SAIC Project Number: 01-0813-04-2273

NOTICE

This report presents the results of the 2002 follow-up examination of the Air Force Health Study, the sixth examination in a series of epidemiologic studies to investigate the health effects in Air Force personnel following exposure to herbicides. The results of the 1982 baseline examination and the 1985, 1987, 1992, and 1997 follow-up examinations were presented in six reports: the Baseline Morbidity Study Results (24 February 1987), the Air Force Health Study First Followup Examination Results (15 July 1987), the Air Force Health Study 1987 Followup Examination Results (16 January 1990), the Air Force Health Study Serum Dioxin Analysis of 1987 Examination Results (7 February 1991), the Air Force Health Study 1992 Followup Examination Results (2 May 1995), and the Air Force Health Study 1997 Follow-up Examination Results (22 February 2000).

Given the relationship of the 2002 follow-up examination to the previous examinations, portions of these documents have been reproduced or paraphrased in this report. In addition, portions of the Air Force Health Study Statistical Plan for the 2002 follow-up examination (20 May 1998) have been used in the development of this report. The purpose of this notice is to acknowledge the authors of these previous study reports and documents.

PREFACE

The current report is the last summarizing the results of physical examinations conducted during the Air Force Health Study that began in 1982. For reasons of consistency, all reports follow the same basic analytical plan. This report is comprehensive and detailed, but limited in that (a) it included only those veterans who attended the final physical examination, (b) it addressed only those risk factors that were thought to be important when the study was designed, and (c) it did not account for potentially important risk factors that were discovered after the analytical plan was set. In addition to these six reports, study results have been summarized in articles published in peer-reviewed scientific journals. Such articles differ from the reports in that they (a) incorporate all participants who attended at least one physical examination, (b) use different methods of analysis, (c) focus on particular health endpoints, and (d) include recently discovered risk factors. The results in the journal articles are often consistent, but sometimes lead to conclusions that differ from the six reports. For example, published articles on diabetes in Ranch Hand veterans revealed an association with dioxin exposure consistent with the current report. Published articles on peripheral neuropathy, memory loss, and cancer, however, revealed associations not discussed in this report.

Many of the analyses in this report show no significant differences in health outcomes in the Ranch Hand group. As noted in Section 1.6.7, the lack of a particular finding does not prove that no association exists and should not lead the reader to conclude that there is no association between herbicide exposure and adverse health. In particular, a recently published analysis showed an increase in cancer risk with increased dioxin body burden in Ranch Hand veterans who spent less than 2 years in Southeast Asia; a stratified analysis was performed because years of service in Southeast Asia was identified as a risk factor for cancer in Comparison veterans. These patterns require that more sophisticated statistical models be used to study cancer in Ranch Hand veterans. Consistent with the protocol, study investigators continue to question the underlying assumptions of all analyses, explore new ways to analyze data, and collaborate with specialists to determine whether exposure to Agent Orange adversely affected the health of Ranch Hand veterans.

In the remaining months of this study, articles submitted to journals, but not accepted for publication by the end of the study, will be released. The National Academy of Sciences is currently considering the disposition of study materials after the study ends on September 30, 2006.

REPORT DOCUMENTATION PAGE				Form Approved OMB No. 0704-0188	
<p>The public reporting burden for this collection of information is estimated to average 1 hour per response, including the time for reviewing instructions, searching existing data sources, gathering and maintaining the data needed, and completing and reviewing the collection of information. Send comments regarding this burden estimate or any other aspect of this collection of information, including suggestions for reducing the burden, to Department of Defense, Washington Headquarters Services, Directorate for Information Operations and Reports (0704-0188), 1215 Jefferson Davis Highway, Suite 1204, Arlington, VA 22202-4302. Respondents should be aware that notwithstanding any other provision of law, no person shall be subject to any penalty for failing to comply with a collection of information if it does not display a currently valid OMB control number.</p> <p>PLEASE DO NOT RETURN YOUR FORM TO THE ABOVE ADDRESS.</p>

13. SUPPLEMENTARY NOTES None					
14. ABSTRACT This report summarizes results from the Air Force Health Study (AFHS) 2002 follow-up physical examination. The AFHS was undertaken to determine whether adverse health effects attributable to exposure to herbicides existed in veterans of Operation Ranch Hand. The men assigned to Operation Ranch Hand flew aerial herbicide spray missions in Vietnam from 1962 to 1971. A comparison cohort comprised Air Force veterans who served in Southeast Asia during the same time period and who were not involved with spraying herbicides. A total of 1,951 veterans participated in the 2002 physical examination - 777 Ranch Hands & 1,174 Comparisons. Statistical analyses assessed differences between Ranch Hands & Comparisons & associations between health-related endpoints & extrapolated initial dioxin, dioxin category, and dioxin measured in 1987. The study has insufficient statistical power to assess increases in the risk of rare diseases. Consistent with past AFHS reports, current results indicate a significant & clinically meaningful adverse relation between type 2 diabetes & exposure to dioxin.					
15. SUBJECT TERMS Agent Orange, Air Force Health Study, Diabetes, Dioxin, Epidemiologic Investigation, Herbicide Orange, Phenoxy Herbicides, Ranch Hand

ACKNOWLEDGMENTS

The United States Air Force (USAF) gratefully acknowledges the outstanding support of all the contributors to this project. To all the individuals, named and unnamed, whose dedication and hard work during the past 4 years have made this report possible, sincere appreciation is extended.

The Air Force Health Study extends their sincere thanks and appreciation to all study participants, Ranch Hands and Comparisons, and their family members and significant others, for their participation in and support of the Study.

21.6	SUMMARY	21-9
21.7	CONCLUSION	21-9

List of Tables

Table 1-1.	Parameters of Exposure Assessment Models	1-6
Table 2-1.	Number of Dioxin Analyses Performed for the AFHS 2002 Physical Examination Participants	2-2
Table 2-2.	Results from Serum Dioxin Measurements	2-4
Table 2-3.	Summary of Number of Assays Used for 2002 Follow-up Examination Participant Dioxin Measures	2-4
Table 2-4.	Summary of Lipid-adjusted Dioxin Results	2-5
Table 4-1.	Elements of the 2002 Follow-up Physical Examination.....	4-2
Table 4-2.	Laboratory Test Procedures Performed	4-2
Table 5-1.	Compliance by Group and Examination Year.....	5-7
Table 5-2.	Participants Newly Compliant in 2002 and Their Previous Compliance Pattern.....	5-8
Table 5-3.	Reasons for Refusal by Group.....	5-10
Table 5-4.	Reasons for Refusal by Group, Age, Military Rank, and Race.....	5-11
Table 5-5.	Reasons for Refusal by Group and Year	5-14
Table 5-6.	Self-reported Health Status of Original Comparisons and Their Replacements	5-15
Table 5-7.	Matched Set Compliance of Noncompliant Original Comparisons	5-15
Table 5-8.	Reported Health Status of Refusals	5-16
Table 5-9.	Reported Health Status by Group, Age, Military Rank, Race, and Compliance.....	5-17
Table 5-10.	Reported Health Status by Group	5-17
Table 5-11.	Reported Health Status of Fully Compliant Participants.....	5-18
Table 5-12.	Reported Medication Use of Fully Compliant Participants.....	5-18
Table 5-13.	Reported Work Loss of Fully Compliant Participants	5-19
Table 7-1.	Model 1: Assessing Health Versus Group Status in Ranch Hands and Comparisons: Assumptions, Advantages, and Disadvantages	7-2
Table 7-2.	Model 2: Assessing Health Versus Initial Dioxin in Ranch Hands: Assumptions, Advantages, and Disadvantages	7-5
Table 7-3.	Model 3: Assessing Health Versus Categorized Dioxin in Ranch Hands and Comparisons: Assumptions, Advantages, and Disadvantages.....	7-7
Table 7-4.	Model 4: Assessing Health Versus 1987 Dioxin in Ranch Hands: Assumptions, Advantages, and Disadvantages	7-9
Table 7-5.	Summary of Statistical Procedures	7-11
Table 7-6.	Summary of Statistical Analysis Situations by Dependent Variable Form, Exposure Estimate, Analysis Cohort, and Analysis Type.....	7-14
Table 7-7.	Approximate Power to Detect a Group Effect at a 5-Percent Level of Significance (Discrete Dependent Variable).....	7-17

Table 7-8.	Approximate Power to Detect a Group Effect at a 5-Percent Level of Significance (Continuous Dependent Variable).....	7-18
Table 7-9.	Location of Table Results from Different Exposure Analysis Models	7-19
Table 8-1.	Associations Between Matching Demographic Variables (Age, Race, and Military Occupation) and Estimates of Herbicide or Dioxin Exposure	8-4
Table 8-2.	Associations Between Alcohol Use and Estimates of Herbicide or Dioxin Exposure	8-7
Table 8-3.	Associations Between Cigarette Smoking and Estimates of Herbicide or Dioxin Exposure.....	8-10
Table 8-4.	Associations Between Exposure to Carcinogens and Estimates of Herbicide or Dioxin Exposure	8-13
Table 8-5.	Associations Between Health Variables and Estimates of Herbicide or Dioxin Exposure.....	8-19
Table 8-6.	Associations Between Sun-Exposure Variables and Estimates of Herbicide or Dioxin Exposure (Non-Blacks Only)	8-29
Table 8-7.	Associations Between Other Miscellaneous Covariates and Estimates of Herbicide or Dioxin Exposure	8-34
Table 9-1.	Statistical Analysis for the General Health Assessment.....	9-6
Table 9-2.	Number of Participants with Missing Data for the General Health Assessment.....	9-9
Table 9-3.	Analysis of Self-perception of Health	9-11
Table 9-4.	Analysis of Appearance of Illness or Distress.....	9-13
Table 9-5.	Analysis of Relative Age Appearance.....	9-16
Table 9-6.	Analysis of Body Mass Index (kg/m ²) (Continuous)	9-19
Table 9-7.	Analysis of Body Mass Index (Discrete).....	9-23
Table 9-8.	Summary of Group Analysis (Model 1) for General Health Variables (Ranch Hands vs. Comparisons).....	9-27
Table 9-9.	Summary of Initial Dioxin Analysis (Model 2) for General Health Variables (Ranch Hands Only)	9-28
Table 9-10.	Summary of Categorized Dioxin Analysis (Model 3) for General Health Variables (Ranch Hands vs. Comparisons)	9-29
Table 9-11.	Summary of 1987 Dioxin Analysis (Model 4) for General Health Variables (Ranch Hands Only)	9-30
Table 9-12.	Summary of Results from Significant Adjusted Analyses in the General Health Assessment.....	9-31
Table 10-1.	Statistical Analysis for the Neoplasia Assessment	10-11
Table 10-2.	Number of Participants Excluded or with Missing Data for the Neoplasia Assessment.....	10-17
Table 10-3.	Analysis of All Skin Neoplasms.....	10-20
Table 10-4.	Analysis of Malignant Skin Neoplasms	10-23
Table 10-5.	Analysis of Benign Skin Neoplasms	10-25

EXECUTIVE SUMMARY – 2002 FOLLOW-UP EXAMINATION REPORT

Purpose

The Air Force launched the Air Force Health Study (AFHS) in 1980 to address concerns of veterans, Congress, and the public regarding the consequences of exposure to Agent Orange and other herbicides sprayed during the Vietnam War. Agent Orange and other phenoxy herbicides were contaminated with 2,3,7,8-tetrachlorodibenzo-p-dioxin (dioxin). The purpose of the AFHS was to determine whether adverse health effects exist in Air Force veterans of Operation Ranch Hand, the unit responsible for spraying Agent Orange and other herbicides in Vietnam from 1962 to 1971, and whether those adverse effects can be attributed to the veterans' occupational exposure to Agent Orange or its dioxin contaminant. This report summarizes the results of the 2002 physical examination.

Study Design

This prospective epidemiologic study included assessments of health, mortality, and reproductive outcomes. Members of the Ranch Hand unit were identified by military records. A comparison group comprising Air Force veterans who flew or serviced C-130 aircraft in Southeast Asia (SEA) during the same time period that the Ranch Hand unit was active, but who were not involved with spraying herbicides, also was formed. The health assessment included six physical examinations. Each physical examination included an in-person interview and laboratory measurements of blood and urine.

The baseline examination was conducted in 1982; follow-up examinations were performed in 1985, 1987, 1992, 1997, and 2002. Participation in this study was voluntary and informed consent was obtained at the examination sites. The protocol and conduct of the study was reviewed and approved by the Institutional Review Boards at the sponsoring and participating organizations.

Prior to the baseline examination and after excluding those killed in action (Ranch Hand: n=22, Comparison: n=109), up to 10 Comparisons were matched to each Ranch Hand based on age, race, and military occupation. Each Ranch Hand, and a randomly selected Comparison from those matched to him, were invited to participate in the baseline examination in 1982. In accordance with the protocol, the Comparisons selected for the baseline examination were called Original Comparisons. All Ranch Hands and Original Comparisons were invited to participate in follow-up examinations. If an Original Comparison declined to attend an examination, he was replaced by a Comparison with a similar self-perception of health as the refusing Original Comparison among those matched to the same Ranch Hand; these were termed Replacement Comparisons. A total of 1,951 veterans (777 Ranch Hands, 737 Original Comparisons, and 437 Replacement Comparisons) participated in the 2002 physical examination, representing 74.5 percent, 67.4 percent, and 46.0 percent compliance, respectively. Physical examination findings, laboratory measurements, and disease histories were studied. Study group (Ranch Hand, Comparison) and serum dioxin measurements were used to assess herbicide exposure. The dioxin measurements were conducted by the Centers for Disease Control and Prevention. The majority of dioxin measurements used in the study were accomplished at the 1987 physical examination. These measurements are referred to as 1987 dioxin. Within Ranch Hands, median dioxin varied with occupation, least among officers, greatest among enlisted groundcrew, and intermediate in enlisted flyers.

Statistical Methods

Four statistical models were used to assess the statistical significance of associations between health and herbicide exposure. Model 1 simply contrasted the two groups as exposed (Ranch Hand) and unexposed (Comparison) to herbicides. The contrasts were conducted both overall and by occupational stratum (officer, enlisted flyer, enlisted groundcrew). Model 1 contrasts did not use serum dioxin measurements. Models 2, 3, and 4 used the serum dioxin measurements. The initial dioxin body burdens in Ranch Hands were estimated using a first-order pharmacokinetic model. Model 2 assessed the significance of the relation between health and the estimated initial dioxin in Ranch Hand veterans. To implement Model 3, the Ranch Hand cohort was stratified according to three dioxin exposure categories: background, low, and high. The background category comprised Ranch Hands with 1987 dioxin of 10 parts per trillion (ppt) or less. The remaining Ranch Hands (above 10 ppt) were separated into low and high categories by the median of their estimated initial dioxin levels. Model 3 contrasted each of the three Ranch Hand dioxin exposure categories with Comparisons. Model 4 assessed the significance of the relation between health and 1987 dioxin in Ranch Hand veterans.

Strengths and Weaknesses

Study strengths included record verification of reported health conditions, rigorous quality control, good compliance, long follow-up, and adjustment for confounding factors. The study benefited from a two-tiered management structure based on separate but parallel management and technical teams, an independently appointed and administered Advisory Committee, and periodic review by the National Academy of Sciences.

Study weaknesses included the sample size (which prevented the study of rare diseases), imperfect exposure metrics, and, possibly, incomplete adjustment for confounding factors.

Parameters of the Study and Statistically Significant Findings

More than 300 health-related endpoints in 12 clinical areas were studied. Associations found significant after adjustment for confounders are summarized by clinical area. Interpretations were based on toxicological data, biological plausibility, dose-response relationship, and consistency with results of other epidemiologic studies.

General Health Assessment

Self-perception of health, appearance of illness or distress, relative age, and body mass index were studied. Body mass index was positively associated with 1987 dioxin, possibly reflecting the pharmacokinetics of dioxin elimination. The other measures of general health appeared unrelated to herbicide exposure.

Neoplasia Assessment

During the 2002 interview, each participant was asked whether a doctor had told him that he had cancer. Affirmative responses were confirmed by a medical records review. At each examination, suspicious skin lesions were biopsied and the pathology determined. During the entire follow-up period, AFHS staff made every effort to contact and encourage participants to see their physicians regarding abnormal x-ray

findings, laboratory measurements, and pathology reports. Other than skin biopsies, no invasive procedures were used to detect neoplasms at the physical examination.

With regard to malignancies, a mixed pattern of associations with no suggestion of internal or external consistency was found. For example, the risk of basal cell carcinoma was increased among Ranch Hand officers, but not among enlisted groundcrew, the occupation with the highest median dioxin. Similarly, the risk of basal cell carcinoma was increased in the Ranch Hand low dioxin exposure category, but not in the high category. The risk of all-sites cancer was also increased in the low, but not the high dioxin category. These patterns did not suggest an adverse relation between cancer and herbicide exposure.

Neurology Assessment

The neurology assessment included an evaluation of cranial and peripheral nerve function and an examination of the central nervous system. Associations between dioxin and cranial nerve and central nervous system function did not appear consistent or clinically important. The risk of an abnormal visual field was increased in the Ranch Hand background exposure category, but not the high exposure category. The risk of abnormal balance and coordination increased with initial dioxin, but was not increased in the high exposure category or in any occupational subgroup. The risks of abnormal reaction to pinprick and absent patellar reflex were increased in the high dioxin exposure category, providing some support for a relation between dioxin exposure and peripheral nerve function.

Psychology Assessment

Psychological health was evaluated with subscales of the Symptom Checklist-90-Revised (SCL-90-R) and the Wechsler Memory Scale-Revised (WMS-R). Psychoses, alcohol and drug dependence, anxiety, and other neuroses as determined by a medical records review were also studied. None of these outcome measures was associated with herbicide or dioxin exposure.

Gastrointestinal Assessment

Liver disorders were determined by a medical records review. Laboratory assessments of liver metabolism and function, such as levels of triglycerides, C3 complement, alkaline phosphatase and other liver enzymes, haptoglobin, and prothrombin were also studied. The risk of abnormally high triglycerides was increased among Ranch Hand enlisted groundcrew and among those in the low and high dioxin exposure categories. The risk of abnormally high triglycerides increased with initial dioxin. These results suggested subclinical relation between dioxin and lipid metabolism. None of the other measures in this assessment exhibited a consistent or meaningful association with herbicide or dioxin exposure.

Dermatology Assessment

Chloracne is a skin condition recognized as a consequence of exposure to high levels of dioxin and other cyclic organochlorine compounds. It usually appears without long latency after a short interval of exposure to dioxin and persists for about 2 to 3 years. Primary lesions of chloracne were not expected to persist and be noted upon physical examination in 2002. Chloracne might be suggested if the secondary lesions such as scarring, hyperpigmentation, and depigmentation had been observed in the typical distribution areas of chloracne around eyes, temples, and ears. No evidence of chloracne was found in the Ranch Hand or Comparison group.

The dermatology assessment included the occurrence of self-reported acne and physical examination. The occurrence and duration of acne were reported by the participants at the 2002 physical examination. The frequency and occurrence of reported acne after service in SEA were increased in Ranch Hand enlisted groundcrew, the subgroup with the highest median dioxin levels. The frequency of reported acne since SEA service was increased in the background, low, and high dioxin exposure categories. The frequency of acneiform lesions on physical examination was increased only in the background category. The duration of reported acne after service in SEA increased with 1987 dioxin.

The interpretation of the increased frequency of reported acne after service in SEA in Ranch Hand enlisted groundcrew is uncertain because secondary lesions that were observed revealed no association with herbicide or dioxin exposure.

Cardiovascular Assessment

Cardiac function and history of heart disease were studied. Central cardiac function was assessed by measuring blood pressure, heart sounds, and a resting electrocardiograph. Peripheral vascular function was assessed by the presence or absence of carotid bruits, various pulse-point readings, a resting blood pressure index, measures of intermittent claudication and vascular insufficiency, and a funduscopic examination of small vessels. The lifetime history of essential hypertension, myocardial infarction, and stroke or transient ischemic attack was also studied.

Associations between these measures and herbicide exposure were not consistent or clinically interpretable as adverse. One of the findings, the risk of abnormally high diastolic blood pressure, was increased among Ranch Hand enlisted flyers and among Ranch Hands in the high dioxin exposure category. The risk of abnormally high systolic blood pressure, however, was decreased among Ranch Hands in the low and high categories combined; this risk increased with 1987 dioxin in all Ranch Hands. Overall, cardiovascular health did not appear to be adversely associated with herbicide or dioxin exposure.

Hematology Assessment

Red blood cell counts, white blood cell counts, counts of segmented neutrophils, neutrophilic bands, lymphocytes, monocytes, eosinophils, basophils, hematocrit, platelet count, fibrinogen, erythrocyte sedimentation rate (ESR), and red blood cell morphology were studied.

The mean platelet count was increased among Ranch Hand enlisted flyers. The risk of abnormal red blood cell morphology was increased in Ranch Hand enlisted groundcrew and in Ranch Hands in the low and high dioxin exposure categories. The mean ESR was increased in the low and high dioxin exposure categories. White blood cell count decreased as 1987 dioxin increased. These associations did not suggest an adverse relation between herbicide or dioxin exposure and any hematologic diagnosis. They may, however, suggest the future development of inflammatory disorders and monoclonal gammopathies.

Renal Assessment

The history of renal disease and laboratory measures of renal function were studied. The laboratory measurements included urinary protein, urine specific gravity, serum creatinine, blood urea nitrogen, urinary microalbumin, urinary creatinine, and an index of creatinine clearance. The few associations found did not indicate an adverse relation between renal function and herbicide or dioxin exposure.

Endocrine Assessment

Thyroid disease and type 2 diabetes were studied through physical examination, laboratory measurements, and medical records review. The risk of diabetes requiring insulin control was increased in the Ranch Hand high dioxin category. Fasting insulin and the risk of diabetes requiring insulin control increased and time to diabetes onset decreased with initial dioxin. The risk of diabetes requiring oral hypoglycemic or insulin control increased and time to diabetes onset decreased with 1987 dioxin. The risk of abnormally high hemoglobin A1c increased with 1987 dioxin.

The mean thyroid-stimulating hormone was increased in Ranch Hand officers and in all Ranch Hands. The mean luteinizing hormone, the risk of an abnormally high 2-hour postprandial urinary glucose, and abnormally high free testosterone were increased only in Ranch Hand officers.

The adverse associations between type 2 diabetes and dioxin exposure were consistent with findings at previous physical examinations. In contrast, associations between herbicide or dioxin exposure and measures of thyroid function or gonadotropins did not appear consistent or clinically important.

Immunology Assessment

Red cell surface markers, lymphocytes, quantitative immunoglobulins, and a lupus panel were studied. The risk of antinuclear antibody increased with initial dioxin. An examination of individual antibodies revealed no consistent association with dioxin exposure. Overall, there was no consistent or interpretable association between any measure of immune function and herbicide or dioxin exposure.

Pulmonary Assessment

Pulmonary disease history, including history of asthma, bronchitis, and pneumonia, forced vital capacity (FVC), forced expiratory volume in one second (FEV₁), the FEV₁ to FVC ratio, obstructive abnormality, and loss of vital capacity were studied. The frequency of reported pneumonia was increased in Ranch Hand enlisted flyers. The mean FVC was decreased in the low dioxin exposure category. Considering all pulmonary data, these associations did not suggest an adverse relation between respiratory health and exposure to herbicides or dioxin.

Clinically Significant Findings

Consistent with previous AFHS reports, current results indicate a significant and clinically meaningful adverse relation between type 2 diabetes and exposure to dioxin. The risk of diabetes was associated with 1987 dioxin in Ranch Hands. This increase was supported by an increase in disease severity, a decrease in time to onset, and an increase in fasting glucose and hemoglobin A1c with dioxin in Ranch Hand veterans. Similar patterns were observed in 1987, 1992, and 1997.

Ranch Hand enlisted groundcrew and those in the low and high dioxin exposure categories experienced an increased risk of abnormally high triglycerides. The risk of abnormally high triglycerides also increased with initial dioxin. These results suggest a possibility of a subclinical relation between dioxin and lipid metabolism.

1 INTRODUCTION

This chapter describes the purpose and background of the Air Force Health Study (AFHS) and provides an overview of the study design and format of this report. In addition, it provides considerations that should be made when interpreting the results provided in this report.

1.1 PURPOSE OF THE REPORT

The subject of this report is the 2002 follow-up examination of the morbidity component of the AFHS. The objective of the morbidity component is to continue the investigation of the possible long-term health effects following exposure to herbicides with specific emphasis on Herbicide Orange, a one-to-one mixture of 2,4-D and 2,4,5-T, contaminated with 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD). In this report, the use of the term “dioxin” refers to TCDD. The principal investigators and the AFHS reports have focused on dioxin for most of the study, as derived from the early peer review groups, review of the literature, and the Ranch Hand Advisory Committee. Model 1, the Ranch Hand versus Comparison contrast, however, does address in a general way the exposure to other herbicides and their components. In addition, dioxin is a biomarker that the study has used as a surrogate to estimate exposure to phenoxy herbicides, described in greater detail in Section 1.6.3 of this chapter. Although there are approximately 75 different congeners of dioxin, TCDD is believed to be the most toxic and the only contaminant of 2,4,5-T.

