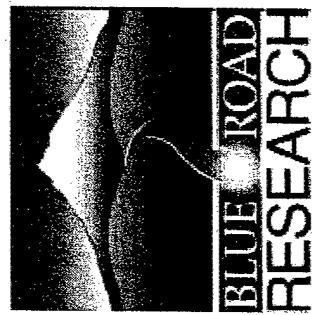

The ability of single and multi-axis fiber grating strain sensors to detect cut tow and Teflon tape defects in a composite pressure vessel have been shown. The multi-axis fiber grating strain sensors have the ability to indicate the direction of damage. Additional work is being pursued to refine and extend the ability of multi-axis fiber grating strain sensor arrays to accurately measure and localize damage in composite parts.

## ACKNOWLEDGEMENTS

This work was supported under the Phase I SBIR contract to Blue Road Research, F04611-01-C-0038, granted by Edwards AFB. Dr. Gregory Ruderman is the Technical Program Monitor. Blue Road Research gratefully acknowledges the support of this SBIR and Dr. Ruderman.

# Summary

---

- Multi-axis fiber grating strain sensors can be used for quantitative damage assessment of adhesive joints
- Cut tow and Teflon tape defects may be detected using multi-axis fiber grating strain sensors
- Quantitative measurements of the evolution of damage due to pressure cycling and impacts can be made using multi-axis fiber grating strain sensors
