PROGRAM OVERVIEW

Objectives:

The objectives of this program as originally stated are:

- Characterize the polymer carbon nanotube interaction in organic matrix composites. Classify interactions, and dispersion mechanisms of high aspect ratio nano-materials (ie. carbon nanotubes). Modify interactions to aid in dispersion of nano-materials to form a maximally-space filled matrix.
- Determine structure properties relationships for potential applications in several model nano-composite systems. Characterize thermal, optical, mechanical and electronic properties of the model systems.
- Demonstrate optical and electronic applications through "proof of principle" devices. Applications include: organic light emitting diode and display technologies, thermally conductive organic coatings, optical filtering and photovoltaics.

Summary Statement:

This program introduced the conceptual novelties of electro-active polymer – carbon nanotube nanocomposites. These nanocomposites are generally composed of a "minority" nanophase and a majority-phase host and interaction between the phases is primarily: exchange of charge, mediation of radiative energy, and morphological based on energy minimization. The meso-structure of the nanophase can strongly influence the properties of the composite to the point of being totally dissimilar to the original pure organic. Thus, charge transfer nanocomposites (CTN's are our new name for these materials) are being increasingly realized as a separate and distinct materials system. A summary of the significant results are given here. More details can be found in the yearly reports.

PROGRAM RESULTS

SWCNT-PEDOT for EMI shielding

Highly conductive, transparent coatings have been created using SWCNT – PEDOT:PSS blends. Figure 1 shows performance characteristics of 80 nm thick films on polycarbonate. No antireflective coatings were used in these measurements suggesting that even better performance might be possible. So far sheet resistances of 100 Ω /square and 2 Ω -cm bulk resistances with 80 % transparency have been achieved

Modification and control of nanotube electronics

We have designed nanotubes that can behave as donors or acceptor in a polymer host through the use of substitutional Nitrogen (donor) and substitutional Boron (acceptor). Shown here in figure 2 is an EDX mapping of nitrogen concentration throughout the nanotubes. Note that this is the first direct demonstration of dopant distribution within a tube. These results have been coupled with EELS, and Raman to insure uniformity of material. This is expected to be of significant use as a photovoltaic material.

Figure 2 Red(Fe)/Green(O)/and Blue (N)

Nanotube metrology

As a "side" result of our growth program, it was develop a technique of necessary to characterization that allowed for dopant levels within the nanotubes to be estimated. We developed (together with Christian Thomsen in Berlin) methods of double resonant Raman scattering to provide detailed and quantitative concentrations on defect in information nanotubes. The relations are:

$$I^{D/D^{\bullet}} = 1.3 + 1.4 \cdot x(\% \text{conc.})^{-1}$$

 $I^{G/D^{\bullet}} = 2.1 + 0.47 \cdot x(\% \text{conc.})^{-1}$

where the Raman intensity is related to the defect concentration. Notice in figure 3 that the defect concentration scales directly with boron concentration in the growth mix. This indicates we can now control to some degree the level of dopant added to nanotubes substitutionally.

Light Emitting Devices

We have demonstrated significant enhancements to performance (luminence) and lifetime in organic light emitting diode structures (OLEDs). We have reported performance enhancements in both total luminence as well as power efficiency and conversion efficiency. Red, green, and blue emitters based on PFO's from Dow Inc. Figure 4 shows the astonishing results in power efficiency for each of the emitters.

Figure 4

Further, significant enhancements in operational lifetimes have been measured. Shown in figure 5 is a standard lifetime test as utilized by Dow and various other companies. Notice the composite devices show little to no degradation in performance.

Figure 5

We have found similar lifetime effect in both organic photovoltaics and organic transistor structures. Studies are ongoing to try to determine the underlying cause of these effects.

Photovoltaics

This program examined the performance of organic based photovoltaic devices using nanocomposites. Detailed analysis suggests hole transfer to the nanophase (not electron as suggested by the literature). This has been determined through time of flight methods coupled with transport data. These results suggest that doping modification to nanotubes may allow electron transfer and substantially greater gains in performance. Current state of the art from this program is a 3% conversion efficiency. Using P3OT hosts and doped nanotubes we estimate an increase of a factor of 2 to 3 over this value based on the ratio of hole to electron mobilities. These studies are ongoing. All of these studies are carried out using a AM1.5g standard.

Actuation and transduction

PVDF based actuation and transduction has been investigated using nanotube additives. It was found that nanotubes nucleated crystallization of the piezo-active beta phase of the polymer thereby enhancing the overall piezo- and pyro- electric effect. The addition of nanotubes further enhances the materials mechanical modulus allowing for tailoring of the mechanical response of the actuator. So far, we have measured a 90% increase in pyroelectric coefficient (@ 30° C) and a 50 % increase in the piezo coefficient. These numbers are the highest recorded for the copolymer of PVDF used.

Mechanical/thermal composites

Two structural composites were examined in this program. The first is the fluoropolymer composite PFCB, the second is a cynate ester based resin. Results from these studies are a set of rheological parameters (viscosity, molecular weight, etc.) for maximal blending. We have achieved 4 W/mK along with 25 S/cm in Cynate Esters.

Fluorination of nanotubes was shown to have the same effect in composite formation as using a fluorinated polymer host. Strength enhancement was further shown to scale directly with persistence length within the matrix. This seems to be a result of interlinking of the nanotubes within the matrix yielding a higher energy cost for fracture. In this way, these results are quite similar to these reported by Baughman et al for nanotube based fibers.

SUMMARY

This program has demonstrated enhance device function in both emissive and photovoltaic devices using nanocomposites. Charge transfer to the nanophase is the underlying mechanism of enhancement for both the OPVs and the OLEDs. In pyroelectric and piezoelectric polymers, morphology and phase selection is the key to enhanced performance.

Significant improvements in thermal and electrical conductivity of non-conjugated systems (structural composites) have also been demonstrated.

In short, this program has demonstrated the usefulness of nanocomposites in electroactive polymer devices. There is some distance to go before we achieve the gains in structural composites sought from nanocomposites.