This report describes the procedures and results of the 2002 follow-up examination. It was written primarily for epidemiologists, clinicians, and biostatisticians. Familiarity with the study protocol and prior mortality and morbidity reports is essential to a full understanding of this 20-year study. The report format has been established to be similar to previous reports so that readers can compare results across study phases. All statistical analyses in this report were prescribed by the Air Force prior to data collection. This report, prepared by Science Applications International Corporation (SAIC), is submitted as partial fulfillment of Air Force Contract No. F41624-01-C-1012.

1.2 BACKGROUND

In January 1962, President John F. Kennedy approved a program of aerial herbicide dissemination for the purpose of defoliation and crop destruction in support of tactical military operations in the Republic of Vietnam (RVN). This program, code-named Operation Ranch Hand, dispersed approximately 19 million gallons of herbicides on an estimated 10 to 20 percent of South Vietnam from 1962 to 1971. The herbicides sprayed were code-named Herbicide Green, Herbicide Pink, Herbicide Purple, Herbicide Orange, Herbicide White, and Herbicide Blue. 2,4,5-T was an active ingredient in Green, Pink, Purple, and Orange, and dioxin was produced as an inadvertent contaminant of 2,4,5-T during the manufacturing process. 2,4-D was an active ingredient in Purple, Orange, and White. Picloram was an active ingredient in White; cacodylic acid was the active ingredient in Blue. Of the 19 million gallons of herbicide dispersed, approximately 11 million gallons were Herbicide Orange, also called Agent Orange, the primary defoliant of the six herbicides used in the program (1, 2). In this report, the term “Agent Orange” will be used.

From the start, Operation Ranch Hand was heavily scrutinized because of the controversial nature of the program and the political sensitivity to charges of chemical warfare contained in enemy propaganda. The concerns were initially based on military, political, and ecological issues, but shifted to the issue of health

in 1970. The primary concern in the controversy over the human health effects of these herbicides was related to dioxin, a component in four of the six herbicides sprayed. The Air Force estimates that 368 pounds of dioxin were released over 6 million acres in South Vietnam (1). Claims of exposure to herbicides, particularly to Agent Orange, and perceived adverse health effects among U.S. military service personnel resulted in substantial controversy and, eventually, a class action litigation. Social concern for the Agent Orange issue continues to be reflected in scientific research, media presentations, congressional hearings, and legal action.

Since 1970, governmental agencies, universities, and industrial firms have funded numerous human and animal studies of dioxin effects. A key scientific issue in these studies was the extent of exposure (e.g., who was exposed and to what extent each individual was exposed). Unfortunately, in many of the human studies, population identification and exposure estimation have been scientifically elusive.

In October 1978, the Air Force Deputy Surgeon General made a commitment to Congress and the White House to conduct a health study on the Operation Ranch Hand population. This population comprised the aviators and ground support crews who disseminated the majority of the defoliants in the RVN. The Surgeon General tasked the U.S. Air Force School of Aerospace Medicine at Brooks Air Force Base, Texas, to develop a study protocol. In 1982, after extensive peer review, the study protocol was published (3) and the epidemiologic study began. The now Brooks City-Base organizations responsible for executing the protocol have been reorganized and renamed several times since 1982. Currently, the Air Force Research Laboratory, Human Effectiveness Directorate, is responsible for the technical aspects of the study, and the Aeronautical Systems Center, Human Systems Program Office, is responsible for program management.

In 1987, when the serum assay became available, the Air Force initiated a collaborative effort with the Centers for Disease Control and Prevention (CDC) to measure the serum dioxin levels in the AFHS population. The results of that effort demonstrated that substantially elevated levels of dioxin could still be found in the serum of some Ranch Hands (4, 5). Studies of serum dioxin levels have suggested that of all the military personnel who served in the RVN, the Ranch Hand cohort was one of the most highly exposed to herbicides. If dioxin caused an adverse health effect, then, based on the principle of dose-response, the Ranch Hands should have manifested more or earlier evidence of adverse health.

1.3 STUDY DESIGN

The purpose of the AFHS is to determine whether adverse health effects relative to a similar but unexposed group of Air Force veterans exist and can be attributed to occupational exposure to Agent Orange. The study, comprising mortality, morbidity, and reproductive outcome components, is based on a matched cohort design in a nonconcurrent prospective setting. A baseline examination and five follow-up examinations over 20 years provide a comprehensive approach to the detection of adverse health effects. Complete details on the design are provided in the study protocol.

For the baseline examination, the population ascertainment process identified 1,264 Ranch Hand personnel who served in Southeast Asia (SEA) between 1962 and 1971. At the beginning of the AFHS, a Comparison group was identified. Comparison veterans flew primarily transport missions in SEA during the same time period that the Ranch Hand unit was active. Their units used C-130 transport planes flown and serviced by crews with similar training and background as those of Ranch Hand veterans. While Ranch Hand veterans spent most of their SEA service in Vietnam, Comparison veterans spent on average less than 30 percent of their SEA service in Vietnam and were stationed mostly in Taiwan, the Philippines, Guam, Japan, and Thailand. These veterans may have been stationed in one but usually in at

least two countries and many had repeated tours of duty in the region. A computerized selection procedure was used to identify Comparisons with similar characteristics to each Ranch Hand veteran. A maximum of 10 Comparisons for each Ranch Hand was selected, matching on age, race, and military occupation (officer-pilot, officer-navigator, officer-other, enlisted flyer, enlisted groundcrew). After personnel records review, an average of eight Comparison subjects were matched to each Ranch Hand.

A replacement strategy was devised to maintain participation of the Comparisons. Noncompliant Comparisons were to be replaced by Comparisons with the same values of the matching variables (age, race, and military occupation in SEA) and the same health perception. In this way, the Replacement Comparisons would serve as surrogates for Comparisons who did not participate. Complete information on the selection and participation of study subjects can be found in Chapter 5, Study Selection and Participation.

1.4 MORTALITY AND MORBIDITY COMPONENTS

The mortality component addresses noncombat mortality from the time of the SEA assignment. A baseline mortality review was conducted in 1982, and the mortality follow-up reports include periodic mortality updates for 20 years. For the baseline mortality review and the first four updates, five individuals were randomly selected from the matched Comparison set for each Ranch Hand for a 1:5 design. After 1987, the design was expanded to include all 19,078 veterans in the Comparison population.

The baseline morbidity component, begun in 1982, reconstructed the medical history of each participant by reviewing and coding past medical records. A cross-sectional element, designed to assess the participant's current state of physical and mental health, was based on comprehensive physical examinations and questionnaires. For the morbidity component of the study, each living Ranch Hand and a random living member of his Comparison set were selected to participate in the examination. The morbidity follow-up examination comprises sequential questionnaires, medical records review, and physical examinations in 1985, 1987, 1992, 1997, and 2002. Participation was voluntary and each participant signed an informed consent form at the examination site.

The baseline morbidity assessment, conducted in 1982, disclosed few differences between the Ranch Hands and Comparisons (6). The sustained commitment to pursue the Agent Orange question to its scientific conclusion was demonstrated by the conduct of the morbidity follow-up examinations. These examinations provided the opportunity to confirm or refute some of the baseline findings and to explore subtle longitudinal changes. In the follow-up examinations, the physical and mental health status of the participants during the time interval since the baseline examination was assessed. The results of the follow-up examinations did not reveal major differences in the health status of Ranch Hands and Comparisons since 1982. There was not sufficient evidence to implicate a relation between herbicide exposure and adverse health in the Ranch Hand group.

For the baseline examination and the 1985 and 1987 follow-up examinations, the major focus of the analyses was to compare the health status of the Ranch Hands (i.e., the exposed cohort) with that of the Comparisons (i.e., the unexposed cohort). Methodology to measure dioxin body burden in blood was not made available until February 1987. During the 1987 physical examination, the Air Force initiated a collaborative study with CDC to measure dioxin levels in the serum of Ranch Hands and Comparisons (4, 5, 7). The measurement of serum dioxin levels led to a statistical evaluation to assess dose-response relations between dioxin and the approximately 300 health endpoints in 12 clinical areas. This was the first large-scale study of dose-response effects based on a direct measurement of dioxin. The statistical

analyses associated with the serum data evaluated the association between a specified health endpoint and dioxin among the Ranch Hands. The analyses also contrasted the health of various categories of Ranch Hands having differing serum dioxin levels with the health of Comparisons having background levels (10 parts per trillion [ppt] or less) of serum dioxin (8). The analysis of dose-response relations based on serum assays provided an important enhancement to the previous AFHS investigations.

In 1992, the fourth examination was initiated. During a 10-month period, data for 12 clinical areas were collected. For the next 2 years, the data were prepared and analyzed, and the 1992 follow-up examination report was written. As in previous reports, the analysis focused on group differences between the Ranch Hand and Comparison cohorts and on the association of each health endpoint with serum dioxin levels. Findings revealed a consistent relation between dioxin and body fat that was initially noted in the analysis of the 1987 examination results. Cholesterol and the cholesterol-to-high-density lipoprotein (HDL) ratio were found to be associated with 1987 serum dioxin levels (9). Evidence for a possible association between glucose intolerance, impaired insulin production, and dioxin levels was revealed. Also revealed was a significant association between selected peripheral pulse abnormalities and dioxin levels, and a significant decrement in self-perceived health status of Ranch Hands. Other health endpoints revealed no consistent patterns within or across clinical areas that were suggestive of an adverse relation between health and herbicide or dioxin exposure.

The fifth examination began in 1997 (10). Data were collected and analyzed for 12 clinical areas. The analysis focused on group differences between the Ranch Hand and Comparison cohorts and on the association of each health endpoint with extrapolated initial and 1987 serum dioxin levels. Diabetes and cardiovascular abnormalities represented the most important dioxin-related health problems seen in the 1997 examination. Consistent with previously reported results, the 1997 follow-up examination data indicated a significant and potentially meaningful adverse relation between serum dioxin levels and diabetes. A significant dose-response relation was found, with Ranch Hands in the high dioxin category exhibiting an increase in diabetes prevalence. As a group, Ranch Hands experienced a statistically significant increase in the prevalence of heart disease (excluding essential hypertension). The prevalence of diagnosed essential hypertension and the percentage of Ranch Hands with electrocardiograph (ECG) findings of prior myocardial infarction increased significantly with initial dioxin. Peripheral pulse abnormalities in 1987 and 1992 increased with 1987 dioxin levels, while 1997 peripheral pulse abnormalities did not. Indices of bilateral peripheral polyneuropathy significantly increased with initial and 1987 dioxin levels. These indices also were increased in the high dioxin category. These findings were new and appeared consistent with polyneuropathies observed in studies of industrial exposure; however, the numbers of affected veterans were small and the clinical importance of the findings was uncertain. There were consistent and significant increases in cholesterol, triglycerides, and the cholesterol-HDL ratio with initial and 1987 dioxin. HDL decreased significantly as dioxin increased. These findings also were observed in 1987 and 1992. Isolated group differences existed, but 1987 dioxin levels were strongly related to increases in hepatic enzymes, such as aspartate aminotransferase (AST), alanine aminotransferase (ALT), and gamma glutamyltransferase (GGT) and, as previously noted, cholesterol, triglycerides, and HDL.

The sixth and final examination began in May 2002. As in 1985, 1987, 1992, and 1997, this examination was conducted by SAIC in conjunction with Scripps Clinic and the National Opinion Research Center (NORC). Analysis of data collected at the 2002 follow-up examination was the basis for this report.

1.5 ORGANIZATION OF THE REPORT

This report is organized as follows:

- Chapter 1 (Introduction) provides summary background information on the AFHS and discusses specific technical items and issues that may affect the different clinical area assessments.
- Chapter 2 (Dioxin Assay) describes the procedure used to draw blood for the serum dioxin measurements, the analytical method used to determine the dioxin level from the serum, and the quality control (QC) procedures associated with the serum dioxin data.
- Chapter 3 (Questionnaire Methods) gives an overview of the development and implementation of the participant questionnaires.
- Chapter 4 (Physical Examination Methods) describes the conduct and content of the physical examinations.
- Chapter 5 (Study Selection and Participation) presents the methods by which participants were selected and scheduled. This chapter also presents a discussion of the participant replacement strategy, the factors known or suspected to influence study participation, and sources of potential bias.
- Chapter 6 (Quality Control) provides an overview of the specific quality assurance and QC measures developed and used throughout the 2002 follow-up examination.
- Chapter 7 (Statistical Methods) documents the statistical methods used in the individual clinical area assessments and the statistical procedures and results of the half-life analyses performed by the Air Force.
- Chapter 8 (Covariate Associations with Estimates of Dioxin Exposure) examines the associations between exposure (Ranch Hand, Comparison, and measures of dioxin exposure) and the individual covariates used in the different clinical assessments.
- Chapters 9 through 20 present the results and medical discussions of the statistical analyses of the dependent variables for each clinical area. Each chapter also contains a brief overview of pertinent scientific literature. The 12 clinical chapters are as follows:
 - Chapter 9: General Health Assessment
 - Chapter 10: Neoplasia Assessment
 - Chapter 11: Neurology Assessment
 - Chapter 12: Psychology Assessment
 - Chapter 13: Gastrointestinal Assessment
 - Chapter 14: Dermatology Assessment
 - Chapter 15: Cardiovascular Assessment
 - Chapter 16: Hematology Assessment
 - Chapter 17: Renal Assessment
 - Chapter 18: Endocrinology Assessment
 - Chapter 19: Immunology Assessment
 - Chapter 20: Pulmonary Assessment
- Chapter 21 (Conclusions) summarizes the findings and medical discussions of the 12 clinical areas.

1.6 INTERPRETIVE CONSIDERATIONS

In interpreting results from any epidemiologic study, no single result should be evaluated in isolation or at face value. Rather, interpretations should be addressed in the context of the overall study design, the data collection procedures, the data analysis methods, dose-response effects, strength of association, temporal relation, biological plausibility, and internal and external consistency. This especially applies to the AFHS. This effort is a large-scale, prospective observational study in which thousands of measurements and diagnoses are made on each participant. Those measurements and diagnoses are subjected to extensive statistical analyses, testing thousands of individual hypotheses. Each positive result should be scrutinized relative to findings in other studies, and relative to the statistical methods used and the medical and biological plausibility of the results. Conversely, the lack of a positive result only denotes that the hypothesis of no association was not rejected. This has a very different conclusion than the possibly incorrect assertion that there is no effect. In addition, no epidemiologic study can establish that there is no effect; i.e., that dioxin is safe (11). Critical considerations in the evaluation of results from this study are reviewed below. Other interpretive considerations, such as adjustments to analyses for known confounders, multiple testing, trends in results within a clinical area, and power limitations, are discussed in greater detail in Chapter 7, Statistical Methods.

1.6.1 Study Design and Modeling Considerations

Biased results will be produced if the assumptions underlying any of the statistical models are violated. Four models were used in this report to analyze the health effects of herbicide exposure in Vietnam. The first model contrasts the exposed population (Ranch Hands) with an unexposed group (Comparisons). The second model evaluates the relation between estimated serum dioxin levels from the time of exposure (i.e., initial dioxin) with each health endpoint. The group contrast model is extended in the third model so that the Ranch Hand group is divided into three categories depending on both 1987 levels and estimated initial levels of serum dioxin, and each category is contrasted with the Comparison group. The fourth model evaluates the association between the dependent variables and lipid-adjusted 1987 dioxin levels. The parameters of these four models are summarized in Table 1-1.

Table 1-1. Parameters of Exposure Assessment Models

Model	Cohort(s)	Subset of Cohort	Exposure Characterized by:	Covariates in Analysis (not including endpoint-specific covariates)
1	Ranch Hands and Comparisons	All participants	Group (Ranch Hands versus Comparisons and military occupation)	--
2	Ranch Hands	Lipid-adjusted 1987 dioxin measurement >10 ppt	Extrapolated initial dioxin	Body mass index at the time of the blood measurement of dioxin
3	Ranch Hands and Comparisons	All participants	Group (Ranch Hands versus Comparisons); Ranch Hands categorized according to 1987 dioxin and estimated initial dioxin levels	Body mass index at the time of the blood measurement of dioxin
4	Ranch Hands	1987 dioxin measurement	Lipid-adjusted 1987 dioxin: (102.6*whole-weight 1987 dioxin/total lipids)	--

As in any epidemiologic study, the group contrast (Ranch Hands versus Comparisons) is susceptible to bias toward the null hypothesis of no exposure effect, because of possible exposure misclassification. It may not be true that all Ranch Hands and no Comparisons were occupationally exposed. Recent dioxin data indicate that 45 percent of the Ranch Hands have only background serum dioxin levels. Either these Ranch Hands were never exposed or their initially elevated serum dioxin levels may have decreased to background levels during the time period between exposure and serum dioxin measurement. The AFHS has no additional data with which to determine whether Ranch Hands currently having background dioxin levels had elevated levels in the past because there was no method of measuring dioxin in blood prior to 1987 and because no blood was collected and saved prior to 1982.

The model analyzing the association between health endpoints and extrapolated initial dioxin levels (Model 2) also is vulnerable to bias because it directly depends on two unvalidated assumptions: (a) that dioxin elimination is by first-order pharmacokinetics, and (b) that all Ranch Hands have the same dioxin half-life (7.6 years) (12). If dioxin elimination is first-order, but some Ranch Hands have a shorter half-life than others do, then there would have been misclassification of initial dioxin levels.

The half-life of dioxin has been found to change significantly with body mass index in 213 Ranch Hand veterans with up to four dioxin measurements, derived from serum drawn in 1982, 1987, 1992, and 1997 (12). The half-life increased significantly with higher levels of obesity. The constant 7.6-year half-life used in this report was an estimate derived without adjustment for body mass index (12). As a partial solution to the observed relation between half-life and obesity, analyses using dioxin or initial dioxin (Models 2 and 3) were adjusted for body mass index at the time of the blood measurement of dioxin (see Chapter 7, Statistical Methods). A study of dioxin elimination in 20 men exposed during the accident in Seveso, Italy, has validated the first-order model (13), which was the basis for the half-life estimate used in this report. Validated models of dioxin elimination adjusted for body mass index or changes in body mass index, however, have not yet been derived.

To account for the possible misclassification of exposure between groups, the third statistical model categorizes Ranch Hands into three levels of exposure: background levels of lipid-adjusted dioxin and low and high levels of estimated initial dioxin. Each Ranch Hand dioxin category is contrasted with all Comparisons. Although this model is less dependent on the accuracy of the initial dioxin estimation procedure than the model using continuous initial dioxin estimates, the classification of the Ranch Hands is subject to bias if the half-life and first-order dioxin elimination assumptions are not true. In addition, the Ranch Hands with background levels of lipid-adjusted serum dioxin may contain both unexposed Ranch Hands and exposed Ranch Hands whose serum dioxin levels have decreased to background levels. This will result in a bias toward the null hypothesis of no dioxin effect on the health endpoint.

The model that analyzes the association between a 1987 dioxin measurement and health endpoints (Model 4) may be less subject to bias than Models 1, 2, and 3; however, recent dioxin levels may not be a good measure of exposure if serum dioxin elimination rates differ among individuals. Serum dioxin levels were extrapolated from 1992 measurements to 1987 for Ranch Hand veterans without serum dioxin levels measured in 1987. Serum dioxin levels also were extrapolated from 1997 measurements to 1987 for Ranch Hand veterans without levels measured in 1987 or 1992. In addition, serum dioxin levels were extrapolated from 2002 measurements to 1987 for Ranch Hand veterans without levels measured in 1987, 1992, or 1997. These extrapolations were performed only if the most recent measurement was greater than 10 ppt. Therefore, these 1987 dioxin measurements are subject to bias from a possible violation of the half-life and first-order elimination assumptions that affect the initial dioxin estimates.

1.6.2 Information Bias

Information bias, represented by the over- or under-reporting of disease symptoms, was minimized by verifying all diseases and conditions with medical records. It is possible that conditions in Ranch Hands may be more verifiable because they may have been seen by physicians more often than Comparisons. This would be revealed by group differences in the quantity and content of medical records. Because there is no way to quantify these aspects, this potential source of bias remains unexplored. This bias, if it exists, would affect only the models contrasting Ranch Hands and Comparisons (Models 1 and 3) because Comparison data were not used in Models 2 and 4. Information bias due to errors in the data introduced through data entry or machine error is negligible. All laboratory results were subject to strict QC procedures, historical data were verified completely by medical records review, and medical data were subjected to strict QC standards (see Chapter 6, Quality Control).

1.6.3 The Air Force Exposure Index

In the first three AFHS reports, summarizing results of physical examinations conducted in 1982, 1985, and 1987, the potential relation between health endpoints and herbicide exposure in Ranch Hand veterans was assessed using a calculated estimate of herbicide and dioxin exposure. This was called the Air Force exposure index.

Six different herbicides were used in Vietnam by Operation Ranch Hand to defoliate, by aerial spraying from C-123 aircraft. From 1962 through 1965 small quantities of Agents Purple (2,4-D; 2,4,5-T), Blue (cacodylic acid), Pink (2,4,5-T), and Green (2,4,5-T) were sprayed. From 1965 through 1970 more than 11 million gallons of Agent Orange (2,4-D; 2,4,5-T), and smaller quantities of White (2,4-D; picloram) and Blue were sprayed; from 1970 through 1971 only Agents White and Blue were used for defoliation purposes (14). The Air Force exposure index was calculated from military records to measure the potential exposure of a Ranch Hand to any of four dioxin-containing herbicides: Agents Orange, Purple, Pink, and Green. The index was only an estimate of dioxin exposure because the actual concentration of dioxin in the herbicides varied with type and lot and because exposure varied with individual work habits and duties. The calculation of the index was necessary because direct measures of dioxin exposure were not available at that time. Subsequent to 1987, all outcomes in this study have been assessed with group contrasts and the dioxin body burden measured in serum. The 1987 results were analyzed twice, first using the Air Force exposure index (15), and then using the dioxin body burden as the measure of exposure (8).

The Air Force exposure index for a Ranch Hand was defined as the product of a dioxin weighting factor and the gallons of dioxin-containing herbicides sprayed during his tour divided by the number of men sharing his duties during his tour. This formula was based on the untested assumption that the exposure of an individual decreased as the number of men available increased. The calculation was performed for each month of his tour, and the monthly results were summed to produce a single exposure index for each Ranch Hand veteran. Each veteran was then assigned to a low, medium, or high exposure category depending on his calculated index and the tertiles of the index for his job category (officer-pilot, officer-navigator, officer-nonflying, enlisted flyer, or enlisted groundcrew). Additional details of the calculation are given in Thomas et al. (15).

Both measures, the Air Force exposure index and the serum dioxin measurement, have limitations. The exposure index was approximate in that the number of gallons sprayed was based on the totals across all bases rather than at a specific base. In addition, the assumption that exposure decreased as the number of men available increased may not have been reasonable. Interviews with Ranch Hand groundcrew in 1989 revealed that as the workload increased, more men were added to the job, resulting in more men

becoming exposed rather than each man becoming less exposed. Finally, the spectrum of behaviors, skills, duties, weather-related work stoppages, work surges due to war conditions, and other factors (some known, some unknown) were not included in the calculation. For example, some Ranch Hand groundcrew had direct contact with bulk quantities of herbicide by filling the tanks and servicing the equipment, while others drove trucks or forklifts. The index did not distinguish between these two kinds of exposure patterns. In addition, some Ranch Hands were assigned to administrative duties, which were indicated in their military records. The Air Force exposure index was defined as zero for those assigned to administrative duties.

The serum dioxin measurement is also limited as a measure of exposure. Although the half-life of dioxin is long (7.6 years), pharmacokinetic studies of Ranch Hand veterans suggest that the half-life varies with body fat (12). Thus, some veterans may eliminate dioxin quickly and others more slowly. Variation of the dioxin half-life with body fat contributes to variation in the extrapolated initial dose at the time of exposure. In addition, more than 45 percent of Ranch Hand veterans have background levels, precluding extrapolation. Some of those with background levels may have had elevated levels while in Vietnam, while others may not have been occupationally exposed at all. The exposure status of Ranch Hands with background levels cannot be resolved with available data. Furthermore, no validated model exists to assess the adequacy of the estimated initial dose as an estimate of actual exposure among those with dioxin levels above background in 1987, 1992, 1997, or 2002. Use of serum dioxin measurements as a measure of exposure in Vietnam is further confounded by the other possible sources of dioxin exposure. These sources include industrial exposure and environmental factors, such as burning of plastics and fish consumption.

The correlation between the Air Force exposure index and serum dioxin levels was described in the dioxin analysis of the 1987 physical examination results (8). These correlations reflected the high percentage of veterans who would be misclassified with regard to dioxin level if the Air Force exposure index was assumed as the standard. For example, 77 of 287 (26.8%) Ranch Hand veterans in the high Air Force exposure index category had dioxin levels less than 9 ppt (see Table 3.5 of reference 9).

Despite these limitations, the serum dioxin level appears to be the most appropriate measure of exposure in this study because of the following:

- The authors of this report believed it was the best available assessment of dioxin and herbicide exposure.
- It is a direct measurement of the contaminant.
- It has been accurately measured (16).
- It correlates with reported skin exposure to herbicides among enlisted Ranch Hand veterans (17).
- Its elimination in Ranch Hand veterans has followed a plausible pharmacokinetic pattern (12).
- It has been found to be plausibly associated with health conditions in this study and in other studies (18).

Throughout this report, dioxin levels are used as measures of both exposure to dioxin itself and exposure to dioxin-contaminated herbicides, including Agent Orange. Direct contrasts of Ranch Hand and Comparison veterans (Model 1) address the hypothesis of health effects attributable to any herbicide exposure experienced by Ranch Hand veterans during Operation Ranch Hand. Models involving dioxin measurements address the hypothesis that health effects change with the amount of exposure. Dioxin measurements are used as a measure of exposure to dioxin-contaminated herbicides because it is expected

that as exposure to such herbicides increased, dioxin levels should increase. Therefore, the dioxin measurement serves as a direct biomarker of exposure to dioxin-contaminated herbicides. No other direct measure or estimate of herbicide exposure is available with which to address hypothetical dose-response relations with health. Some indirect measures, such as self-report of skin contact among enlisted groundcrew, or simply being a Ranch Hand enlisted groundcrew member, are valuable alternatives because dioxin measures suggest that enlisted groundcrew experienced the heaviest exposures. Reported skin exposure is not addressed in this report, but enlisted groundcrew status is addressed in Model 1. The use of dioxin as a measure of exposure to dioxin-contaminated herbicides is consistent with the goal of the study, which is to determine whether health effects exist and can be attributed to occupational exposure to Agent Orange (3).

1.6.4 Consistency of Results

All statistically significant findings in this report were subjected to clinical review, ensuring internal consistency throughout the report. In addition, these findings were compared to published results from other studies to ensure external consistency.

1.6.5 Strength of Association

A strong adverse association between exposure and a disease condition, if it exists, would be revealed by an increased relative risk. Some authors have suggested that a statistically significant relative risk greater than 2.0 is cause for concern (19). Statistically significant relative risks less than 2.0 are generally considered to be less important than larger risks because relative risks less than 2.0 can arise more easily because of unrecognized bias or confounding. Relative risks greater than 5.0 are less subject to this concern. The numbers 2.0 and 5.0 are epidemiologic guidelines regarding analyses of association between a dichotomous endpoint (disease, no disease) and exposure (yes, no). No such general guidelines have been formulated regarding the analysis of continuously distributed endpoints (such as cholesterol) versus continuously distributed exposure (such as initial or recent serum dioxin measurements).

Statistical power is also an issue in a study with a population this size. A study with a population of 1,951 lacks power to determine increases in relative risks for rare events (such as soft tissue sarcoma) because such events are unlikely to occur in large numbers in a group this small. While certain occupational toxins have a clear diagnostic pathology (e.g., mesothelioma for asbestos, hepatic angiosarcoma for vinyl chloride) virtually nonexistent in the absence of the toxin, other toxins merely increase the risk of nondiagnostic pathology. For example, the AFHS would likely not discern an increase in the relative risk for a rare tumor that does not have a clear diagnostic pathology. By assessing the pathology observed in association with other known environmental risk factors (e.g., tobacco use, alcohol use), it is sometimes possible to provide a limit in the magnitude of effect missed; however, this study has inherent bounds in detecting modest increases in relative risk for infrequent pathology.

1.6.6 Biological Plausibility

The assessment of biological plausibility requires consideration of a biological mechanism relating the exposure and effect of interest. While a lack of biological credibility or even a contradiction of biological knowledge can lead to the dismissal of a significant result, the failure to perceive a mechanism may reflect only ignorance of the state of nature. On the other hand, it is easy to hypothesize biological mechanisms that relate almost any exposure to almost any disease. Thus, while important, the biological explanation of results must be interpreted with caution. In the AFHS, statistically significant results are

subjected to medical review and comparison with previously published results in order to identify consistent and biologically plausible results.

1.6.7 Interpretation of Nonsignificant Results

In this study, a lack of significant results relating dioxin to a particular disease only means that the study is unable to detect a relation between dioxin and health. This does not imply that a relation may not exist, but that if it does exist, it was not detected. A lack of significant results does not mean that dioxin is safe or that there is no relation between dioxin and health. The AFHS was not designed to establish safety; rather, this study was designed to determine whether a hazard existed for the exposed personnel. Determination of safety would require a study at least 10 times as large, as determined in a 1985 study presenting minimal sample size criteria for proof of safety and hazard in studies of environmental and occupational exposures (11).

1.6.8 Extrapolation to Armed Forces Ground Troops

Extrapolation of the serum dioxin results to the general population of ground troops who served in Vietnam was difficult because Ranch Hand and ground troop exposure situations were very different. Based on serum dioxin testing results obtained by the CDC (5) and others (20), nearly all ground troops tested had current levels of dioxin similar to background levels. Even combat troops who served in herbicide-sprayed areas of Vietnam had current levels similar to those in men who never left the United States (with mean dioxin levels of 4.2 ppt and 4.1 ppt, respectively). There is little scientific basis for an extrapolation of these results to the larger population of Vietnam veterans. We cannot exclude the possibility that a limited number of veterans could have been exposed to levels of dioxin comparable to the Ranch Hand veterans, but because blood or adipose tissue were not collected immediately after their return from Vietnam, the actual exposures of these veterans cannot be known. Others may have received long-term low dose exposure. These possibilities and a multitude of factors, including differential elimination and exposures to other persistent organic pollutants, suggest that existing data do not provide an adequate basis for extrapolation.

1.6.9 Considerations for Summarizing Results

A study of this scope with a multitude of endpoints demands, and at the same time defies, meaningful summary tabulation. Such summaries can be misleading because they ignore correlations between the endpoints, correlations between examination results, and the nonquantifiable medical importance of each endpoint. In fact, many endpoints are correlated (e.g., psychological scales and indices developed from combining multiple variables). In addition, such tabulations combine endpoints that are not medically or biologically comparable. For example, diminished sense of smell may be of less medical importance than the presence of a malignant neoplasm. Nevertheless, the AFHS presents a summary of all statistical results in Appendix G of this report. These summaries, however, can be misleading and must be interpreted carefully—an elementary tally of significant, or nonsignificant, results is not appropriate.

2 THE DIOXIN ASSAY

2.1 PARTICIPANTS SELECTED FOR DIOXIN MEASUREMENT

All participants provided approximately 64 mL of blood at the 2002 physical examination to be possibly used for dioxin testing at a later date. Eleven Ranch Hand participants had never provided blood for dioxin testing previously. An additional Ranch Hand had provided blood in 1987, but a dioxin value could not be obtained from that sample. A total of 85 Comparisons had never provided blood for dioxin testing previously. Nine Comparisons had provided blood for dioxin testing at previous examinations, but a result could not be obtained from the sample. The dioxin value was determined for these 12 Ranch Hands and 94 Comparisons in 2003 and was incorporated into the statistical analysis for this report.

2.2 SAMPLE ACQUISITION

After obtaining informed consent and following a Centers for Disease Control and Prevention (CDC) protocol, approximately 64 mL of blood was drawn from all participants for the serum dioxin assay on the morning of the first day of the 2002 physical examination. The participants were instructed to fast after midnight (water was allowed). Samples were drawn with a 19-gauge needle into six 10-mL red-top tubes and one 4-mL lavender tube supplied by the CDC. After the draw, the six 10-mL red-top tubes were allowed to clot at room temperature for 20 to 30 minutes. The lavender tube contained an anticoagulant that prevented clotting and allowed the extraction of plasma, rather than serum, after centrifugation.

The seven tubes of specimens were spun in a 14.5-cm radius centrifuge for 15 minutes at 3,000 revolutions per minute. Plasma then was transferred with a disposable pipette from the lavender tube to a 1.8-mL nunc vial. The serum from the six 10-mL red-top tubes was then transferred to a CDC-supplied 2-ounce glass jar with a Teflon[®]-lined screw cap. Serum samples were catalogued and stored at -70 °C until shipment. Specimen containers and materials provided by the CDC were dioxin-free.

Appendix A contains the detailed procedures used by Scripps Clinic for the dioxin blood collection and processing. Frozen samples were packed in dry ice in Styrofoam[®] boxes and shipped from Scripps Clinic in La Jolla, California, to Brooks City-Base, Texas. Specimens were shipped on Tuesdays and Thursdays, the day after specimen collection. At Brooks City-Base, inventory was taken and the specimens were stored at -70 °C until shipment to the CDC. All samples were coded so that the CDC staff were blinded to the exposure group status (Ranch Hand, Comparison) of each specimen.

2.3 ANALYTICAL METHOD

The serum samples were analyzed for dioxin in groupings consisting of a method blank, three unknown samples, and a quality control (QC) pool sample (1, 2). Cholesterol esters, triglycerides, and high-density lipoprotein cholesterol were determined in duplicate by standard methods. Total phospholipids were determined in duplicate by modifying the Folch et al. procedure (3, 4). Free cholesterol was determined in duplicate by an enzymatic method (5). For each analysis, the mean result of duplicate analyses was used to calculate the concentrations of total lipids using the summation method (6), low-density lipoprotein cholesterol, and very low-density lipoprotein cholesterol (7).

2.4 QUALITY CONTROL

Quality assurance was maintained with matrix-based materials well characterized for dioxin concentration and isotope ratios to ensure that the analytical system was within control limits. The concentration in the QC sample from each analytical run was required to be within established 99-percent confidence limits (8, 9). The unlabeled and carbon-13 labeled internal standard isotope ratios were required to be within 95-percent confidence limits. All analytical runs for the dioxin and lipid measurements were within control limits. No dioxin was detected in the blanks (on-column injection of 100 femtograms from a standard solution produces detectable signals greater than three times the background noise).

2.5 DATA DESCRIPTION

The CDC delivered whole-weight and lipid-adjusted dioxin concentrations to the Air Force, together with the total sample weight, weights of lipid fractions, total lipid weight, detection limit, quantitation limit, and all associated QC information, including results from blank samples. The lipid-adjusted dioxin concentration was calculated using the whole-weight dioxin concentration and the total lipid weight. Details of the calculation are discussed subsequently in this chapter.

The Air Force Health Study (AFHS) dioxin database is a combination of the dioxin assay results from the 1987, 1992, 1997, and 2002 examinations. Results that are usable in the statistical analysis have a result code of “G” (good result) or “GND” (good result, but below the limit of detection). Table 2-1 shows the number of usable serum measurements of dioxin by year. Of the 1,951 fully compliant participants for the 2002 follow-up examination, 1,950 (99.9%) had at least one serum measurement of dioxin determined in the 1987, 1992, 1997, or 2002 examination.

Table 2-1. Number of Dioxin Analyses Performed for the AFHS 2002 Physical Examination Participants

Years of Serum Dioxin Analysis	Ranch Hand	Comparison	Total
1987 Only	277	771	1,048
1992 Only	76	179	255
1997 Only	18	95	113
2002 Only	12	94	106
1987 and 1992	30	35	65
1987 and 1997	146	0	146
1987, 1992, and 1997	218	0	218
Total	777	1,174	1,951

Note: References to 1987 include participants from both the 1987 pilot dioxin study and the 1987 follow-up physical examination.

Participants may have been assayed during any combination of five events: the pilot dioxin study conducted in April 1987 (8), the 1987 follow-up examination (May 1987 to March 1988), the 1992 follow-up examination (May 1992 to March 1993), the 1997 follow-up examination (May 1997 to April 1998), or the 2002 follow-up examination (May 2002 to April 2003). The majority of participants had an assay in 1987 through either the pilot dioxin study or the 1987 follow-up examination. Consequently, 1987 was designated as the reference point for post-Southeast Asia (SEA) serum dioxin levels, termed “current dioxin” in some previous AFHS reports and “1987 dioxin” subsequently in this report and the report on the 1997 follow-up examination.

Each participant with a G or GND dioxin result was given a “reference” dioxin assay result derived from the good result. When a participant had multiple assay results, first priority was given to the 1987 pilot dioxin study results, second priority was given to results derived from serum collected at the 1987 physical examination, third priority was given to the 1992 results, fourth priority was given to the 1997 results, and fifth priority was given to the 2002 results. Figure 2-1 outlines this decision process and shows that the first quantitative result was used. Samples with a good result, but below the limit of quantitation, are denoted by GNQ. Samples where no result was obtained are denoted by NR.

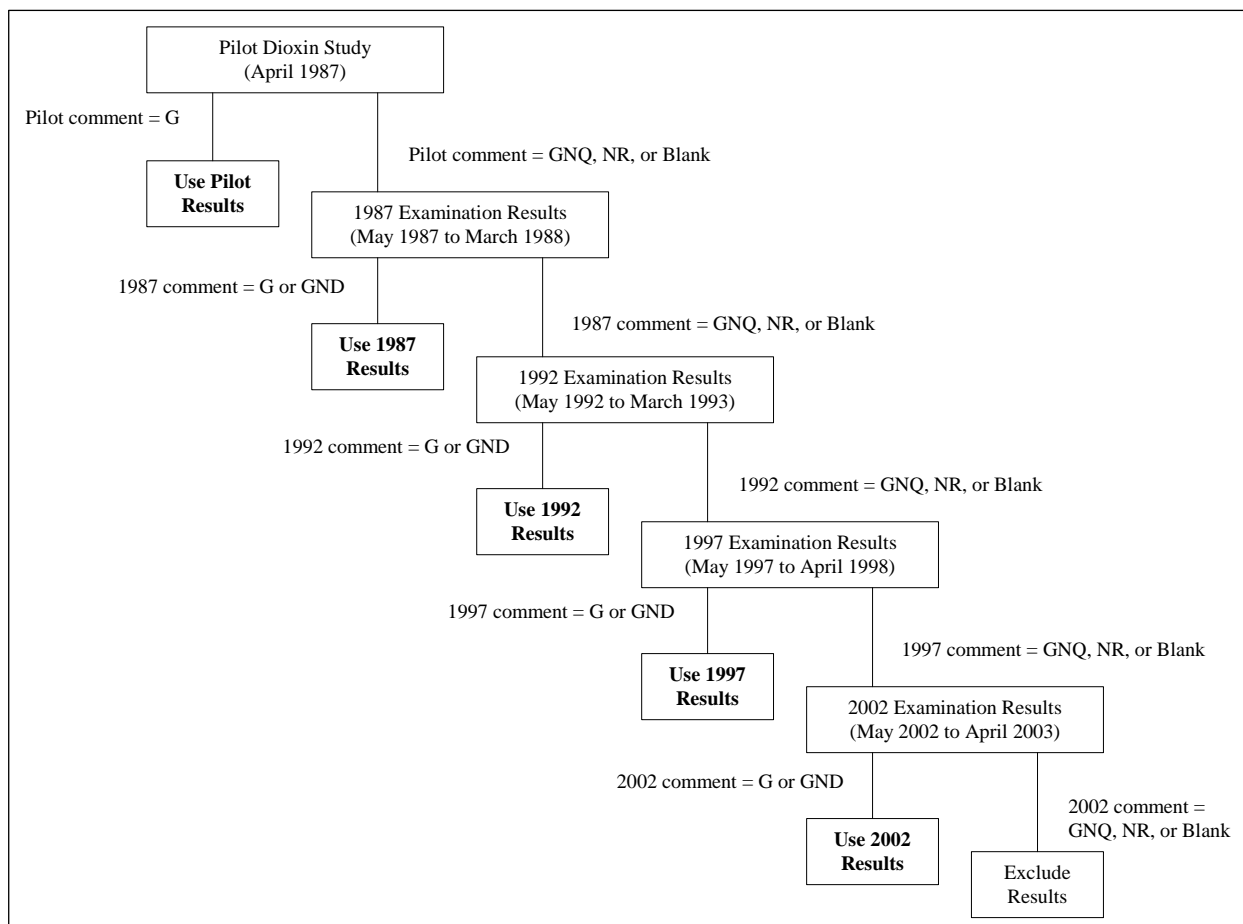

Figure 2-1. Decision Process for Determination of Dioxin Results for Analysis

Of the 1,951 fully compliant participants at the 2002 physical examination, 777 were Ranch Hands and 1,174 were Comparisons. One lipid measurement was not available for a Ranch Hand. A total of 1,950 participants (776 Ranch Hands and 1,174 Comparisons) had quantitative dioxin measurements. Table 2-2 summarizes the sample sizes by exposure group.

Table 2-2. Results from Serum Dioxin Measurements

Summary of Sample Size Reduction	Ranch Hand	Comparison	Total
2002 Follow-up examination	777	1,174	1,951
Less: Lipid measurement not available	(1)	(0)	(1)
2002 Follow-up examination participants with a quantitative dioxin result	776	1,174	1,950

If the 1987 pilot dioxin study or follow-up examination measurement was not used, the 1987 dioxin level was derived for each Ranch Hand in the following manner. If the 1992 measurement was used, the level was extrapolated to 1987 levels when the 1992 dioxin concentration surpassed 10 parts per trillion (ppt). If the 1997 measurement was used, the level was extrapolated to 1987 levels when the 1997 dioxin concentration surpassed 10 ppt. If the 2002 measurement was used, the level was extrapolated to 1987 levels when the 2002 dioxin concentration surpassed 10 ppt. These extrapolated lipid-adjusted dioxin values were calculated using a first-order elimination model with a half-life of 7.6 years (10) and a background level of 4 ppt. Levels at or below 10 ppt were not extrapolated because the first-order elimination model was not considered to be valid at background levels (lipid-adjusted 1987 dioxin levels ≤ 10 ppt). Dioxin results below the limit of detection were calculated as the limit of detection divided by the square root of 2 (11). Details on the extrapolation method are given in Chapter 7, Statistical Methods. A summary detailing the year the measurement was used and whether the dioxin level was extrapolated to 1987 dioxin levels is provided in Table 2-3 by exposure group.

Table 2-3. Summary of Number of Assays Used for 2002 Follow-up Examination Participant Dioxin Measures

Time of Assay for Dioxin Measurement	Ranch Hand	Comparison	Total
Pilot (1987) Dioxin Study	114	36	150
1987 Follow-up Examination	556	770	1,326
1992 Follow-up Examination	76	179	255
Extrapolated to 1987	[23]	[0]	[23]
Not Extrapolated to 1987	[53]	[179]	[232]
1997 Follow-up Examination	18	95	113
Extrapolated to 1987	[3]	[0]	[3]
Not Extrapolated to 1987	[15]	[95]	[110]
2002 Follow-up Examination	12	94	106
Extrapolated to 1987	[1]	[0]	[1]
Not Extrapolated to 1987	[11]	[94]	[105]
Total	776	1,174	1,950

Note: Numbers in brackets represent subtotals and are not part of the overall total.

2.6 LIPID-ADJUSTED AND WHOLE-WEIGHT 1987 DIOXIN MEASUREMENTS

Serum dioxin is defined as the serum concentration of 2,3,7,8-tetrachlorodibenzo-p-dioxin (dioxin). It can be expressed as a lipid-adjusted or a whole-weight measurement. The lipid-adjusted dioxin measurement, also called “1987 dioxin body burden,” is a derived quantity calculated from the formula

$ppt = ppq \cdot 102.6/W$, where ppt is the lipid-adjusted concentration, ppq (parts per quadrillion) is the actual weight of dioxin in the sample (also known as whole-weight dioxin) in femtograms, 102.6 corrects for the average density of serum, and W is the total lipid weight of the sample (9).

The correlation between the serum lipid-adjusted concentration and adipose tissue lipid-adjusted concentration of dioxin has been observed to be 0.98 in 50 persons from Missouri (12). Using the same data, Patterson et al. calculated the partitioning ratio of dioxin between adipose tissue and serum on a lipid-adjusted basis as 1.09 (95% confidence interval: [0.97,1.21]). On the basis of these data, a one-to-one partitioning ratio of dioxin between lipids in adipose tissue and lipids in serum could not be excluded. Measurements of dioxin in adipose tissue generally have been accepted as representing the body burden concentration of dioxin. The high correlation between serum dioxin levels and adipose tissue dioxin levels in the study by Patterson et al. suggests that serum dioxin is also a valid measurement of dioxin body burden.

Table 2-4 summarizes by military occupation and exposure group the serum lipid-adjusted dioxin results of the 776 Ranch Hands and 1,174 Comparisons who had valid dioxin measurements. For Ranch Hands the median level was greatest for enlisted groundcrew and least for officers.

Table 2-4. Summary of Lipid-adjusted Dioxin Results

Military Occupation	Ranch Hand			Comparison		
	n	Median (ppt)	Range (ppt)	n	Median (ppt)	Range (ppt)
Officer	307	7.26	0.42-35.95	462	3.96	0.42-17.26
Enlisted Flyer	132	16.03	0.42-195.45	185	3.68	0.49-15.77
Enlisted Groundcrew	337	24.03	0.64-617.75	527	3.59	0.42-32.31
Total	776	11.43	0.42-617.75	1,174	3.76	0.42-32.31

Note: ppt = parts per trillion.

Figures 2-2 and 2-3 show the distribution of serum lipid-adjusted dioxin for the 776 Ranch Hands and 1,174 Comparisons, respectively, who had valid dioxin measurements. Figure 2-4 compares distributions of serum lipid-adjusted dioxin concentrations for Ranch Hands and Comparisons on the same scale (ppt). Figure 2-5 compares distributions of the logarithm (base 2) of serum lipid-adjusted dioxin concentrations for Ranch Hands and Comparisons on the same scale.

The Ranch Hand dioxin distribution was shifted to the right of the Comparison distribution as shown by the histograms in Figures 2-2 through 2-5. The Ranch Hand dioxin levels ranged from 0 to 617.75 and the Comparison levels ranged up to 32.31. The distributions were approximately lognormally distributed in each group, as revealed in Figure 2-5 by the approximate bell-shaped histogram of logtransformed (base 2) dioxin levels within each cohort. The approximate lognormal distributions motivated the log transformation of dioxin prior to analysis in Models 2 and 4 (see Chapter 7 for a further description of these models).

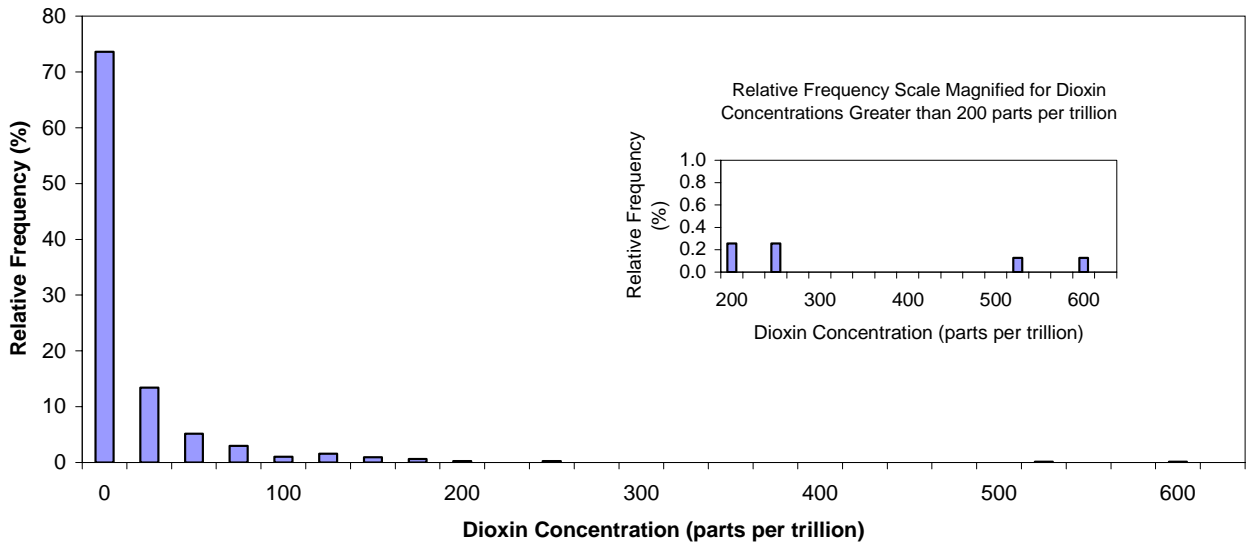

Figure 2-2. Relative Frequency Distribution of Lipid-adjusted Dioxin Concentrations for 776 Ranch Hands

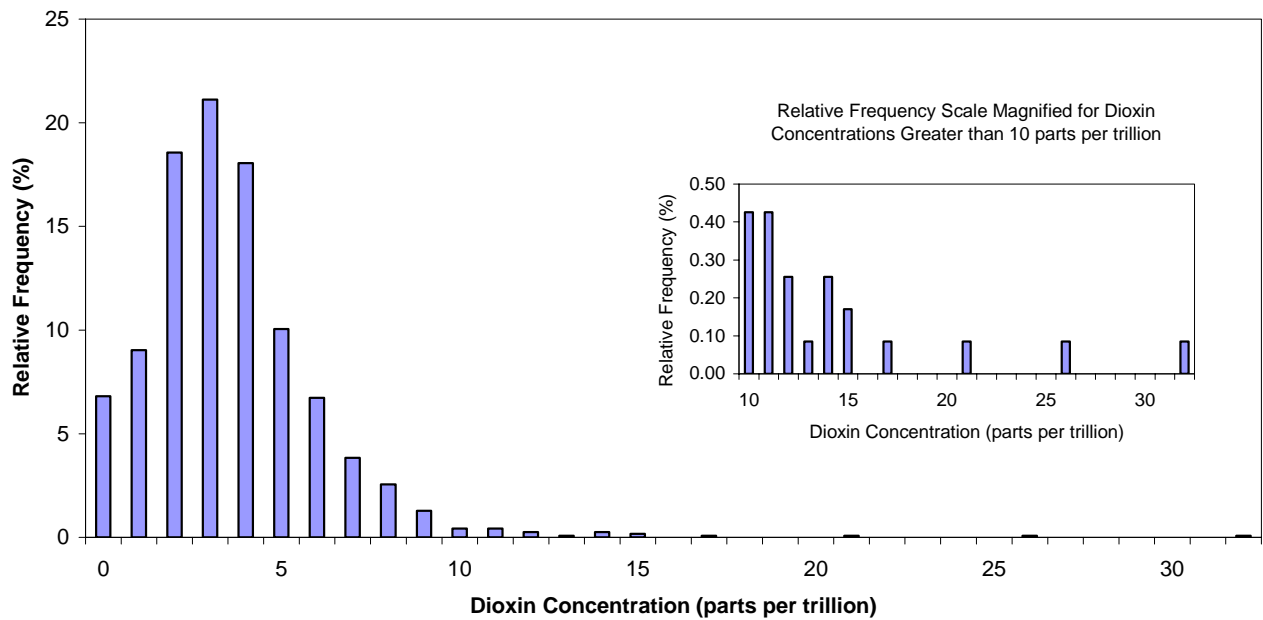

Figure 2-3. Relative Frequency Distribution of Lipid-adjusted Dioxin Concentrations for 1,174 Comparisons

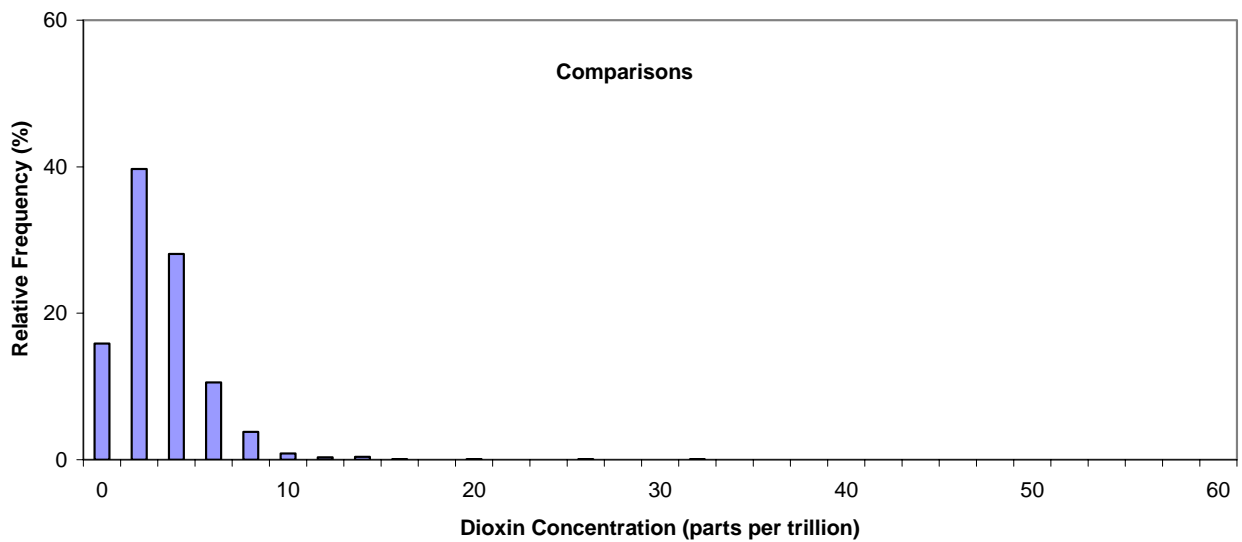

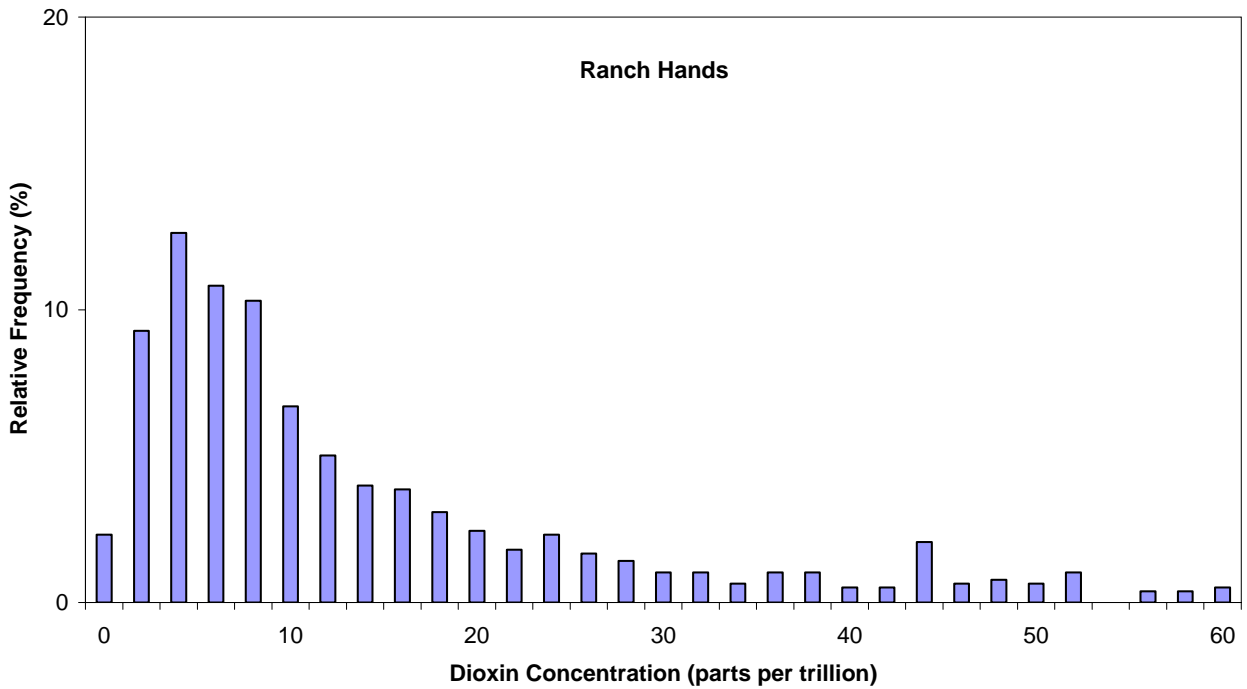

Figure 2-4. Relative Frequency Distribution of Lipid-adjusted Dioxin Concentrations

Figure 2-5. Relative Frequency Distribution of the Logarithm (Base 2) of Lipid-adjusted Dioxin Concentrations

2.7 SUMMARY

In summary, serum was collected and archived for all participants at the 2002 follow-up examination at Scripps Clinic, and dioxin levels were determined for 12 Ranch Hands and 94 Comparisons for whom a usable dioxin value had not previously been obtained. The serum was shipped from Scripps Clinic to Brooks City-Base to the CDC according to rigid protocols. The data collected for the 12 Ranch Hands and 94 Comparisons from the 2002 follow-up examination assays were combined with data from the 1987 pilot dioxin study, 1987 follow-up examination, 1992 follow-up examination, and 1997 follow-up examination for use in pharmacokinetic studies and for determining post-SEA dioxin levels. After combining data from this and previous follow-up examinations, 776 of the 777 Ranch Hands (99.9%) and all of the 1,174 Comparisons attending the 2002 follow-up examination had quantitative dioxin assay results.

3 QUESTIONNAIRE METHODS

This chapter describes the development and implementation of the two participant questionnaires used in the Air Force Health Study (AFHS) 2002 follow-up examination: the 2002-03 Study Subject Health Interval Questionnaire and the 2002-03 Study Subject Baseline Questionnaire. Both questionnaires were formatted and administered by the National Opinion Research Center (NORC), a social science research center at the University of Chicago.

The two 2002 questionnaires were comparable to those used in the baseline examination and the 1985, 1987, 1992, and 1997 follow-up examination efforts. In the 1982 baseline examination, interviews were conducted in the participants' homes. In the 1985 follow-up examinations and for a portion of the 1987 follow-up examination, the baseline interview was conducted for participants new to the AFHS at the participants' homes. The baseline interview was conducted for the remainder of the participants new to the AFHS at the 1987 follow-up examination, as well as participants new to the AFHS at the 1992 and 1997 follow-up examinations, at the physical examination site. In the 1985, 1987, 1992, and 1997 follow-up examinations, the interval interviews were conducted in person at the physical examination site. Administration at the physical examination site proved to be more efficient and subject to better quality control (QC). In all examinations before 1997, the questionnaires were administered in hard copy, which was later edited and keyed into the final SAS^{®1} data set. Since the 1997 follow-up examination, the interview responses have been recorded electronically on laptop computers using a computer-assisted personal interviewing (CAPI) system. This method affords an added measure of QC.

While the interval questionnaire was administered to all participants in the current examination², the baseline questionnaire was administered to only those participants who had not previously completed that questionnaire. With the exception of the 1997 translation into the CAPI format, the baseline questionnaire has not changed since 1982. The interval questionnaire was designed to capture the participant's health history in the interval since participation in previous follow-up examinations. In addition, the interval questionnaire elicited general health measures for use by the debriefing physicians.

3.1 QUESTIONNAIRE DEVELOPMENT

An objective of questionnaire development in each follow-up examination has been to maintain, to the maximum extent possible, the question wording, context, and procedures used in the 1982 baseline examination. In addition, the interval questionnaire was often augmented to obtain data on new areas of inquiry. The central task of questionnaire development has been to obtain interval histories on questionnaire items, thereby updating the information provided in previous follow-up examinations. For instance, if a study subject participated in the 1997 follow-up examinations, the 2002 interval questionnaire elicited an interval history for the period from 1997 to the present (i.e., date of interview); however, if the subject last participated in the baseline examination or the 1985 follow-up examination, the 2002 interval questionnaire elicited an interval history from that date through the present.

¹ SAS and all other SAS Institute, Inc., product and service names are registered trademarks or trademarks of SAS Institute, Inc., in the USA and other countries.

² Although all participants in the 2002 follow-up examinations were expected to complete the interval questionnaire, two participants were unable to do so. One participant could not complete the questionnaire due to poor health, and the other participant departed early from the examination for family reasons.

3.1.1 Baseline Questionnaire

The baseline questionnaire used during the 2002 examination was developed in 1982 and the questions have not been changed. The 1982 Study Subject Baseline Questionnaire obtained information on demographics, education, occupation, medical history, study compliance, toxic exposures, and reproductive history. In general, responses to histories and other questions where the response does not change over time were obtained in the baseline questionnaire. Each participant completed the baseline questionnaire the first time he participated in the study.

3.1.2 Interval Questionnaire

All participants were asked questions to update their histories since their last interviews. These data were obtained in the interval questionnaire. While the core content of the interval questionnaire has remained constant since its inception, questions have been added to it over the years to support additional research questions and areas of inquiry. With each introduction of a new question, the question was re-asked at each follow-up examination to provide longitudinal data on this item. For the 1985 follow-up examination, questions on risk factors for skin cancer were added. Other questions pertaining to birth defects, drinking habits and history, smoking habits and history, sleep disorders, and occupational exposure to heavy metals and vibrating power tools were subsequently added, as were one-time questions about facts that do not change, such as ethnicity or experiences during service in Vietnam. These one-time questions were administered only to those participants who had not answered them before.

With the exception of the diet assessment, which was administered in the 1992 follow-up examination but discontinued thereafter, the 2002 interval questionnaire contained all the questions in the 1992-93 Study Subject Health Interval Questionnaire, the Interval Supplement Recording Book, and AFHS Forms 1, 1B, 2A, and 8 (the “self-administered” forms). Copies of the 1992-93 Study Subject Health Interval Questionnaire and the Interval Supplement Recording Book were provided in Appendix B of the 1992 Final Report (1). AFHS Forms 1, 1B, 2A, and 8 are provided in Appendix C of the same report.

The following two questions concerning herbicide exposure were added for the 1997 interval questionnaire:

- What percentage of the missions that you flew as part of the aircrew during the Ranch Hand operation were herbicide spraying missions?
- It has been reported that some Vietnam veterans have intentionally drunk herbicides. Have you ever intentionally drunk herbicides?

In the 2002 interval questionnaire, the first question was asked of only those Ranch Hand flight crew members who had not previously answered it. All participants were asked the second question at either the 1997 or 2002 follow-up examination.

The following five questions were added to the 2002 interval questionnaire:

- How many alcoholic drinks did you have in the 2 weeks before you departed for your trip to La Jolla? Please count a drink of alcohol as one can of beer, one glass of wine, one can or bottle of wine cooler, one cocktail, or one shot of liquor.
- Now, I would like to ask you about your personal relationships. Are you currently married, divorced, widowed, separated, never married, or a member of an unmarried couple?

- Now I'd like to ask you some questions about your current employment. Last week were you working full time, including self-employed or regular volunteer work; working part time, including self-employed or regular volunteer work; with a job, but not at work because of temporary illness, vacation, or strike; unemployed, laid off, or looking for work; retired; in school; keeping house; or other (please specify)?
- Do you have a child under 18 living at home? (Please include your children, grandchildren, stepchildren, foster, or adopted children.)
- Now you will be shown a list of your tours of duty in Southeast Asia during the Vietnam War. We are interested in the possibility that you may have volunteered for or otherwise actively sought any of these tours.

Our records show your [FIRST] tour was [PRELOADED NAME OF TOUR1]. It started [PRELOADED MONTH, YEAR] and ended [PRELOADED MONTH, YEAR], did you volunteer for this tour of duty, not volunteer for this tour of duty, or do you not know or not remember?

Despite the continual introduction of new questions into the interval questionnaire, the administration actually became less burdensome to participants. The CAPI questionnaire grouped questions topically and avoided asking the same question more than once. Data processing procedures allowed certain information known from previous interviews to be carried forward, thus avoiding asking participants information already collected (e.g., causes of deaths of parents, names of siblings).

The goals in developing the CAPI interval questionnaire for the 2002 follow-up examinations included the following:

1. To replicate the 1997 questionnaire, which encompassed the pre-CAPI interval questionnaires and "self-administered" forms. Questions from the additional forms were inserted throughout the questionnaire into sections covering similar subjects.
2. To print health history responses onsite after the interview for use in participant debriefing. These responses were previously available from the hard-copy self-administered forms.
3. To eliminate item nonresponse.
4. To use "bounded recall" techniques to improve participants' abilities to recall information. A longitudinal questionnaire is dependent on the respondent's ability to remember events and to place those events in time. Even when given a precise starting date, respondents frequently repeat information given earlier, neglect to report new information because they thought they had previously reported it, and otherwise misplace events in time or forget them completely. One method of preventing such errors is through the use of "bounded recall," in which the respondent is reminded of information that he has already reported and asked to provide new information. For the 1992 interview, interviewers worked from a hard-copy information sheet containing summaries of key responses from the previous examination. These responses included date of birth, highest educational degree, military status at the last interview, marital status at the last interview, name of spouse or partner at the last interview, and a cumulative list of all children reported during previous interviews. This practice was replicated online for the 1997 and 2002 questionnaires.
5. To minimize redundancies of items asked of participants and to avoid reminders of previously reported sensitive family history items during their interview. These goals were accomplished by including the items from the self-administered forms in the CAPI questionnaire and by

programming the CAPI questionnaire to skip any sensitive family history items, such as parents or children previously reported as deceased.

6. To replicate, to the maximum extent possible, the 1992 and 1997 variables, names, labels, and formats in the final SAS[®] data set.
7. To lessen the time burden on the participant for the administration of the questionnaires. By combining the self-administered forms with the interval questionnaire and reducing the redundancy of questions, the participants were able to complete this portion of their examinations in a more timely manner.
8. To increase the spelling quality of responses provided by the participant by encouraging good spelling habits among interviewers and performing spellchecking on verbatim data during data processing.

3.2 INTERVIEWER TRAINING

Shortly before the 2002 follow-up examinations began, NORC's Chicago office staff trained 10 interviewers and 1 field manager to administer the 2002-03 Study Subject Health Interval and Study Subject Baseline questionnaires. Two interviewers had administered questionnaires previously in the 1997 follow-up examination. In addition, the senior site supervisor had worked on the AFHS since the 1992 follow-up examination. The interviewers reported to the Field Manager, who in turn reported to the Data Collection Task Leader in Chicago. The Field Manager observed interviews by each interviewer and presented summaries of these assessments each quarter. The NORC Project Director made quarterly visits to the interviewing site. As part of the training process, the NORC interviewing staff was not informed of the exposure status of any study participant either before or after questionnaire completion.

3.3 DATA COLLECTION

Upon arrival at Scripps Clinic, the participant received a schedule that included the time and place for the interval interview (and, if appropriate, the baseline interview) and was assigned an interviewer. In each personal interview conducted for the AFHS, interviewers were required to ask questions exactly as written, were not allowed to interpret questions or interject personal commentary, and were instructed to probe "don't know" responses at least once. As an added QC measure, the CAPI system did not permit them to skip around among sections of the questionnaire.

During the interviews, participants signed both a consent form to obtain health history information and medical records release forms. If a participant did not have all of the information with him to complete the medical release form during the interview, he was given blank medical records release forms and instructed to mail the completed forms to the Air Force. If the medical records required pertained to his now-adult children and required their signature, he was again given blank medical records release forms and instructed to mail the completed forms to the Air Force. If the participant informed the interviewer that he had brought the relevant records with him, that the records had already been submitted to the AFHS, or that the condition had been diagnosed at Scripps Clinic, the interviewer recorded this and did not ask him to complete the medical release form.

After each interview, interviewers used an onsite printing program that was built into the CAPI system to produce a six- or seven-page form containing items from the questionnaire that were needed for the participant debriefings. These forms were transferred to the participants' folders each day. Each evening, the completed interviews were uploaded via modem to the NORC home office in Chicago. At that time,

new participant data and refinements to the questionnaire software also could be downloaded to the interviewing site.

4 PHYSICAL EXAMINATION METHODS

The 2002 Air Force Health Study (AFHS) follow-up examination, which was given to 1,951 invited and scheduled participants at Scripps Clinic in La Jolla, California, included the following:

- Laboratory testing
- Physical examinations
- Psychological testing
- Specialized testing (e.g., nerve conduction velocity testing)
- Medical debriefings.

The Combat Experience Questionnaire and skin, hair, and eye color determinations (components of the 1985 follow-up examination) were administered to all participants who did not attend the 1985, 1987, 1992, or 1997 follow-up examinations.

The Air Force carefully prescribed the details of the above examination elements in the Examiners' Handbook, provided in Appendix B. All physical examination procedures were approved by the Air Force Research Laboratory Institutional Review Board (IRB) at Brooks City-Base and by the Scripps Clinic IRB. Clinical variations were neither desired nor authorized; all proposed examination procedural changes were reviewed in detail by Air Force technical and contractual personnel prior to the start of the examinations. An important objective of the entire physical examination process was to ensure that bias was not created by any procedural change. This objective was carried out successfully.

The requirement to maintain blind examinations was particularly stringent. The clinical staff was prohibited from knowing or seeking information as to the group identity (i.e., Ranch Hand, Comparison) of any participant. At the end of his examination, each participant was asked to note on the critique form whether such information was sought by any member of the clinical or paramedical staff. In 2002, three participants indicated that an examining physician had asked them about specific duties in Southeast Asia (SEA). One of these participants later stated that he had answered erroneously. Another stated that he had not been questioned, but rather had volunteered information in casual conversation. The other participant could not be identified because he chose to remain anonymous. In all known cases, the physician or technician involved was reminded to be more careful in his or her conversations.

4.1 EXAMINATION CONTENT

The examination content, as designed by the Air Force, emphasized detection of medical endpoints suspected of being associated with exposure to phenoxy herbicides, chlorophenols, or dioxin. In each follow-up examination, the Air Force has used findings from the previous examination to refine the current examination.

Table 4-1 shows the general content of the 2002 physical examination and psychological test battery. Table 4-2 displays the complete laboratory test series accomplished at Scripps Clinic and Brooks City-Base. Absolute lymphocytes, immunoglobulin measurements, and lupus panel tests were conducted for all subjects. Cell surface markers were studied on a random sample of approximately 40 percent of the combined cohort due to the complexity of the assay and the expense of the tests (Ranch Hand n=302,

Comparison n=462). Randomization was based on the (randomly assigned) 5-digit case number; those with a case number ending with 0, 3, 6, or 9 were selected.

Table 4-1. Elements of the 2002 Follow-up Physical Examination

Elements	Comments
Chest X Ray	Radiologist
Dermatologic Examination	Dermatologist
Peripheral Vascular Examination using Doppler	Technician; Nicotine Abstinence
Electrocardiogram	Cardiologist; Caffeine and Nicotine Abstinence
General Physical Examination	Internist
Immunologic Studies	40% Random Sample of all participants
Neurological Examination	Neurologist
Patient Debriefing	Internist
Psychological Evaluation:	Psychologist
Symptom Checklist 90-Revised (SCL-90-R)

Urinary Color	Urine Creatinine (mg/dL)
Urinary Comment	Urine Specific Gravity
Urinary Crystals (per high-powered field)	Urobilinogen (mg/dL)
Urinary Epithelial Cells (per high-powered field)	

4.2 QUALITY CONTROL

As in the baseline and 1985, 1987, 1992, and 1997 follow-up examinations, quality control (QC) requirements for both laboratory testing and clinical procedures were extensive. Although details are provided in Chapter 6, the following categories summarize the extent of the emphasis on quality. For laboratory testing, Westgard rules (1_{2s}) were used throughout the examination. Single reagent lots and control standards were used when practical, duplicate specimens were routinely and blindly retested, and testing overlaps were mandatory when test reagent lots were changed.

The Scripps clinical team was instructed on examination procedures to ensure clinician consistency. All physicians were board-certified in their examination area. Nineteen physicians participated in the internal medicine, neurology, and dermatology examinations. In addition, 15 radiologists, 3 pulmonologists, and 4 cardiologists performed tests and interpreted results. To reduce observer variability, turnover in the clinical and paramedical staffs was minimized during the 11 months of examinations. One Scripps Clinic physician served as the Project Medical Director responsible for the scheduling, conduct, and QC of the examinations. All examining physicians reviewed the mark-sense examination forms prior to an examination test. As an added quality assurance (QA) and QC measure, formal meetings were held with the examining physicians and technicians to review the data collection forms. These meetings were held by medical specialty so that the attending staff could review and make comments on their specific forms, as well as reach a consensus on diagnostic techniques and abbreviations. To minimize recording errors, the layout of the form was designed to parallel the flow of the clinical examination. Because data transcription was not permitted, each physician was responsible for filling in the bubbled form. To a large extent, the use of these mark-sense forms and subsequent QC measures was the primary reason for a clean clinical data set. Appendix B includes a complete set of these forms.

Additional QC included the following elements:

- A detailed onsite QC process was employed by Scripps Clinic, Science Applications International Corporation (SAIC), and Air Force monitors and personnel.
- Clinical QA meetings were conducted to detect and correct problems.
- Automated blood pressure recording was performed.

4.3 CONDUCT OF EXAMINATIONS

All examinations, from May 2002 to April 2003, were conducted in accordance with the Examiners' Handbook. Excluding weeks with national holidays, two groups of participants, averaging approximately 24 per group, were examined weekly.

A demanding logistics effort was required to contact, transport, and examine the 1,951 study participants. Pre-examination contact included making telephone calls to recruit participants, determining special requirements (e.g., wheelchair assistance), and arranging transportation. Once scheduling was reasonably firm, the SAIC logistics coordinator sent each participant a detailed information package that included an outline of dietary requirements, a stool occult blood testing kit (Hemoccult®) with instructions for compliance, orientation schedules, important telephone numbers, a request for medical records, and local maps designating examination site dining and recreational facilities.

In addition to a participant orientation meeting held on the evening before the examinations, an informational meeting open to accompanying family members and friends was held on the first morning of examinations. Proctosigmoidoscopy, as well as treadmill tests, were made available to participants for a nominal fee. Accompanying family members also were offered the opportunity to use the clinic facilities at a discounted rate.

Each morning of the examinations, the current group of participants, having fasted and abstained from nicotine and caffeine since midnight the previous evening, was transported to the Scripps Clinic. Alcohol was prohibited from 24 hours before the first day of the examination through the second day of the examination. On the first day, each participant was given an individualized 2- or 3-day schedule outlining his medical, interviewing, and laboratory appointments. The schedule carefully noted the specific required periods of caffeine and nicotine abstinence for generalized periods in relation to electrocardiograph, pulmonary function, and Doppler testing. Although the clinic schedules generally were assigned at random, consideration was given to smokers and diabetics because of the fasting and abstinence restrictions. Figure 4-1 shows a typical 2-day schedule prepared for a participant. This schedule was designed for a smoker in good self-reported health.

As in the previous examinations, schedules with specific directions were provided to aid participants in locating clinic departments, even though for many tests, participants were escorted from the waiting room. Throughout the examination day, time was provided for waiting-room activities (i.e., renewal of past friendships, discussions of experiences in SEA, consumption of refreshments when permitted, and completion of paperwork). On the second day of the examination, a portion of the participants completed testing and examinations and received debriefings from an internist. The remaining participants received their debriefings on the third day.

The SCL-90-R psychological test was self-administered and reviewed by a Scripps Clinic psychologist, while the WMS-R was administered and graded by a Scripps Clinic psychologist (see Table 4-1). If a problem was indicated, the participant was advised of the issue during his medical debriefing. Upon

completion of these debriefings, the participants were asked to complete an examination evaluation form. They were also paid their stipends and reimbursed for travel expenses at this time.

On the first examination day, participants were asked to collect their fasting first urine void of the day at the hotel. Upon their arrival at the clinic, each participant had up to 220 mL of blood collected. Two reclining chairs and four standard blood-draw chairs were used for the blood draws. In previous AFHS examinations, participants who were pilots were concerned about the adverse career effects of fainting during blood draws. To avoid fainting, the Scripps Clinic staff asked each participant if he becomes “light-headed” or faint when having his blood drawn. If a participant responded “yes” or was an active pilot, he was assigned to one of the reclining chairs. These chairs were selected because they could be shifted easily into the Trendelenburg position if a participant felt faint.

Detailed immunology testing (see Table 4-2) was conducted on approximately 40 percent of the participants. These participants were identified by the last digit of their participant study identification number used for previous testing, thus establishing a longitudinal connection between examinations. The immunologic tests were subjected to highly structured QC procedures set forth by the Air Force. An additional blood collection of 5 mL was taken 2 hours after the first blood collection to assess 2-hour postprandial glucose and insulin. At that time, a second urine sample was also collected. Of the 220 mL of blood collected from each participant, the Air Force was provided 35 cc of serum and 10cc of whole blood for archival purposes and for HIV, syphilis (Fluorescent Treponemal Antibody – Absorption (FTA-ABS) – confirmatory test for VDRL test), hepatitis B surface antigen, hepatitis B core antibody, hepatitis C, and hepatitis D testing.

5 STUDY SELECTION AND PARTICIPATION

5.1 INTRODUCTION

This chapter reviews the 2002 follow-up examination selection process and the compliance and noncompliance of veterans selected for the Air Force Health Study (AFHS). Refusal rates between Ranch Hands and Comparisons are compared, as are the reasons for refusal. These reasons are examined by age, race, and military rank in an attempt to detect possible differences among refusal rates. According to the study protocol (1), all noncompliant Original Comparisons were to be replaced by Comparisons, matched appropriately according to age, race, military rank, and self-reported health status. This chapter assesses the adherence to the replacement strategy as defined in the protocol, and compares the health status of noncompliant Original Comparisons with their Replacement Comparisons. Differences in perception of health are evaluated according to group, age, race, military rank, and 2002 compliance status. Self-reported health status is compared among fully compliant study participants. Because perception of health may differ between Ranch Hands and Comparisons, medication use and work loss are compared as possible surrogate measures of actual health status.

Throughout this chapter, several terms are used to describe veterans who did not participate in the 2002 follow-up examination. These terms include “passive refusal,” “hostile refusal,” and “final refusal.” An individual who communicated a desire not to have any contact with or from the AFHS under any circumstances was classified as a “hostile refusal.” Veterans who were classified as hostile refusals in the past were not invited to the 2002 examination (see Section 5.5.2.2). A veteran was classified a “passive refusal” if he was scheduled for a physical examination but twice cancelled the appointment or failed to appear for it. He was also classified a passive refusal if he was unreachable by telephone because of a “gatekeeper” (see Section 5.4.1) or if he failed to respond to correspondence. A veteran who was determined to be a hostile refusal or refused to participate twice was classified as a “final refusal.” Veterans who could not attend due to one of the following reasons and their problem could not be resolved were also classified as a “final refusal:”

- Health reasons
- No interest or no time
- Job commitment
- Travel distance, family concerns
- Dissatisfaction with U.S. Air Force or U.S. Government
- Confidentiality, adverse impact on career
- Financial hardship
- Dissatisfaction with AFHS
- Fear of physical exam
- Dissatisfied with previous exams
- Other.

5.2 FACTORS KNOWN OR SUSPECTED TO INFLUENCE STUDY PARTICIPATION

A multitude of factors may influence study participation. These may be classified broadly as health, logistics, demographic, operational, or publicity factors. For example, health factors are thought to include self-perception of health (compared to others of the same age), as well as demonstrable health indicators, such as medication use and workdays lost due to illness or injury. Logistics factors include no time or interest, reluctance to spend time away from family or job, distance to the examination site, confidentiality, or financial hardship. Demographic factors include flying status, age, race, or military duty status (active, retired, separated). Operational factors include any aspect of study operation that may cause differential compliance, such as differential treatment of Ranch Hands and Comparisons during scheduling, physical examination, interview, or debriefing. Publicity factors are related to national attitudes and media presentations regarding the Agent Orange issue, the Vietnam War, veterans' health care, or health care in general. In addition, these considerations may influence Ranch Hands differently than Comparisons.

The issues involved in deciding whether to volunteer for this study are complex, making statistical assessment of compliance bias difficult and necessarily crude in that many of the factors contributing to self-selection cannot be measured directly. Compliance bias was investigated at the 2002 follow-up examination with respect to self-perception of health, medication use, and work loss. Medication use and days lost from work due to illness or injury were obtained from questionnaire and physical examination data and, therefore, were available only for fully compliant participants. In 2002, as in 1992 and 1997, no partial compliance (defined as compliant to the questionnaire and noncompliant to the physical examination) occurred because both the physical examination and the questionnaire were administered at the examination site.

5.3 REPLACEMENT PROTOCOL

During the design phase of the AFHS, the authors of the study protocol anticipated that a loss of participants between follow-up examinations would pose the greatest threat to study validity. In particular, they expected differential compliance, with relatively more Ranch Hands choosing to return to the study than Comparisons and with health differences of unknown character between noncompliant Ranch Hands and noncompliant Comparisons. To partially correct the situation, the study design specified that noncompliant Comparisons would be replaced by Comparisons with the same values of the matching variables (age, race, and military occupation at the baseline examination) and the same current health perception. Military occupation was stratified into the following five categories: (1) flying officer—pilot, (2) flying officer—nonpilot, (3) nonflying officer, (4) flying enlisted, and (5) nonflying enlisted (also referred to as enlisted groundcrew). In this way, the Replacement Comparisons would serve as surrogates for Comparisons who refused to participate. This method of replacement would tend to reduce bias resulting from refusal in the Comparison group and would maintain group size. No corresponding strategy for the Ranch Hands was possible because all living Ranch Hands had been identified and invited to participate.

The first Comparison in each randomized matched set who was asked to participate in the baseline questionnaire and physical examination was identified as the Original Comparison for his respective Ranch Hand (in accordance with the study protocol). If the Original Comparison was noncompliant, a "Replacement" Comparison was invited in his place. Noncompliance was determined if any of the following three conditions were met:

1. The Comparison refused to participate.
2. The Comparison was partially compliant (completed the baseline questionnaire but did not complete the baseline physical examination).
3. The Comparison was unlocatable.

Replacement Comparisons were identified as such in the database to satisfy the study protocol requirement that they be matched with the refusing Original Comparisons (also known as refusals) based on self-reported health (excellent, good, fair, or poor). Of course, in the case of an unlocatable Original Comparison, matching with regard to self-reported health was not possible. Original Comparisons who were partially compliant for previous AFHS follow-up examinations were replaced, but deceased Original Comparisons were not. Replacement Comparisons, who like the Original Comparison were matched by age, race, military rank, and military occupation to a Ranch Hand veteran, were selected from a set of up to nine additional candidate Comparisons.

Health matching of replacements was not used during the baseline examination, but was implemented during the 1985, 1987, 1992, 1997, and 2002 follow-up examinations. During the 1985 examination, a telephone questionnaire was administered to refusals and their potential replacements. This questionnaire served as the basis for health matching required by the study protocol, and assessed self-perception of health, days lost from work due to illness, and medication use. Although the study protocol is not explicit on this point, it implies that the decision to include or exclude the replacements from the study should be based only on this health contrast. At the 1987 follow-up examination, instead of using a telephone questionnaire, refusals were asked during the scheduling process for their self-perception of health. During the 1992, 1997, and 2002 follow-up examinations, schedulers requested a current perception of health from all potential participants (compared to others their age) contacted by telephone. Self-perception of health was used in the replacement strategy (described subsequently in Section 5.4.2) to address the possibility that Replacement Comparisons might differ from the noncompliant Original Comparisons they replaced with regard to health, which might bias the study either toward or against the null hypothesis of no difference in health between Ranch Hands and Comparisons.

The complete algorithm for replacing Comparisons is presented as a flowchart in Appendix C for reference purposes.

5.4 2002 FOLLOW-UP SCHEDULING AND REPLACEMENT OPERATION

5.4.1 Scheduling Strategy

The scheduling process included the following three objectives:

1. Maximizing participation rates
2. Ensuring that Ranch Hands and Comparisons were recruited using consistent procedures and amount of effort
3. Ensuring that, whenever possible, each Ranch Hand had at least one compliant Comparison who was matched with that Ranch Hand on age, race, and military occupation.

These objectives led to a set of conflicting priorities: maximizing participation rates meant giving each potential participant every opportunity and encouragement to participate, without being so persistent as to lose the cooperation of somewhat ambivalent veterans. This careful approach had to be balanced against the need to quickly identify noncompliant Comparisons. Until these noncompliant Comparisons were removed from the scheduling process, they could not be replaced. In general, prospective participants were contacted for scheduling in random order; however, priority was given to certain potential participants who needed to be contacted early in the scheduling period. These included the following:

- Veterans residing overseas, because they would be more difficult to contact and require advance time to make travel arrangements
- Passive refusals or “no-shows” for previous physical examinations.

During the first 2 months of scheduling, an attempt was made to contact all veterans invited to previous examinations who were not categorized as hostile. In addition, all previously invited veterans were sent a refrigerator magnet that stated the date that scheduling would begin and the toll-free number of the scheduling operation.

Although every reasonable attempt was made to contact eligible veterans, accommodate unusual schedules, and convert refusals, experience in past examinations had shown that certain types of potential participants ultimately would not schedule appointments. To continue with the replacement of Comparisons, these cases needed to be closed early. Therefore, the following rules were observed to limit the number of calls to certain types of individuals who were not likely to participate:

- An individual classified as hostile to the study in previous follow-up examinations was not contacted in 2002.
- An individual who was extremely hostile in his refusal to initial scheduling contacts was coded as a final refusal.
- If the scheduler did not get an answer on the telephone after eight attempts, a certified letter was sent to that individual. If there was direct evidence that the individual appeared at the post office to claim the letter, but did not contact the scheduling office, he was considered a passive refusal.
- An individual who broke an examination appointment and did not attempt to reschedule (“passive refusal”) was considered a final refusal.
- An individual who equivocated about attending the physical examinations twice during the first two contacts was considered a final refusal.

Some potential participants were particularly difficult to reach because of the presence of a “gatekeeper” who did not allow the schedulers to speak directly to the potential participant. A potential participant was designated as a final passive refusal after a minimum of three contacts with a gatekeeper and failure to reach the participant by other means. These contact methods included varying calling times, leaving messages, or sending a certified letter. Up to eight gatekeeper contacts were allowed if the scheduling supervisor decided additional attempts were still warranted (e.g., if an individual had previously scheduled and canceled or if it seemed reasonable that he might reschedule). After these gatekeeper contacts had been exhausted, the individuals were designated as final passive refusals and, if eligible for replacement, replaced. Potential participants who were designated as final refusals at any stage in the scheduling process were provided with the toll-free number for the study and allowed to volunteer to participate at any time, even if a Replacement Comparison had been invited to participate.

Figure 5-1 plots the percentage of persons completing the 2002 follow-up examination by calendar date for Ranch Hands, Original Comparisons, Replacement Comparisons, and all Comparisons. These patterns are similar to those seen at previous follow-up examinations and reflect the study protocol specification that scheduling be random with respect to group. Completion rates are similar between Ranch Hands and Original Comparisons. Replacement Comparisons completed the physical examinations later in the scheduling process, as expected, because new Replacement Comparisons were not recruited until an Original Comparison had refused.

5.4.2 Replacement Strategy

All Comparisons who had participated or had been invited to participate in the baseline, 1985, 1987, 1992, or 1997 follow-up examinations were invited to participate in the 2002 examination. If no previously invited Comparisons for a particular Ranch Hand agreed to participate in 2002, schedulers attempted to recruit a replacement. These replacements were selected from a set of up to nine candidate Comparisons, matched by age, race, military rank, and military occupation, whose self-reported health status in 2002 matched that of the noncompliant Original Comparison for a given Ranch Hand. Health status was recorded in four categories: excellent, good, fair, or poor. If a willing health-matched participant was not found in the matched set, self-reported perceptions of health status were dichotomized into “excellent or good” and “fair or poor” categories and these dichotomized health statuses were matched. If this second method for identifying a suitable replacement failed, no replacement was made. There were two exceptions to the replacement strategy. First, the study protocol required that the noncompliant Original Comparisons report their health status during the scheduling effort so that they could be used to recruit Replacement Comparisons with the same health status. On occasion, Original Comparisons refused to speak with the scheduler or respond to questions. In these cases, a Replacement Comparison for the Original Comparison was recruited in the order in which he was listed in the randomized matched set. This strategy also was used for unlocatable Original Comparisons and hostile Original Comparison refusals. Second, as specified in the study protocol, no replacement was made if all formerly invited Comparisons in a matched set were deceased.

5.5 COMPLIANCE

Of the 1,043 eligible Ranch Hands, 777 (74.5%) participated in the 2002 follow-up examination, while 737 (67.4%) of the 1,093 eligible Original Comparisons participated. Of the 951 Replacement Comparisons eligible for the 2002 follow-up examination, 437 (46.0%) chose to attend the examination. Table 5-1 provides compliance counts for Ranch Hands, all Comparisons as a group, and Original and Replacement Comparisons. Appendix C contains tables that describe these counts by compliance at the baseline examination. Table C-1 provides counts for the Ranch Hands. Table C-2 summarizes total Comparison counts. Table C-3 provides Original Comparison counts and Table C-4 lists Replacement Comparison counts.

In Table 5-1 and Appendix C, the “New to Study” rows include potential Replacement Comparisons who were found to be deceased when contact was attempted. The same deceased potential replacements are then accounted for in the rows marked “Deceased.” Undefined categories are indicated by dashes. For example, in Table 5-1, dashes are shown for Ranch Hands and Original Comparisons for the row designated as “No Health Match.” As described in Section 5.4.2, attempts were made to find a Replacement Comparison if the Original Comparison did not attend. Thus, health matching is applicable for Replacement Comparisons only and not for Original Comparisons and Ranch Hands.

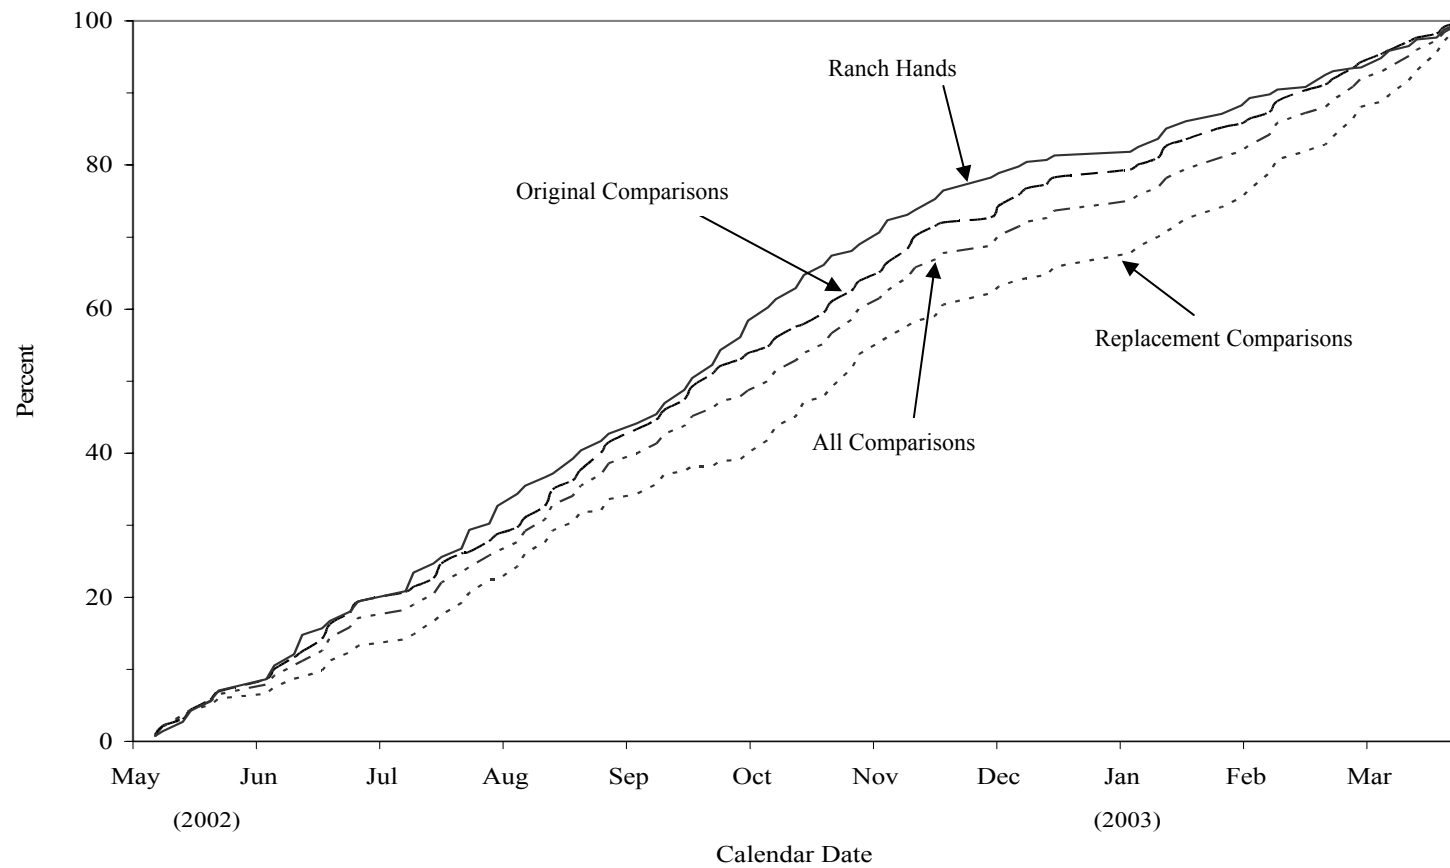

Figure 5-1. Cumulative Percentage of Participants Who Completed the Physical Examination (by Calendar Date)

Table 5-1. Compliance by Group and Examination Year

	Not Contacted	(1)	(0)	(0)	(0)
	Fully Compliant	777	1,174	737	437

Table 5-2 describes the newly compliant participants in terms of their compliance at previous examinations. Four Ranch Hands, 1 Original Comparison, and 71 Replacement Comparisons were fully compliant and examined for the first time at the 2002 follow-up examination. Of these, one Ranch Hand and 56 Replacement Comparisons had not been invited previously to participate. This new Ranch Hand had not been listed as a member of the Ranch Hand operation for previous examinations but made contact with personnel at Brooks City-Base and was verified to be a Ranch Hand. Three Ranch Hands, 1 Original Comparison, and 15 Replacement Comparisons had been previously invited and had refused to participate in one or more previous examinations.

Table 5-2. Participants Newly Compliant in 2002 and Their Previous Compliance Pattern

Compliance Pattern						Comparisons			
Baseline	1985	1987	1992	1997	2002	Ranch Hand	Original	Replacement	Total
Partial	Partial	Refused	Refused	Refused	Compliant	1	0	0	1

			Unlocated	Refused	Compliant	0	0	1	1
				No Health Match	Compliant	0	0	5	5
				Refused	Compliant	0	0	8	8
					Newly Compliant	1	0	56	57
					Total	4	1	71	76

5.5.1 Corrections to Previously Reported Study Compliance Totals

Some changes were made to the historical cell counts shown in Table 5-1 (and the tables in Appendix C) so that they now differ from compliance tables presented during previous examinations (in particular, Table 5-1 and Appendix Tables C-1 through C-4 of the 1997 follow-up examination report). In addition, some circumstances regarding new and ineligible Ranch Hands for the 2002 follow-up examination occurred. The differences from previous tables and an explanation of the new and ineligible Ranch Hands are described below.

1. One Ranch Hand and one Original Comparison were reclassified from “Refused” to “Partially Compliant” at the 1985 follow-up examination. These veterans were discovered to have completed a questionnaire, but not the physical examination, in 1985. This change affects Tables 5-1, C-2, and C-3.
2. One Replacement Comparison was thought to be deceased at the 1997 follow-up examination, but was later discovered to be alive, but unlocatable, for the 1997 follow-up examination. This veteran was fully compliant for the 2002 follow-up examination. This change affects the “Deceased” and “Unlocatable” rows for the 1997 follow-up examination in Table 5-1, C-2, and C-4.

3. One Ranch Hand was thought to be deceased for the 1997 follow-up examination, but his death could not be confirmed in a subsequent review of his records after the 2002 follow-up examination had been completed. Additional attempts to contact him or clarify his status after the 2002 follow-up examination have been unsuccessful. Although this veteran may be deceased, his classification for the 1997 and 2002 follow-up examinations has been changed from “Deceased” to “Not Contacted” because of the lack of verification of his death. This change affects Tables 5-1 and C-1.
4. One additional Ranch Hand was discovered during the 2002 follow-up examination. This new Ranch Hand had not been listed as a member of the Ranch Hand operation for previous examinations but made contact with personnel at Brooks City-Base and was verified to be a Ranch Hand. This new Ranch Hand accepted an invitation and participated in the 2002 follow-up examination. A matched cohort of Comparisons was chosen for this Ranch Hand. The Original Comparison refused, but a Replacement Comparison accepted an invitation and participated in the 2002 follow-up examination. This new Ranch Hand, his Original Comparison, and the participating Replacement Comparison are all included in the “New to Study” line for the 2002 follow-up examination in Tables 5-1, C-1, C-2, C-3, and C-4.
5. Two Ranch Hands were assigned to the 309th Air Commando Squadron but not assigned to the Special Aerial Spray Flight, thus they were misclassified as Ranch Hands in 1982. These Ranch Hands and their matched Comparisons (two Original Comparisons and one Replacement Comparison) were considered “ineligible” and excluded from further analysis. This change affects Tables 5-1, C-1, C-2, C-3, and C-4.

5.5.2 Analysis of Refusals

Of the 1,043 Ranch Hands and 2,044 Comparisons eligible for the 2002 follow-up examination, 262 Ranch Hands and 778 Comparisons (349 Original and 429 Replacement) refused. Their reasons for refusal are summarized in Table 5-3. The “no health match” potential Replacement Comparisons and those not located or contacted, as summarized in Table 5-1, are not shown in Table 5-3 and are not used in the analysis of refusals that follows. They may have been willing to participate, but were excluded by the specifications of the study protocol or the inability to contact them.

As shown in Table 5-3, a greater percentage of Comparisons than Ranch Hands refused (31.9% versus 25.1%), and a greater percentage of Replacement Comparisons than Original Comparisons refused (45.1% versus 31.9%). Of the total invited, nearly the same percentages of Ranch Hands, Original Comparisons, and Replacement Comparisons refused due to health reasons (5.4%, 5.1%, and 5.6%, respectively). More Replacement Comparisons than Ranch Hands or Original Comparisons declined due to “job commitments,” “no time,” or “travel distance or family concerns.” In addition, more Replacement Comparisons (16.1%) than Original Comparisons (7.3%) were “passive refusals,” indicating that this group of Comparisons did not respond to formal correspondence from the National Opinion Research Center (NORC) or the Air Force. More Original Comparisons were hostile refusals (9.5%) than either Replacement Comparisons (6.3%) or Ranch Hands (5.8%).

Table 5-3. Reasons for Refusal by Group

Reason	Group							
	Ranch Hand		Original Comparison		Replacement Comparison		Total

^aPercent of veterans eligible to participate.

Table 5-4 summarizes reasons for refusal by group, age, military rank, and race. Reasons for refusal have been collapsed into the following five categories:

1. Health (health reasons)
2. Logistics (job commitment, no time or interest, travel distance or family concerns, confidentiality, or financial hardship)
3. Passive (passive refusal)
4. Hostile (hostile refusal)
5. Other (fear of physical examination; dissatisfaction with the USAF, U.S. Government, the AFHS, or previous examinations; confidentiality; or other reasons).

Table 5-4. Reasons for Refusal by Group, Age, Military Rank, and Race

Category	Reason for Refusal										Total	Unadjusted p-Value

Note: Percentages represent the percent of total refusals.

** : Statistically significant (p-value≤0.010).

Age, military rank, and race have been dichotomized for analysis purposes (born before 1942 and born in or after 1942; officer and enlisted; Black and non-Black, respectively). As noted in Table 5-3, of the total number of veterans invited, nearly the same percentages of Ranch Hands, Original Comparisons, and Replacement Comparisons refused due to health reasons (5.4%, 5.1%, and 5.6%, respectively). Based on only refusing veterans, and without adjustment for age, military rank, or race, the association between reason for refusal and group was significant ($p<0.001$). Excluding veterans who refused for other reasons described above, Ranch Hand refusals were almost evenly distributed among health reasons, logistical reasons, passive refusals, or hostile refusals. The Comparisons, however, tended to be passive refusals (29.9%) or refuse for logistical reasons (30.7%) more often than being hostile or refusing for health reasons. Therefore, hostile refusals and refusals for health reasons were a smaller percentage of the total number of Comparison refusals, which caused the significant difference in the distribution of refusals between groups. A test of association between reason for refusal and group (adjusted for age, military rank, and race) was performed and also found to be significant ($p<0.001$) due to the majority of Comparisons being either passive refusals or refusing for logistical reasons.

There was a significant association between reason for refusal and age ($p<0.001$) and between reason for refusal and military rank ($p<0.001$). Younger veterans (born in 1942 or after) were less likely to refuse for health reasons than older veterans (5.7% versus 25.6%). Younger veterans were more likely to be passive refusals (35.0% versus 22.4%) or refuse for logistics reasons (31.7% versus 25.9%). Officers were more likely to be hostile refusals than enlisted men (33.0% versus 16.7%) and were less likely to refuse because of logistics reasons (23.8% versus 30.9%) and to be passive refusals (16.5% versus 33.8%) than enlisted personnel. No significant association was found between reason for refusal and race ($p=0.084$).

5.5.2.1 Passive Refusals

A veteran was classified as a passive refusal if he was scheduled for a physical examination but twice cancelled the appointment or failed to appear for it. A veteran also was classified as a passive refusal for other reasons, including the inability to contact the participant directly because of the presence of a “gatekeeper” (see Section 5.4.1). A veteran was designated as a final passive refusal after a minimum of three contacts with a gatekeeper and failure to reach the participant by other means. Up to eight gatekeeper contacts were allowed if the scheduling supervisor decided additional attempts were still warranted. Passive refusals were provided with the toll-free number for the study and allowed to volunteer to participate at any time.

For the 2002 follow-up examination, the Air Force introduced a procedure to facilitate the scheduling process for those potential participants who refused to participate in the 1997 follow-up examinations. All refusals from the 1997 follow-up examination were sent a letter by the Air Force 6 to 9 months prior to the beginning of the scheduling process in March 2002. The letter asked each refusal in 1997 if he wished to participate in the 2002 follow-up examination. If the veteran did not wish to participate in the 2002 physical examination process, he was asked to return a card that was enclosed with the letter stating his wishes and to provide a reason for his nonparticipation. He was given the toll-free number and invited to contact the AFHS if he changed his mind. Veterans who did not return the card were classified as passive refusals.

Passive refusals accounted for 28.6 percent of the refusals at the 2002 follow-up examination. As described above, 29.9 percent of Comparisons were classified as passive refusal, whereas 24.4 percent of Ranch Hands were designated as passive refusals.

5.5.2.2 Hostile Refusals

Hostile refusals accounted for 23.3 percent of refusing Ranch Hands and 21.1 percent of refusing Comparisons for the 2002 physical examination. As shown in Table 5-5, 197 veterans (139 Comparisons and 58 Ranch Hands) were initially classified as hostile refusals during the 1992 physical examination process. Five additional veterans were added to the list of hostile individuals after the 1992 report was completed to bring the total to 202 individuals. Between the 1992 and 1997 examinations, this list of 202 veterans was reviewed and some individuals were redesignated as refusals that should be contacted for the 1997 follow-up examination. Some hostile individuals on this list also contacted the Air Force and expressed a desire to participate in the 1997 follow-up examination. Consequently, 17 veterans were removed from the list of hostile individuals. Six additional veterans on the list of hostile individuals died between the 1992 and 1997 follow-up examinations. The list of 202 hostile individuals was therefore reduced to 179 veterans that were not to be contacted by schedulers for the 1997 examination. During the course of the 1997 examination, 21 additional veterans were designated as “newly” hostile individuals, resulting in a total of 200 veterans designated as hostile for the 1997 follow-up examination, as shown in Table 5-5.

Of the 200 veterans who were designated as “hostile” for the 1997 physical examination, six veterans died between the 1997 and 2002 physical examination, one veteran who was previously designated as hostile asked to be and was allowed to become part of the 2002 follow-up physical examination, and one veteran who was previously designated as hostile was designated as ineligible (see Section 5.5.1). Consequently, 192 of the 200 previously designated hostile veterans were considered hostile as the 2002 physical examination process began. A total of 33 additional veterans were designated as hostile, based on contacts with these individuals by either mail or telephone, bringing the total of hostile veterans to 225 at the end of the 2002 follow-up physical examination process.

5.5.2.3 Reasons for Refusal Across AFHS Examinations

The reasons for refusal for the baseline, 1987, 1992, 1997, and 2002 examinations are shown in Table 5-5, presented separately for Ranch Hands and Comparisons. The reasons for refusal to participate in the 1985 examination are not addressed in Table 5-5 because the data were not collected in a manner consistent with that in the other examinations. In 1985, the data were collected verbatim as part of the record of telephone contacts. Therefore, no meaningful comparisons can be made between the 1985 study data on refusals and other years. Table 5-5 shows a consistent increase in total refusals across time. Of particular note is the steady increase in refusals for health reasons.

5.5.3 Replacement Comparisons

As stated previously, the process of choosing replacements for Original Comparisons who refused, matched on health status, as well as age, race, military rank, and occupation, was maintained at the 2002 follow-up examination. The reported health status of new replacements was obtained at the time of telephone scheduling. At the 2002 follow-up examination, 437 Replacement Comparisons were fully compliant (see Table 5-1). Table 5-6 summarizes the health-matching results for the 56 Replacement Comparisons invited to the study for the first time in 2002 (see Table 5-2) and their replaced Original Comparisons.

Of the 56 Replacement Comparisons, 35 were matched perfectly on health status to the Original Comparisons. Two additional Replacement Comparisons were matched according to the dichotomized health status indicated in the study protocol. Nineteen Original Comparisons (labeled “Unknown”) did not provide a self-perception of health. The health status of the 19 Replacement Comparisons is shown in Table 5-6.

At the 2002 follow-up examination, 166 Original Comparisons were deceased, 7 could not be located, and 349 refused (see Table 5-7). The entire matched set of replacement candidates for each noncompliant Original Comparison was reviewed to determine if the appropriate replacement strategy was followed. Results are presented in Table 5-7. Of the 522 Original Comparisons who were not fully compliant for the 2002 follow-up examination, 316 compliant replacements were found. A total of 152 matched sets were closed because all previously invited Comparisons were deceased and, consistent with the protocol, no replacements were to be contacted, or because all replacements were contacted and no replacements were found that were willing to participate or were able to be health matched. No Replacement Comparisons were contacted for 13 of the noncompliant Original Comparisons. A review of the record of telephone calls showed that all 13 had declined late in the scheduling process. For 41 of the noncompliant Original Comparisons, some replacements, but not all, were contacted and none complied. A review of the cohort of the 41 Original Comparisons, where replacement contact was not fully exhausted, showed that the Original Comparison or one or more of the Replacement Comparisons also had declined late in the process. It is noted that all compliant Ranch Hands were included in the analysis, regardless of whether they had a matched Comparison.

5.6 MATCHING OF SELF-REPORTED HEALTH STATUS

5.6.1 Self-reported Health Status of Refusals

Ideally, compliance bias between the groups should be assessed by comparing the health of refusing veterans to fully compliant participants with adjustment for the matching variables. The only current data available on the refusing veterans are self-reported responses to the health status question asked during the scheduling procedure.

Of the 1,040 refusals, reported health status, as obtained by telephone at the time of scheduling, was available for a total of 512 Ranch Hands and Comparisons. Table 5-8 summarizes their responses. Data were obtained from 150 (57.3%) of 262 refusing Ranch Hands and 362 (46.5%) of 778 refusing Comparisons. Among the 512 refusals responding to the health status question, there was no significant association between group and reported health ($p=0.072$).

Table 5-8. Reported Health Status of Refusals

Reported Health Status	Group				Total		Unadjusted p-Value
	Ranch Hand		Comparison		n	%	
	n	%	n	%			
Excellent	14	9.3	57	15.7	71	13.9	0.072
Good	84	56.0	192	53.0	276	53.9	
Fair	28	18.7	77	21.3	105	20.5	
Poor	24	16.0	36	9.9	60	11.7	
Total	150		362		512		

Note: Does not include 14 Ranch Hands and 80 Comparisons from whom health status was not provided, 56 Ranch Hands and 152 Comparisons who were hostile, and 42 Ranch Hands and 184 Comparisons who were passive refusals.

A test of association between reported dichotomized health status and group, age, military rank, race, and compliance was performed. The results of this test are shown in Table 5-9. For analysis purposes, reported health status was classified into two categories: excellent or good, and fair or poor. The covariates age, military rank, race, and compliance were dichotomized (born before 1942 and born in 1942 or after, officer and enlisted, Black and non-Black, and fully compliant and refusal, respectively). No significant association was found between group ($p=0.278$) or race ($p=0.833$) and reported health status. Age ($p=0.017$), military rank ($p<0.001$), and compliance ($p<0.001$) were associated significantly with reported health. Enlisted men were more likely to report fair or poor health than were officers (24.4% versus 12.0%). As expected, refusals (32.2%) and older veterans (21.6%) were more likely to report fair or poor health than were fully compliant (16.5%) or younger veterans (17.7%).

The association between reported health status and group, adjusted for age, military rank, race, and compliance was significant ($p=0.048$). Ranch Hands were more likely to report their health as fair or poor (21.0%) than Comparisons (19.1%). The adjusted association between reported health status and compliance was statistically significant ($p<0.001$), as were the adjusted associations between health status and age ($p<0.001$) and military rank ($p<0.001$).

Table 5-10 shows the reported health status versus compliance separately by group. For both Ranch Hands and Comparisons, significantly more refusals reported fair or poor health ($p<0.001$ for both groups) than fully compliant participants. When adjusted for age, race, and military rank, the relation between health status and compliance did not change significantly with group ($p=0.980$). This result showed that the difference in health status between refusals and fully compliant participants was similar between Ranch Hands and Comparisons.

Table 5-9. Reported Health Status by Group, Age, Military Rank, Race, and Compliance

Category	Reported Health Status				Total	Unadjusted p-Value
	Excellent/Good n	%	Fair/Poor n	%

5.6.2 Self-reported Health Status of Fully Compliant Participants

Tables 5-11 through 5-13 summarize the reported health status, medication use, and work loss of the fully compliant participants at the 2002 follow-up examination. Table 5-11 summarizes the reported health status of participants fully compliant with the 2002 physical examination. Among fully compliant participants, no significant association was found between reported health at the time of scheduling and group (Ranch Hand, Comparison) (p=0.367).

Table 5-11. Reported Health Status of Fully Compliant Participants

Reported Health Status	Group				Total		Unadjusted p-Value
	Ranch Hand		Comparison				
	n ^a	%	n ^a	%	n ^a	%	
Excellent	227	29.3	359	30.6	586	30.1	0.367
Good	406	52.4	634	54.0	1,040	53.4	
Fair	118	15.2	147	12.5	265	13.6	
Poor	24	3.1	33	2.8	57	2.9	
Total	775		1,173		1,948		

^aDoes not include two Ranch Hands and one Comparison who did not answer or refused to answer the question on reported health status at the time of scheduling for the 2002 follow-up examination.

Table 5-12 presents the results of reported medication use by group. At the 2002 follow-up physical examination, a greater percentage of Ranch Hands reported using medication than Comparisons (74.3% versus 70.3%), but the difference was nonsignificant ($p=0.064$). Use of medication increased in both groups since 1997. Approximately 72 percent of all participants reported medication use at the 2002 follow-up physical examination, as compared to 57 percent of participants at the 1997 follow-up examination. The increase in medication use between the 1997 and 2002 follow-up examinations was consistent between groups, however, with approximately 4 percent more Ranch Hands reporting the use of medication than Comparisons at both examinations (58.9% and 55.0% for Ranch Hands and Comparisons, respectively, at the 1997 follow-up examination).

Table 5-12. Reported Medication Use of Fully Compliant Participants

Medication Use	Group						Unadjusted p-Value
	Ranch Hand		Comparison		Total		
	n	%	n	%	n	%	
Yes	577	74.3	824	70.3	1,401	71.9	0.064
No	200	25.7	348	29.7	548	28.1	
Total	777		1,172		1,949		

Note: Two Comparisons did not take the 2002 follow-up examination questionnaire.

Table 5-13 shows reported work loss from illness or injury in the 6 months prior to the 2002 follow-up physical examination for fully compliant Ranch Hands and Comparisons. The difference in work loss between the two groups was nonsignificant ($p=0.754$).

Table 5-13. Reported Work Loss of Fully Compliant Participants

Work Loss	Group				Total		Unadjusted p-Value
	Ranch Hand		Comparison				
	n	%	n	%	n	%	
Yes	82	17.7	135	18.6	217	18.3	0.754
No	380	82.3	589	81.4	969	81.7	
Total	462		724		1,186		

Note: Analysis does not include the following:

- 17 unemployed (6 Ranch Hands, 11 Comparisons)
- 707 retired (289 Ranch Hands, 418 Comparisons)
- 39 who did not answer the question (20 Ranch Hands, 19 Comparisons)
- 2 participants (both were Comparisons) who did not take the 2002 follow-up examination questionnaire.

5.7 CONCLUSION

A greater percentage of Comparisons than Ranch Hands refused and a greater percentage of Replacement Comparisons than Original Comparisons refused. Of the total invited, nearly the same percentages of Ranch Hands, Original Comparisons, and Replacement Comparisons refused due to health reasons (5.4%, 5.1%, and 5.6%, respectively). More Replacement Comparisons than Ranch Hands or Original Comparisons declined due to “job commitments,” “no time,” or “travel distance or family concerns.” In addition, more Replacement Comparisons were “passive refusals,” indicating that this group of Comparisons did not respond to formal correspondence through NORC or the Air Force. More Original Comparisons were hostile refusals (9.5%) than either Replacement Comparisons or Ranch Hands. Ranch Hand refusals were similarly distributed among health reasons, logistical reasons, passive refusals, and hostile refusals. The Comparisons, however, tended to be passive refusals or refuse for logistical reasons more often than being hostile or refusing for health reasons. Younger veterans were less likely to refuse for health reasons than older veterans and were more likely to be passive refusals or refuse for logistics reasons. Officers were more likely to be hostile refusals than enlisted men and were less likely to refuse because of logistics reasons and were less likely to be passive refusals than enlisted personnel.

In replacing noncompliant Original Comparisons, either compliant replacements were found or no replacement was necessary (i.e., the Original Comparison was deceased and no Replacement Comparison had been contacted previously) for approximately 89 percent of the Original Comparisons. For the remaining 11 percent of the Original Comparisons, a review of the record of telephone calls showed that the Original Comparison or one or more of the Replacement Comparisons had declined late in the scheduling and examination process.

Self-reported health status differed with age, military rank, and compliance status among those reporting their health status at the time of scheduling for the 2002 follow-up examination. After adjustment for age, military rank, race, and compliance status, Ranch Hands were found to be more likely to report fair or poor health than Comparisons. In both groups, veterans who refused were more likely to report fair or poor health than those who were fully compliant. This pattern of Ranch Hands reporting poorer health has been observed since the baseline examination. Using work loss and medication use as more objective indicators of health than health perception, no difference was seen in reported work loss or in medication use between Ranch Hands and Comparisons. The increase in medication use between the 1997 and 2002

follow-up examinations was similar in both Ranch Hands and Comparisons and the difference was nonsignificant. A further analysis of self-perception of health, as reported by fully compliant participants at the 2002 follow-up examination, is given in Chapter 9, General Health Assessment.

In summary, of the total invited, nearly the same percentages of Ranch Hands, Original Comparisons, and Replacement Comparisons refused due to health reasons. Further analysis suggested that, when combining fully compliant and noncompliant veterans and adjusting for age, military rank, race, and compliance status, Ranch Hands reported poorer health than Comparisons.

6 QUALITY CONTROL

Quality control (QC) and quality assurance (QA) procedures were planned for and implemented throughout the 2002 Air Force Health Study (AFHS), from project initiation to final product delivery and acceptance by the Air Force. In-depth discussions of those procedures can be found in the *Quality Assurance Plan for the Air Force Health Study 2002 Follow-up Effort*, delivered to the Air Force as Contract Data Requirements List Item B014.

QC is defined as the procedures put in place to ensure the quality of the data collected. QA refers to the management of those procedures. This chapter provides an overview of the specific QC and QA measures developed and used by the project team, specifically in the areas of questionnaire and physical examination QC, laboratory QC measures, data management QC, statistical QC, and administrative QA. The Air Force, Science Applications International Corporation (SAIC), the National Opinion Research Center (NORC), and Scripps Clinic all participated in the formulation and implementation of the QC and QA procedures described in this chapter.

6.1 QUESTIONNAIRE QC

6.1.1 Design

For the baseline and subsequent follow-up examinations, the baseline and interval questionnaires were administered in person. In the examinations prior to 1997, the questionnaires were administered in hard copy and the data collected were keyed into the final SAS^{®1} data set. For the 1997 and 2002 follow-up examinations, the interview responses were obtained electronically on laptop computers using a computer-assisted personal interviewing (CAPI) data collection technique. As an alternative to paper questionnaires, CAPI allowed improved accessibility to data and made the interviewing process less burdensome to the interviewee.

Effective CAPI design was the first step in QC of the data collection. By combining the two steps of data collection and data entry, the CAPI technique eliminated one possible source of recording error—keying in the data. Further, the logic checks, range checks, and intervariable consistency checks programmed into the CAPI system placed constraints on what the interviewer could type or select for any particular question during the interview. These constraints limited keystroke errors and data problems arising from the interview itself. The structure of the CAPI system ensured that skip patterns were followed correctly and that no questions were left unanswered. In certain sections of the questionnaire, CAPI offered significant enhancements to the flow and accuracy of the questionnaire over a paper-and-pencil execution. These enhancements included automatic unit conversions and elimination of multiform cross-references. These benefits were most notable in the calculations of alcohol and tobacco use and in updating information for children born prior to the last interview.

Using a process of reviewing, commenting, and concurring, Air Force researchers and NORC designers incorporated new questions and streamlined existing questions when possible. The goal was to create a cohesive instrument with questions grouped logically by subject because a cohesive questionnaire would enhance the participant's focus on the subject being discussed and his understanding of the questions. By incorporating data already collected into the questionnaire, NORC was able to program CAPI to skip over questions to which the participant had provided an answer in an earlier follow-up examination. For example, participants previously reporting their mother as deceased were not asked if she was alive;

¹ SAS and all other SAS Institute, Inc., product and service names are registered trademarks or trademarks of SAS Institute, Inc., in the USA and other countries.

however, participants previously reporting their mother as alive were asked. Similarly, if participants had previously provided the names of their siblings, these names were not re-asked, although the vital status of the siblings was updated. These and other streamlining improvements decreased the participants' frustrations with the examination process by eliminating question redundancy, providing a logical sequencing of questions, and decreasing the time spent by the participant.

An additional benefit of the CAPI questionnaire was the ability to print selected participant responses for use by the debriefing physicians. The layout and appearance of the printouts were improved for the 2002 follow-up examination, making them easier for the debriefing physicians to read.

6.1.2 Data Collection

NORC recruited and trained 10 interviewers and 1 field manager to administer the baseline and interval questionnaires. The interviewer training program comprised the following:

- A general interviewing training for new-to-NORC interviewers
- A home-study assignment prior to attending training
- A 3-day intensive training in March, which included daily homework assignments and a mandatory certification test afterward
- A 2-day refresher training in April followed by another mandatory certification test.

A minimum number of interviewers were selected to reduce variability between interviewing techniques. The interviewers were blind to the participants' exposure status, thus avoiding bias.

The field manager, who supervised the interviewing at the examination site, observed the work of all interviewers and presented formal evaluations of their performances to the Air Force each quarter. Interviewers were evaluated on their ability to control the interview and to probe incomplete answers in a neutral manner. They also were graded on their vocal quality, reading quality, and on their use of associated forms and documents. The interviewers were graded on a standardized scale of 1 to 4, where 1 indicated that the interviewer's performance needed improvement, 2 was acceptable, 3 was good practice, and 4 was exceptional performance with no errors. Interviewers typically received a grade of 3 or 4, but there were three cases in which a grade of 1 was assigned. In one instance, a new interviewer was added to the team and needed some additional practice to become more familiar with the questionnaire to improve her reading of the questions. In the other two instances, the new interviewer and an experienced interviewer who had returned from vacation were asked to focus on their completion of some of the associated forms and documents. Both of these interviewers successfully completed their retraining.

Interviewers were required to regularly report questions or problems experienced while executing the questionnaires. "CAPI Problem Forms" and "Policy Decision Forms" were distributed for interviewers to complete, and these forms were faxed daily to the data collection task leader at NORC headquarters in Chicago, Illinois. Items reported on the forms included the following: (1) mistakes made and not corrected during the interview, (2) conditions reported by the participant after the interview was over, (3) technical problems with the CAPI instrument, and (4) problems with the printout for the debriefing physician. The data collection task leader corrected problems when necessary and provided assistance to interviewers in handling confusing or unusual situations. Interviewers were sensitive to participants' reactions to the questionnaires. If interviewers felt that a participant failed to understand or respond to the questions acceptably, due to evasion, age, impaired memory, or disinterest, they recorded these observations in the interviewer comments for the associated question.

6.1.3 Processing and QA of Questionnaire Data

Completed questionnaire data were transmitted daily via modem from the La Jolla, California, site to the receiving computer system in Chicago. As interviews were completed on the laptop computers at the site office, the CAPI system selected the newly completed cases, encrypted the interview data, and transmitted the interview data to the NORC modem pool in Chicago. Once in Chicago, the interview data were unencrypted, archived on a devoted volume of the NORC UNIX computer, and copied to the NORC wide area network. Each CAPI interview comprised one multiple-record ASCII file representing the participant's answers to questions. Using a standard code, the ASCII files were converted to SAS[®] data sets. Programmers then read the horizontal files into SAS[®] and printed frequencies of all variables. Case data received in Chicago were reconciled regularly with the completion log at the interviewing site.

Some of the QC steps used in converting CAPI files to the SAS[®] data files include the following:

1. The case IDs of all completed interviews in the SAS[®] file were compared to the log of completed interviews kept at the site office. This ensured that all completed cases were received and that there were no duplicates.
2. The SAS[®] variables were compared to a hard-copy representation of the CAPI to ensure that all questions in the interview were present in the SAS[®] data file.
3. The response frequencies were reviewed to ensure that the questionnaire was operating correctly, no data items were skipped, and no data items were truncated.

One of the goals in the conversion process was to replicate, to the maximum extent possible, the variable names, formats, and structures used for the 1997 follow-up examination. To accommodate this goal, additional "post-processing" programs were created. The post-processing included renaming variables, assigning the appropriate variable labels and value labels, creating variables based on values of answers to more than one question (such as calculations of cigarette use), and merging variables collected outside the interview into the data set.

Several steps were taken to ensure that the SAS[®] data file created from the post-processing programs contained the correct information:

- A list was created that mapped CAPI variables to SAS[®] variables. This allowed the NORC staff to ensure that variables were named properly and that all required variables were included in the SAS[®] data set.
- The list of SAS variables from the 2002 data set was compared to that from the 1997 data set to ensure the inclusion and correctness of all necessary variables.
- Format statements and frequencies were proofed against three representations of the questionnaire (the CAPI form, the 1997 hard copy representation, and the 1992 hard copy) to detect problems.
- Cross-tabulations and printouts of data items at the case level were generated to investigate complicated questions, such as whether a calculation was working correctly or why there was a missing value in a certain variable.
- Continuous reviews of the frequencies were performed until no more errors were detected.
- A cumulative data set of all interviews completed to date, accompanied by a footnote file explaining any anomalies or programming issues still to be resolved, was delivered quarterly and then monthly to the Air Force for review. All errors identified by the Air Force were

corrected by NORC, the data set was corrected and delivered a final time, and the corrections were accepted.

Response frequencies for all data fields were reviewed regularly to ensure that data for all variables were captured, answers made logical sense, and the skips and checks programmed by CAPI were operating correctly. These QC checks revealed a problem in the programming of two new preload variables that determine entry into two series of questions: the “Combat Questionnaire” and the “Ever Drink Herbicide” question. Some participants who should have been asked these questions skipped them, and some participants who did not need these questions were asked them. The following three steps taken to correct this situation are more fully documented in NORC’s Methodology Report:

1. Immediately upon discovery of the problems, a hard-copy version of these questions was distributed to NORC’s interviewers so that in the upcoming groups information would be obtained from the required participants in the event that the CAPI system did not properly direct them to the questions.
2. The questionnaire code was reviewed and corrected, and the revised CAPI instrument was transmitted to the laptops.
3. NORC schedulers telephoned the 15 participants who should have been asked these questions but were not in order to collect the information. Data were successfully retrieved from all but one of these participants. These data were then merged into the full questionnaire database.

To increase the quality of the spelling on verbatim data, NORC implemented a spellchecking process for the 2002 follow-up examination. Interviewers were encouraged to take the time to spell carefully and to consult a spelling list of common medical terms to the extent that this did not interfere with the interview or increase the participant’s burden. The spellchecking of the collected data occurred during the data review process. Data supplied for verbatim variables were extracted from the SAS® data and loaded into a Microsoft® Excel spreadsheet. A data clerk ran the Microsoft® Excel spellchecker program using a dictionary customized to include common medical terms and medications. The clerk could agree with Microsoft’s suggested change, make his or her own change, or leave the supplied data unchanged. Both the original collected data and the spellchecked version of the data were delivered in the final data set.

During final QA of the questionnaire data, it was discovered that a series of three questions meant to assess self-reported intermittent claudication and vascular insufficiency were not administered as planned. The question “Do you get a pain in either or both of your legs while walking?” was asked of all participants. A total of 415 participants responded affirmatively. For these 415 participants, the second question, “Does this pain ever begin when you are standing or still sitting?”, was subsequently asked. A total of 254 participants replied “yes” to this question and 161 participants replied “no.” The participants who responded “no” to this question were supposed to be asked the third question, “Do you get this pain in either or both of your calf muscles?” Because of an unintentional change to the programming code, however, this question was asked of the participants who replied “yes” to the second question and not of the participants who responded “no.” The participants who responded “no” to the third question were telephoned by Air Force staff and their responses to the third question of the series were collected.

6.2 PHYSICAL EXAMINATION QC

The Scripps Clinic selection process for all personnel who were to interact directly with the participants ensured a high-quality physical examination. Each staff member was hand-selected for the AFHS on the basis of expertise, experience, and a commitment to remain with the study throughout the examination process. Further, the Air Force reviewed the credentials of all key staff members and approved their participation in the study.

A complete examination test was held. Eleven volunteers completed the physical examinations, interviews, psychological tests, and laboratory analyses several weeks before the scheduled start of the examination. A twelfth volunteer completed the psychological tests only. All aspects of patient contact were reviewed: the initial inbriefing of the participants, the logistics of transportation and patient flow within the clinic, and the final outbriefing by the internist.

During the actual examinations, refinements were made whenever operational problems were detected. Whether detected by the Scripps Clinic staff, the Air Force onsite monitor, or the participants, problems were addressed during periodic clinical QA meetings of key Scripps staff.

During the physical examination, the identification of one chest x-ray film was found to be questionable because of improper labeling. The overall chest x-ray assessment was used in the analysis of the pulmonary function, and the participant whose x-ray film was in question was contacted and the x ray was reaccomplished.

Following examination of each participant group, the Scripps Clinic staff reviewed all physical examination forms for omissions, incomplete examinations, and inconsistencies. When issues were found, the examiners or technicians were contacted to correct the data. Special effort was made to complete this review while the participants were at the examination site. In all cases in which data were corrected, the form was initialed by the doctor or technician making the correction. (This subject is discussed in more detail in Section 6.4 of this chapter.) An optical scanner read all mark-sense physical examination forms as an ongoing QA of form completion.

The Air Force onsite monitors and the Scripps Clinic administrative team monitored compliance with the physical examination process. The Scripps Clinic Chief of Medicine and the SAIC Project Manager conducted additional periodic inspections. All such clinical reviews were performed unobtrusively and with the full consent of the participant; suggestions or corrections to the examination procedure always were discussed privately with the attending physician. These inspections emphasized aspects of clinical techniques, sequence, and completeness of the clinical data with respect to the examination forms and the blindness of the examinations. Of particular note were the detailed daily log entries of the Air Force monitors. These entries ensured continuity of knowledge (the monitors rotated approximately every 2 weeks) by documenting daily activities and, when needed, recording events requiring follow-up by either the Air Force or SAIC.

Establishing a rapport with each study participant was a primary goal of all the organizations involved in the study. Although this may not be a traditional QA parameter in most research studies, it is paramount in the AFHS. Maintaining participant satisfaction encourages the participants to continue in the study, thus avoiding the need for substantial replacement, which can reduce future statistical power or introduce bias, or both. Therefore, every staff member emphasized courtesy, empathy, and personalized treatment of each participant.

Participants were asked to fill out an evaluation form after completing their 2002 follow-up physical examinations. The participant evaluations provided insight into the participants' experiences, including strong points of the programs and areas in need of improvement. These forms were reviewed by all study management staff.

Based on the participants' evaluation forms, 80.9 percent evaluated their overall clinic experience as excellent, and 17.8 percent classified it as good. No participants felt that the overall clinic experience was unsatisfactory, and 1.3 percent of the participants rated it as satisfactory. These evaluations are charted in Figure 6-1.

Figure 6-1. Participant Evaluations of the 2002 AFHS Clinic Experience

6.3 LABORATORY QC

Before the examination began, specific QC laboratory procedures were designed, developed, and implemented to detect problems related to test and assay performance, validity of reagents, analysis of data, and reporting of results. All laboratory assays for the examination were performed with state-of-the-art laboratory equipment and techniques. Laboratory facilities all had the equivalent of National Institutes of Health Biosafety Level 2 approval ratings and were certified by the College of American Pathology.

6.3.1 QC Procedures for the Clinical Laboratory

The following list outlines the tests performed and the methods and equipment used:

- Hematology assays were performed on Abbott Cell-Dyn 4000 equipment.
- Erythrocyte sedimentation rate (ESR) determinations were performed using the Ves-Matic™ equipment.
- Coagulation assays were performed using Dade Behring Blood Coagulation System equipment.
- Biochemical assays were performed using the Dade Behring Dimension® RxL automated chemical analyzer.
- Insulin and C-Peptide assays were performed on the DPC Immulite chemistry analyzer.
- Hemoglobin A1c was performed on Bio-Rad Variant equipment.

- Radioimmunoassays and immunofluorescent assays were performed with standard test kits.
- Immunochemistries were performed using the Bayer ADVIA Centaur[®] instrument.
- Occult blood tests were performed manually.
- Hepatitis A assays were performed using Abbott Commander[®] equipment.
- Monospecific antibodies were used for immunoglobulin assays using the Beckman Coulter IMMAGE[®] system.
- T & B lymphocytes were analyzed on Becton Dickinson FACScan equipment.
- Blood cell counts were performed with standard microscopy.
- All urinalyses were performed using Bayer Atlas[®] equipment.
- All other assays were performed using industry-standard equipment and techniques.

All laboratory operations were controlled with the use of an integrated medical laboratory management information system that incorporated direct device-to-database interfaces for automated testing equipment. Laboratory technologists performed data entry for manual tests. An automated audit trail and a set of comments for technologist remarks were kept for each test so that any QC results could be retraced.

Procedural QC included using the same instrument and reagents from the same lot numbers whenever possible throughout the examination. If single lots were unavailable, analyses were conducted to calibrate subsequent lots and establish target levels and associated standard deviations. Strict standards of calibration for all automated laboratory equipment were maintained at all times.

Tri-level or bi-level controls were used as the primary means for monitoring the quality of all tests. On every group of participant samples, one control (low, medium, or high) was run at the start, after every ninth sample, and at the end of each test run. Each tri-level control was used before repeating it in the run when more than 18 experimental samples were analyzed. In addition, split aliquots were created from every 10th participant sample and were analyzed separately to measure test reproducibility. In radioimmunoassays, all three control levels were run initially to validate the standard curve generated.

Scripps Clinic Medical Laboratory has defined quality requirements of accuracy above 99 percent and levels of precision above 97 percent. A variation of the Westgard Rules (1, 2) QC technique is routinely used in the Scripps Laboratory and was used for AFHS assays. In this variation, the 1_{2s} single rule and 4_{1s} multiple rule are used. The 1_{2s} rule indicates rejection of any run when the control value of any one of the three controls (low, mid, high) exceeds two standard deviations from the mean. The 4_{1s} rule indicates rejection of a run when four consecutive control measurements exceed one standard deviation on the same side. This approach ensures an effective system for reducing the probability of false rejection to the lowest acceptable level while maintaining error detection at more than 98 percent.

All QC data were analyzed and summarized in formal QC reports generated monthly. QC data were subjected to independent statistical analysis by the Air Force to produce and analyze time-dependent trends. For all equipment malfunctions or other exceptions, a formal QC exception report was prepared by the responsible individual and forwarded to the project management team. A summary of the coefficients of variation for each quantitative laboratory assay is presented in Appendix D. These coefficients of variation are given separately for each control level and lot.

During the period 21 August 2002 to 18 September 2002 the Ves-Matic™ 20 instrument that performs ESR on whole blood was inoperable. The Ves-Matic™ 20 ESR measures the ESR directly from the collection tube. Results equivalent to a 60 minutes ESR are available in 20 minutes. The back-up manual technique called the Modified Wintergreen method was employed during that period. There was a change in the quality control target and standard deviation during those dates.

6.4 MEDICAL DATA QC

6.4.1 Overview of QC Procedures

The QC procedures for the medical data included multiple checks at all stages of the examination, data collection, and data processing cycle. Figure 6-2 charts the QC process. Although improvements were made throughout the physical examination period, QC procedures for data collection, conversion, and integration were developed before the clinical examinations began. All data collection instruments were tested at the examination test conducted several weeks before the start of participant physical examinations. In addition, during the first 2 months of the clinical examinations, all data collection activities were routinely scrutinized to detect and correct procedural deficiencies. Other QC activities included the following:

- Automated QC techniques applied to laboratory data
- Clinical evaluations of all laboratory outliers
- Review of all physical examination findings by one of three internists
- Automated and manual data quality checking of hard copy against transcribed computer files.

Four interwoven layers of QC were instituted to ensure data integrity. These efforts focused on (1) data processing system design, (2) design and administration of all exams, (3) data completeness checks, and (4) data validation. In addition, Air Force project personnel reviewed all physical examination forms and entries. Forms that were found to be questionable, inaccurate, or incorrect were returned to Scripps Clinic for adjudication.

6.4.2 Data Processing System Design

Standards were established for data element formats (character or numeric), data element naming conventions, data element text labels, numeric codes for qualitative responses and results, QC range checks for continuous data elements, and QC validity checks for categorical data. A data dictionary provided detailed information on each data element.

A systems integration approach was applied to the design and implementation of data collection procedures so that data emanating from the physical examination, questionnaire, and laboratory were consistent in file format and structure. This approach was necessary to ensure that all data could be integrated into a single database for analysis.

Data collection forms were carefully designed to ensure that all required data elements would be collected in accordance with the study protocol and in a standardized format. These instruments were designed to reflect the order in which the examination itself would be administered and to provide for the sequential coding of information.

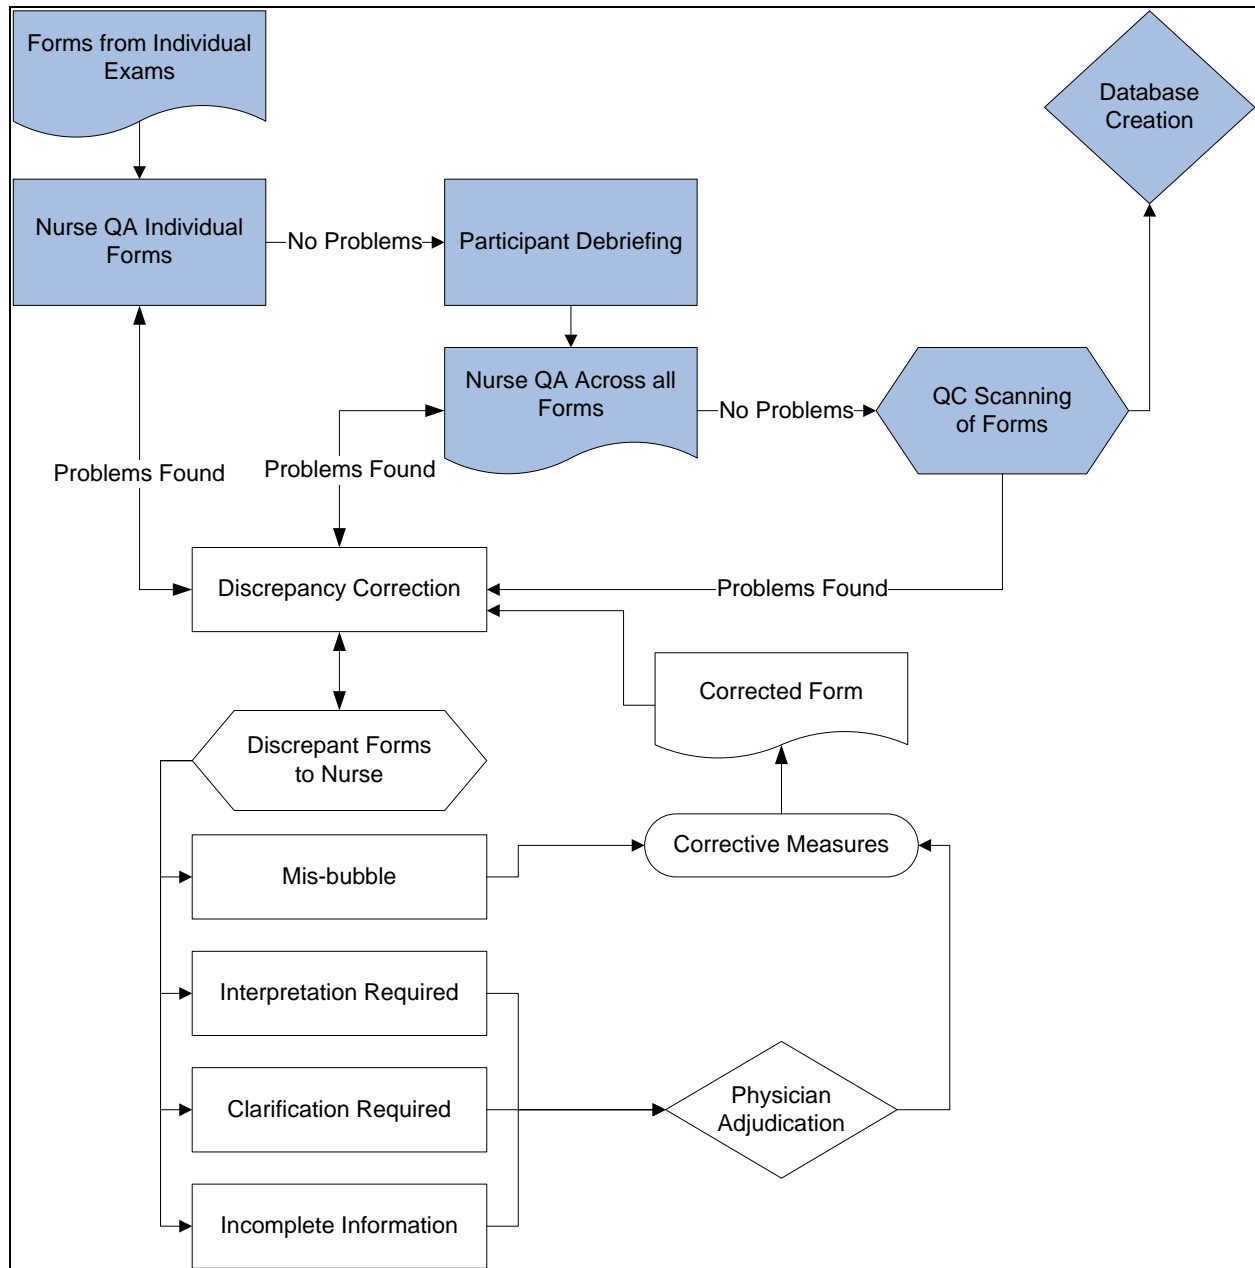

Figure 6-2. Physical Examination Form QC Process

Completed clinical examination forms were converted from hard copy to machine-readable images using optical mark reading (OMR) equipment. Verification procedures were performed to ensure that a uniquely identified participant record existed within each data file and that the appropriate number of responses for each applicable field was provided. Data files were then translated into a SAS[®] data set, verified against original data sheets, and corrected as necessary. All corrections to the original data sets were saved in the processing program, which was delivered to the Air Force for verification.

Next, the SAS[®] data sets were subjected to validity checks. All potentially conflicting results, as well as any data values falling at the extremes of expected ranges, were reviewed manually. Extreme values were verified against the original data forms and either corrected or documented as valid results. Potentially

conflicting results, either within one form or among forms, were returned to the examiners for review. These results were then documented as having been correctly recorded, corrected, or flagged for exclusion from analysis because of unresolvable examiner errors or omissions. This process was continued until all results were properly documented.

The validity checks were tested with the delivery of the first cumulative medical results data. At that time, it was discovered that some data were not properly cross-checked between collection forms. The discrepancies were adjudicated by the appropriate Scripps Clinic staff and corrected on the forms and in the database in accordance with the QC procedure. Additional QC steps were added to the procedures because of these discrepancies.

Once the edits were completed and the data verified, the “cleaned” files were transferred to the data analysis center for final inspection and integration into the study database. In this QC measure, descriptive analyses were run. The validation, correction, transmission, and analysis QC procedures were repeated as necessary to ensure that all extreme or suspicious values had been validated. As an additional measure of QC, cumulative result data sets were delivered quarterly during the physical examination phase for Air Force review. The data sets were finalized following the close of the physical examinations and before the start of statistical analysis. Figure 6-3 displays the process for cleaning and converting the collected data into final data sets.

6.4.3 Design and Administration of Physical and Psychological Examination Forms

The examination forms were designed to elicit all required data while minimizing recording time, enhancing comprehension, and automating data input. Customized mark-sense forms were developed and OMR technology was used to eliminate the risk of transcription errors. The use of mark-sense forms allowed computerized data files to be created directly from the raw data recorded on these forms.

As an added QA and QC measure, formal meetings were held with the examining physicians and technicians to review the data collection forms. These meetings were held by medical specialty so that the attending staff could review and make comments on their specific forms, as well as reach a consensus on diagnostic techniques and abbreviations.

QC procedures for all data collection instruments began with both manual and electronic reviews of each form as it was completed. A mark-sense reader was used at Scripps Clinic to scan for completeness and to conduct some broad-based logic checks. Special efforts were made to have any forms containing missing, incomplete, or contradictory examination results returned to the examining physician for completion before the participants left the site. Any questionable results or “hard-to-diagnose” conditions (such as heart sounds or peripheral pulses) were verified by the internist at the outbriefing. In addition, any differences in interpretation among examiners were identified, and adjustments in recording protocols and programmed data extraction were made as necessary. All examination forms were signed by the examining physician, and the examiner identification number was coded in the database.

6.4.4 Data Completeness Checks

Customized programming of the OMR allowed for the identification of those forms (and their corresponding data records) with missing responses, as well as those with multiple responses to questions that required a single response. The OMR scanner was programmed to reject forms that failed completeness and multiple response checks and to generate a control code for each rejected form. The control code identified the location of all verification checks failed for a given form.

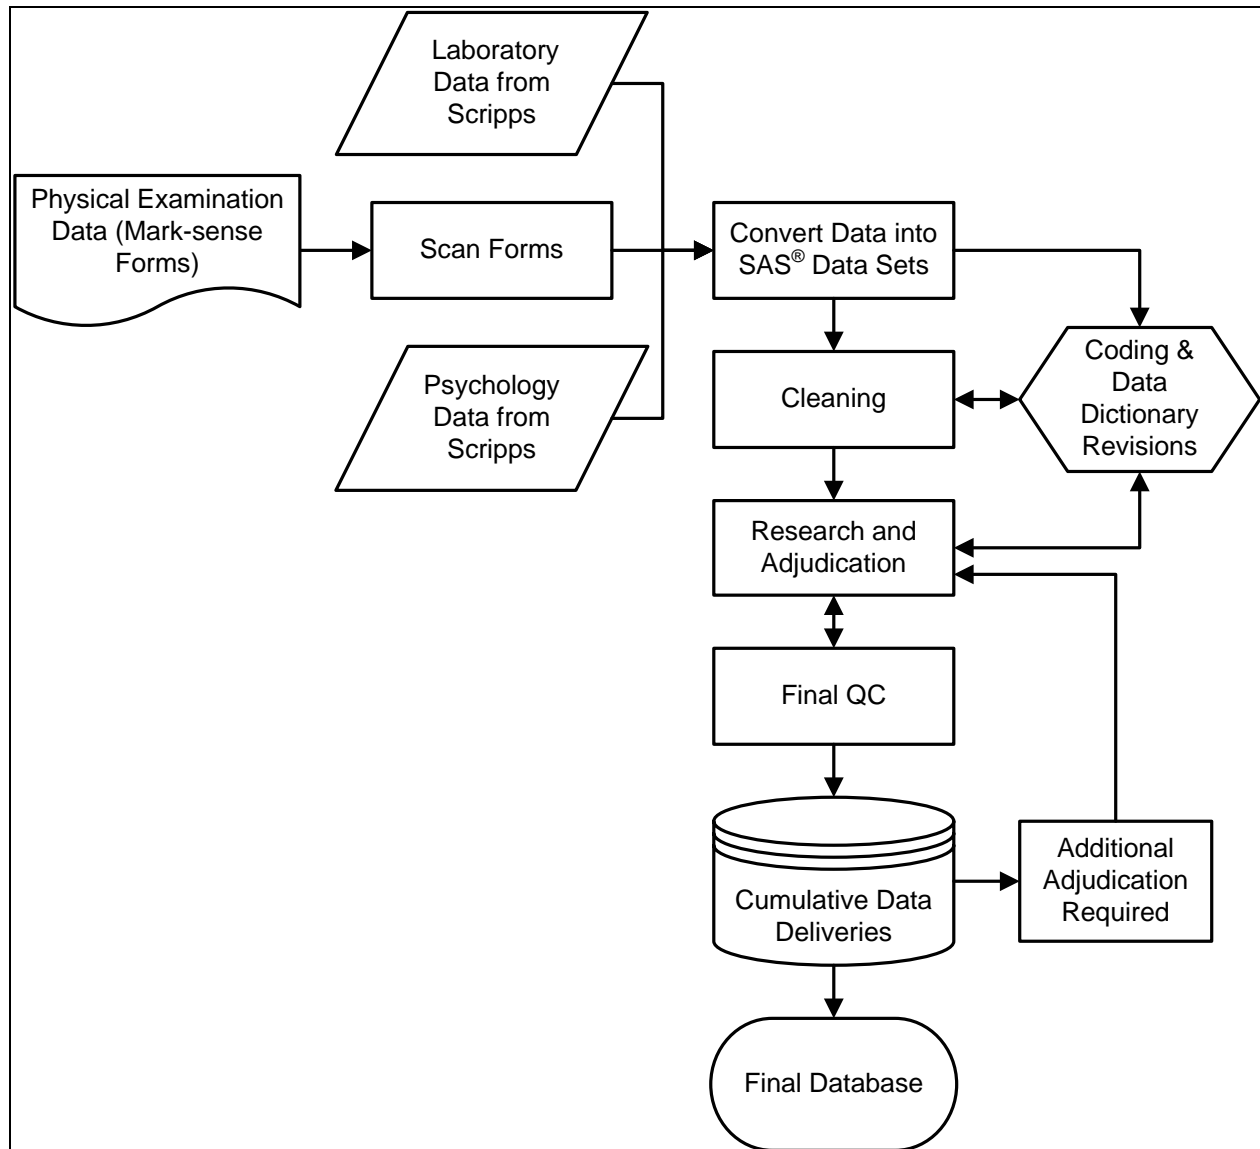

Figure 6-3. Conversion and Cleaning Process for Medical Data

When a data collection form was rejected, the reason for the rejection was determined. The exact data element was then corrected by comparing the rejected form to the values recorded in the data record created by the scanner. Some of the rejected forms did not contain actual data errors, but rather anomalies created in using mark-sense forms for data collection. For example, the scanner incorrectly counted incompletely erased responses and missed responses marked with too little graphite. Failure of the form to provide the correct number of expected responses always resulted in rejection. These errors were resolved, as were the anticipated, more traditional errors.

Out-of-range results and data omissions were monitored to detect trends, possible bias situations, and other data-quality problems. This information was reviewed and relayed to examiners and internal auditors to assist in preventing or correcting chronic, but avoidable, problems. Refresher training was provided to examining physicians to avoid data omissions. Physicians were consulted to correct clinical data, and laboratory out-of-range results were reviewed for logical validity by an independent clinician.

6.4.5 Data Validation

Data files were examined in a series of verification and validation procedures developed to check the results within each participant's record for logical consistency and abnormal findings. Any records noted to have ambiguous findings, incongruent observations, extreme results, errors, or omissions were listed and submitted for review to a physician.

Certain data items were assigned codes to indicate that data values were not available. Some reasons for unavailable data included the following:

- Participant refusal
- Test not ordered (e.g., immunology tests, which were only ordered for a subset of the participants)
- Exemption from testing (e.g., exemption from postprandial glucose testing because of diabetes).

These unavailable data were excluded from subsequent analysis. The number of values not available for analysis is presented in each clinical chapter by variable.

As the examination portion of this study ended, an independent clinician analyzed laboratory outliers for logical validity. Each outlier was adjudicated using the following four codes:

1. Clinically explained or plausible (participant has single outlier)
2. Clinically explained or plausible (participant has multiple outliers)
3. Abnormal outlier not clinically explained but plausible
4. Abnormal outlier not clinically explained and not plausible.

In the 2002 follow-up examination, all potential out-of-range results were found to be clinically explainable or clinically possible. Therefore, no clinical laboratory data were excluded from the report analyses. Subjects with missing values were excluded if the value was required for the statistical model.

6.5 MEDICAL RECORDS CODING QC

SAIC forwarded completed physical examination records and questionnaire data to the Air Force at Brooks City-Base, Texas, for diagnostic coding and verification of all subjectively reported conditions. The Air Force used the International Classification of Diseases, 9th Revision, Clinical Modification (ICD-9-CM) for morbidity coding; the Systematized Nomenclature of Medicine for anatomic site coding; and the American Hospital Formulary Service for medication coding. Two medical records technicians independently processed each questionnaire and physical examination. Both codings were then subjected to a 100-percent QA review, during which every posted code was checked against medical records. A third medical records technician adjudicated any discrepancies.

6.6 STATISTICAL ANALYSIS QC

Specific QC measures were developed for the statistical analysis efforts. The tasks requiring QC included construction of databases for the analysis of each clinical chapter, the statistical analysis itself, and preparation of the clinical chapters.

Each specialized statistical database was constructed by defining and locating every variable within the many subparts of the composite database. Although the data had been subjected to QA procedures during collection, statistical checks for outliers and other improbable values were conducted. Anomalies

identified by the statisticians were discussed with those responsible for the data collection (i.e., NORC, Scripps Clinic, or the Air Force).

QA largely depended on regular communication and general agreement among statisticians. Several meetings and consultations between the Air Force team and SAIC statisticians were held in conjunction with the development of the data analysis plan. In addition, many telephone conversations took place during the course of the statistical analysis. Any problems identified in the statistical analysis were resolved through team discussion. Specialized SAS[®] programs were developed by the task manager for each type of analysis (exposure or dependent variable-covariate associations) and form of the dependent variable (continuous, dichotomous, polytomous). These programs allowed many of the results to be saved in a Microsoft[®] Excel spreadsheet, which was used to import the results into the final report, a Microsoft[®] Word document. The software was checked by comparing results from analyses on the same variable by different programs. These programs were adapted for use in all clinical areas by changing the data source, dependent variable, covariates, and exclusions so that a consistent statistical methodology could be applied to all clinical areas. Modifications to the programs were made only as necessary (e.g., a sparse number of abnormalities that necessitated the exclusion of a particular covariate). Each analysis and the summary statistics reported for the analysis were replicated independently by a statistician not directly involved in the analysis for the report. The analyses were conducted in accordance with the data analysis plan, which was reviewed extensively by SAIC and the Air Force. Throughout the 2002 follow-up examination effort, the Air Force and SAIC maintained duplicate databases. Upon completion of the analyses, SAIC delivered all analysis software and SAS[®] data sets for each clinical area to the Air Force for final review and archiving.

All tables and statistical results were checked against the computer output from which they were derived, and all statistical statements in the texts were checked for consistency with the results given in the tables. In addition, drafts of each chapter in this report were reviewed by the Air Force and SAIC investigators.

6.7 ADMINISTRATIVE QA

In recognition of the magnitude, complexity, and importance of the AFHS, SAIC created an internal Quality Review Committee (QRC). The QRC was established at the initiation of the 1985 follow-up examination and continued through the 1987, 1992, 1997, and 2002 follow-up examination. Its purpose was to provide general oversight to the AFHS program and advice on the appropriateness of program management and QC actions. The QRC comprised SAIC senior corporate personnel and consultants. These independent reviewers remained separate from the project management staff. The QRC met periodically to review study progress and any issues that either had an impact on study quality or were perceived as a potential problem. Members of the QRC also conducted first-hand evaluations of ongoing program operations.

7 STATISTICAL METHODS

7.1 INTRODUCTION

This chapter summarizes the statistical methods used in the analysis of Air Force Health Study (AFHS) 2002 follow-up examination data to investigate relations between the health status of the participants attending this examination and their corresponding group (Ranch Hand or Comparison) or serum dioxin estimates and measurements. Group contrast models were similar to analyses performed for the 1982 baseline and 1985, 1987, 1992, and 1997 follow-up examinations (1, 2, 3, 4, 5). Models relating health to dioxin estimates and measurements were based on analyses performed for the serum dioxin analysis report for the 1987 follow-up examination and the 1992 and 1997 follow-up examinations (4, 5, 6).

The statistical methods used in the analysis of AFHS 2002 follow-up examination data encompass four different forms of hypotheses or models applied to study endpoints. Each of these models specifies the study cohort or subset of participants included in the respective analyses together with the dioxin exposure or proxy estimates to be used in the analysis. The first model (Model 1) specifies contrasts between Ranch Hands and Comparisons using group as a proxy for exposure; it does not incorporate serum dioxin measurements. The remaining three models (Models 2, 3, and 4) all incorporate serum dioxin measurements. The four statistical models used in this report and described in this chapter are a legacy from previous reports. Other approaches have been used in articles by AFHS staff published in peer-reviewed scientific journals. Those approaches sometimes used different statistical models and different methods of adjustment, and were restricted by clinical area to fewer outcome variables. The statistical models summarized here are intentionally consistent with those used in previous reports, to enable comparisons of study results across time, but do not include adjustments for recently discovered confounding variables. A summary description of each of the four statistical models is provided in Section 7.2.

Each statistical model and exposure estimate combination was implemented for study variables and type of analysis (unadjusted or adjusted). The specific statistical procedures (e.g., analysis of variance or logistic regression) that were used are presented in Section 7.3. The relation between the factors that influence the use of a particular statistical procedure and the statistical procedure used is presented in Section 7.4, followed by a discussion of interpretive considerations in Section 7.5. Section 7.6 describes the contents of the tables used to report statistical analysis results throughout the report.

7.2 STATISTICAL MODELS AND ASSUMPTIONS

The statistical analyses in this report are based primarily on four statistical models, each using a different measure of exposure. The first model uses group and military occupation (officer, enlisted flyer, and enlisted groundcrew) to assess health effects and dose-response relations related to exposure. Serum dioxin measurements were not used in this model. The other three statistical models accounted for dioxin effects either through estimated initial dioxin levels for Ranch Hands or using 1987 serum dioxin levels for Ranch Hands and Comparisons to assess health effects and dose-response relations related to exposure. Analyses based on these statistical models were carried out both unadjusted and adjusted for covariates.

7.2.1 Model 1: Group and Military Occupation as Estimates of Exposure

This section describes the statistical model that used the exposure group (Ranch Hand, Comparison) to assess the relation between health status and dioxin exposure. Statistical analyses based on this model were termed “Model 1” in the assessment of the clinical areas. Analyses of this type are straightforward, easy to interpret, and well established in epidemiologic studies when a better measure of exposure is not available. In this statistical model, exposure was defined as “yes” for Ranch Hands and “no” for Comparisons without regard to the magnitude of the exposure. As an attempt to quantify exposure, three contrasts of Ranch Hands and Comparisons were performed along with the overall Ranch Hand versus Comparison contrast. These three contrasts compared Ranch Hands and Comparisons within each military occupational category (officers, enlisted flyers, and enlisted groundcrew). As described in the serum dioxin analysis report for the 1987 follow-up examination (6), among Ranch Hands the average levels of exposure to dioxin were highest for enlisted groundcrew, followed by enlisted flyers, then officers.

Table 7-1 provides a description of Model 1 and gives the assumptions, advantages, and disadvantages for a continuously distributed health endpoint, y . The statistical model presented in Table 7-1 is unadjusted for any covariates—adjusted models are a straightforward extension. It should be noted that this statistical model is considered the “full model” in statistical terms and the coefficients corresponding to group, military occupation, and the interaction between group and military occupation are not estimable. Reparameterization must be performed to estimate a linear combination of these coefficients.

Table 7-1. Model 1: Assessing Health Versus Group Status in Ranch Hands and Comparisons: Assumptions, Advantages, and Disadvantages

Model 1: $y = \mu + G_i + e$ (All Ranch Hands and Comparisons) $y = \mu + G_i + O_j + (GO)_{ij} + e$ (Ranch Hands and Comparisons by military occupation)	
where	y = health variable in group i and military occupation j μ = intercept of the y -axis in the statistical model G_i = effect due to group status ($i = 1, 2$ – Comparisons, Ranch Hands) O_j = effect due to military occupation ($j = 1, 2, 3$ – Officers, Enlisted Flyers, Enlisted Groundcrew) $(GO)_{ij}$ = interaction between group status and military occupation ($i = 1, 2; j = 1, 2, 3$); used to examine Ranch Hand and Comparison differences for each military occupation e = zero mean error.
Assumptions:	<p>Comparisons were unexposed and Ranch Hands were exposed.</p> <p>For the purposes of investigating dose-response effects, enlisted groundcrew were more heavily exposed than enlisted flyers, and enlisted flyers were more heavily exposed than officers.</p> <p>The error variance does not change with group status or military occupation.</p>
Advantages:	Easily interpretable.
Disadvantages:	Results are biased toward the null hypothesis of no dioxin effect if unexposed Ranch Hands are misclassified (i.e., remain in the analysis as exposed Ranch Hands). It is not possible to fully distinguish unexposed Ranch Hands from exposed Ranch Hands.

An advantage of Model 1 is that it follows the original design of the study, contrasting Ranch Hand with Comparisons overall and by military occupation. A disadvantage of Model 1 is that no account is taken of the dioxin body burden of each individual. Approximately 40 percent of the Ranch Hand cohort has dioxin values less than 10 parts per trillion (ppt) (the 98th percentile of the dioxin distribution of Comparisons). Thus the potential bias toward the null due to misclassification on exposure may be severe. This potential bias is partially balanced by the group contrast within the enlisted groundcrew stratum because enlisted groundcrew Ranch Hand veterans have the highest median dioxin of the three military occupations. Misclassification is even possible within this stratum, however, because some Ranch Hand enlisted ground veterans have dioxin values less than 10 ppt.

7.2.2 Models 2 through 4: Serum Dioxin as an Estimate of Exposure

1987 dioxin levels were determined by the Centers for Disease Control and Prevention from serum samples taken from approximately 2,000 Ranch Hands and Comparisons at the 1987 follow-up examination. Additional serum samples were taken from selected Ranch Hands and Comparisons at the 1992, 1997, and 2002 follow-up examinations to provide insight on dioxin levels and the elimination of dioxin from the body, and to provide measurements for new subjects and those who were not previously measured.

Investigation of the mechanics of dioxin elimination is currently under study by the Air Force. Based on samples collected in 1982, 1987, 1992, 1997, and 2002, issues such as half-life estimation and first-order pharmacokinetic assumptions are being investigated.

7.2.2.1 Prior Knowledge Regarding Dioxin Elimination

Pharmacokinetic studies of dioxin elimination have been conducted based on repeated dioxin measurements in a subset of 343 Ranch Hand veterans. The term “elimination” denotes the overall removal of dioxin from the body. Section 7.2.2.1 presents analytic strategies based on assumptions and statistical models conceived after the first Ranch Hand pharmacokinetic study performed in 1996 and subsequently updated in 1999 (7). Available data have suggested that the dioxin elimination process is approximately first-order, based on measurements subsequent to the ingestion of dioxin by an individual (8). Data on 213 Ranch Hand veterans with dioxin measured in blood collected in 1982, 1987, 1992, and 1997 produced a half-life estimate of 7.6 years (7); this estimate was used in all calculations involving half-life. Pharmacokinetic studies (7) were restricted to 343 Ranch Hand veterans with 1987 dioxin greater than 10 ppt because it was thought this value represented an upper threshold for background exposure (as evidenced by the fact that 10 ppt was the 98th percentile of the Comparison dioxin distribution) and that the first-order elimination model did not hold at background levels. Subsequent analyses of dioxin elimination in Comparisons, however, have challenged this assumption (9). Nevertheless, 10 ppt has been interpreted as a threshold below which the first-order model does not hold. A Ranch Hand with dioxin less than 10 ppt may have been exposed to dioxin in Vietnam and his body burden decreased to a value less than 10 ppt since his service in Vietnam, or he may not have experienced increased dioxin exposure in Vietnam. Current data is not sufficient to resolve these two possibilities. Hence, the “Background” dioxin exposure category in Model 3 is probably comprised of a mix of individuals, some who experienced dioxin exposure in Vietnam and currently have a value less than 10 ppt and some who did not receive any appreciable dioxin exposure in Vietnam.

Analyses in this report based on Models 2 and 3 have assumed that the amount of dioxin in the body (C) decreases exponentially with time according to the statistical model $C = I \cdot \exp(-rt)$, where I is the initial level, $r = \log(2)/h$ is the elimination rate, h is the half-life, and t is the number of years from the end of the veteran’s last qualifying tour of duty in Southeast Asia (SEA) to the time of the blood collection for

dioxin. If a participant had measurements at more than one point in time, the measurement closest to the time of duty in SEA was used. This exponential elimination law is termed “first-order elimination.”

The first-order elimination assumption is equivalent to assuming a one-compartment model for dioxin distribution within the body. While a multicompartment model incorporating body composition and dioxin binding to tissue receptors would provide a detailed description of dioxin concentrations in different compartments, published multicompartment models for dioxin distribution within the body predict first-order elimination of dioxin, overwhelmingly because of fecal elimination (10).

The lipid-weight concentration of 1987 dioxin, expressed in ppt (11, 12), is a derived quantity calculated from the formula $W_{ppt} = W_{ppq} \cdot 102.6 / W_{lipid}$, where W_{ppt} is the lipid-weight 1987 concentration, W_{ppq} (weight in parts per quadrillion) is the actual whole weight of dioxin in the sample in femtograms, 102.6 corrects for the average density of serum, and W_{lipid} is the total lipid weight of the sample (10).

The relation between the serum lipid-weight concentration of dioxin and lipid-weight concentrations in adipose tissue is a subject of continuing research. The correlation between the serum lipid-weight concentration and adipose tissue lipid-weight concentration of dioxin has been observed by Patterson et al. to be 0.98 in 50 persons from Missouri (13). Using the same data, Patterson et al. calculated the partitioning ratio of dioxin between adipose tissue and serum on a lipid-weight basis as 1.09 (95% confidence interval: [0.97,1.21]). On the basis of these data, a one-to-one partitioning ratio of dioxin between lipids in adipose tissue and the lipids in serum could not be excluded. Measurements of dioxin in adipose tissue generally have been accepted as representing the body burden concentration of dioxin. The high correlation between serum dioxin levels and adipose tissue dioxin levels in the Patterson et al. study suggests that serum dioxin is also a valid measurement of dioxin body burden.

The 1987 dioxin is considered a proxy exposure metric for exposures to dioxin-contaminated phenoxy herbicides (such as Agent Orange) because direct measures of exposure to these herbicides were not available. The elimination rate of dioxin is known to vary across individuals due to obesity and, perhaps, other unmeasured factors (7). Among Ranch Hand veterans with multiple repeated dioxin measurements, the dioxin elimination rate was inversely related to body fat; heavier individuals had a smaller elimination rate and a longer dioxin half-life than lean individuals (7). A statistical model relating dioxin elimination and body fat was not available at this writing. To account for the variation in the dioxin elimination rate with body fat, all statistical analyses based on Models 2 and 3 were adjusted for the body mass index at the time of the blood measurement of dioxin. The adequacy of this adjustment is not known.

7.2.2.2 *Model 2: Health Versus Initial Dioxin in Ranch Hands*

The relation between the estimated dioxin level at the time of exposure, termed “initial dioxin,” and health was assessed in Ranch Hands using the statistical model described in Table 7-2. Statistical analyses based on this model were termed “Model 2” in the assessment of the clinical areas. In this statistical model, an initial dioxin level was estimated for a Ranch Hand from a 1987 lipid-adjusted dioxin measure, the length of time between the end of the veteran’s last qualifying tour of duty in SEA and the date of the blood collection for the dioxin measurement, and an estimated half-life of 7.6 years. Model 2 is the same model that was used for the 1997 follow-up examination report (5), except that a dioxin half-life of 8.7 years was used for that report. From studies conducted by the Air Force, body mass index at the time of the blood measurement of dioxin appeared to be related to the dioxin half-life for a participant (7). Hence, a body mass index measure was included in this statistical model as a covariate. The adequacy of this adjustment is unknown. Model 2 differs from Model 1 in that the estimate of exposure in Model 1 (group: Ranch Hand, Comparison) was not dependent on extrapolation to an earlier date.

Table 7-2 describes Model 2 and also includes assumptions, advantages, and disadvantages of this model for a continuously distributed health variable, y . The statistical model presented in Table 7-2 is unadjusted for any additional risk factors, but extension to an adjusted model is straightforward.

Table 7-2. Model 2: Assessing Health Versus Initial Dioxin in Ranch Hands: Assumptions, Advantages, and Disadvantages

Model 2: $y = b_0 + b_1 \log_2(I) + b_2 \text{BMI} + e$	
where	
	y = health variable b_0 = intercept of the y-axis in the statistical model b_1, b_2 = slope parameters in the statistical model, corresponding to the variables $\log_2(I)$ and BMI, respectively I = extrapolated initial dose, assuming first-order elimination, $I = 4 + (C - 4) \cdot \exp(\log(2) \cdot t/h)$, where 4 ppt is considered the median background level of lipid-adjusted dioxin; t = length of time between the time of duty in SEA and the date of the blood measurement of dioxin in 1987, 1992, 1997, or 2002; C = lipid-adjusted dioxin, determined in 1987, 1992, 1997, or 2002; and h = dioxin half-life in Ranch Hands assuming first-order elimination (7.6 years assumed for analysis) BMI = body mass index at the time of the blood measurement of dioxin, calculated as $\text{weight}/(\text{height})^2$ (14), where the weight is measured in kilograms and the height is measured in meters e = zero mean error.
Assumptions:	Ranch Hands received a single dioxin dose in Vietnam and background exposure thereafter. Ranch Hands experienced first-order dioxin elimination. The error variance does not change with health status or initial dioxin dose.
Advantages:	Easily interpretable. Uses the estimated initial dioxin dose, based on the 1987 value and a first-order model. Most efficient if first-order elimination and half-life are valid and y is linearly related to $\log_2(I)$. The logarithm (base 2) of initial dioxin presents the dioxin data as a more symmetric distribution than the distribution of initial dioxin in its original units. In addition, the relative risk based on the logarithm (base 2) of initial dioxin is more meaningful than on the original scale (i.e., a doubling of initial dioxin rather than a 1 ppt increase in dioxin).
Disadvantages:	Results are biased if first-order elimination or constant half-life assumptions are not valid.

The assumption that Ranch Hands received a single dioxin dose in Vietnam and background exposure thereafter is a simplification of an unknown and most likely complex exposure scenario. The assumption that Ranch Hands experienced first-order dioxin elimination is an approximation. A combined pharmacokinetic analysis of dioxin elimination in Ranch Hands and victims of the Seveso industrial accident (15) suggests that dioxin elimination is not first order and follows an approximate biphasic model, with fast elimination soon after (acute) exposure followed by slower elimination. The first-order model used in this study does not account for biphasic elimination. The same data (15), however, does

suggest that the first-order estimate of the initial dose is at least reasonable. Other more complicated nonlinear physiologically based pharmacokinetic models involving dose-dependence, body mass index, changes in body mass index and age are under development but were not ready for application in this report (16). Current data suggest that the dioxin elimination rate varies inversely with body mass index; heavier individuals have a smaller elimination rate and increased half-life relative to leaner individuals. Account of the dependence of the elimination rate on body mass index was made by adjusting all Model 2 and Model 3 analyses for the body mass index at the time of the blood measurement of dioxin. The adequacy of this adjustment is unknown.

Model 2 analyses were performed on Ranch Hands who had lipid-adjusted dioxin levels greater than 10 ppt at either the 1987, 1992, 1997, or 2002 physical examinations. The value 10 ppt corresponds to the approximate 98th percentile of the Comparison lipid-adjusted dioxin distribution. Based on this Comparison dioxin distribution, it was believed that participants with greater than 10 ppt lipid-adjusted dioxin were definitely exposed. It was not known whether Ranch Hands with dioxin burdens at or below 10 ppt were exposed and their body burdens had decreased to these levels since their time of duty in SEA, or whether they were not exposed at all during their time of duty in SEA. Lipid-adjusted dioxin levels less than 10 ppt were subsequently called “background” levels.

7.2.2.3 *Model 3: Health Versus Dioxin in Ranch Hands and Comparisons*

An assessment of the health consequences of dioxin above background levels was carried out with a statistical model that was applied to both Ranch Hand and Comparison data. This model assessed health versus dioxin body burden categorized into four levels, given below:

- Comparisons—All Comparisons, regardless of lipid-adjusted dioxin level
- Background—Ranch Hands with up to 10 ppt lipid-adjusted dioxin
- Low—Ranch Hands with more than 10 ppt lipid-adjusted dioxin but at most 118 ppt estimated initial dioxin
- High—Ranch Hands with more than 10 ppt lipid-adjusted dioxin and more than 118 ppt estimated initial dioxin.

Statistical analyses based on this model were termed “Model 3” in the assessment of the clinical outcomes. The cutpoint for the low and high Ranch Hand categories, of approximately equal size, was the median estimated initial dioxin level (118 ppt) of the Ranch Hands with more than 10 ppt lipid-adjusted dioxin. Note that the subset of Ranch Hands in the low and high dioxin categories combined is the same subset of Ranch Hands that are used in Model 2. The value of 118 ppt was revised from the value used for the 1997 follow-up examination (94 ppt) based on the updated 7.6-year half-life estimate and the cohort undergoing physical examinations for the 2002 physical examination. In this statistical model, an initial dioxin level (the same one used in Model 2) was estimated for a Ranch Hand from a 1987 lipid-weight dioxin measure, the length of time between the time of duty in SEA and the date of the blood collection for the dioxin measurement, and an estimated half-life of 7.6 years. From studies conducted by the Air Force, body mass index at the time of the blood measurement of dioxin appeared to be related to the dioxin half-life for a participant (7). Hence, a body mass index measure was included in this statistical model as a covariate. Using this body mass index in Model 3 for all Comparisons and Ranch Hands with dioxin measurements allowed body mass index to act as a potential risk factor and as an adjusting variable to explain half-life differences. The adequacy of this adjustment is unknown. It is

also unknown whether there were any individuals in the Background category who had an initial dioxin dose greater than 10 ppt and should have in fact been classified to the low or high dioxin category.

For a continuously distributed health variable, y , for example, the mean values of y within the background, low, high, and the low and high categories combined were contrasted with the mean values of y within the Comparison category. For a continuously distributed variable, the mean value of y for the low and high categories combined was calculated as a weighted average of the low dioxin and the high dioxin category means, with weights based on the sample size in each of these categories. For a discrete variable, the percentage of abnormal values for the low and high categories combined was calculated as a weighted average of the percentage abnormal in the low dioxin and the high dioxin categories, with weights based on the sample size in each of these categories. Table 7-3 shows this statistical model and the assumptions, advantages, and disadvantages for the unadjusted analysis of a continuous variable; extension to an adjusted model is straightforward. It should be noted that this statistical model is considered the “full model” in statistical terms and the coefficients b_0 , b_1 , b_2 , b_3 , and b_4 are not estimable. Reparameterization must be performed to estimate a linear combination of these coefficients.

Table 7-3. Model 3: Assessing Health Versus Categorized Dioxin in Ranch Hands and Comparisons: Assumptions, Advantages, and Disadvantages

Model 3: $y = b_0 + b_1I_1 + b_2I_2 + b_3I_3 + b_4I_4 + b_5BMI + e$	
where	
	y = health variable
	b_0 = intercept of the y-axis in the statistical model
b_1, b_2, b_3, b_4, b_5	= slope parameters in the statistical model, corresponding to the variables I_1, I_2, I_3, I_4 , and BMI, respectively
I_1	= indicator variable for categorized dioxin; $I_1 = 1$ if participant is a Comparison, $I_1 = 0$ if participant is not a Comparison
I_2	= indicator variable for categorized dioxin; $I_2 = 1$ if participant is in background dioxin category, $I_2 = 0$ if participant is not in background dioxin category
I_3	= indicator variable for categorized dioxin; $I_3 = 1$ if participant is in low dioxin category, $I_3 = 0$ if participant is not in low dioxin category
I_4	= indicator variable for categorized dioxin; $I_4 = 1$ if participant is in high dioxin category, $I_4 = 0$ if participant is not in high dioxin category
BMI	= body mass index at the time of the blood measurement of dioxin, calculated as $\text{weight}/(\text{height})^2$ (14), where the weight is measured in kilograms and the height is measured in meters
e	= zero mean error.
Assumptions:	Dioxin body burden is eliminated following a first-order model.
	The error variance does not change with categorized dioxin body burden.
Advantages:	Initial dioxin is probably a better measure for determining low and high exposure than current or recent lipid-adjusted dioxin measurements.
	Less dependent on the accuracy of the estimation algorithm for determining initial dioxin than Model 2.

Table 7-3. Model 3: Assessing Health Versus Categorized Dioxin in Ranch Hands and Comparisons (Continued)

Disadvantages:	Makes no use of prior belief that some Ranch Hands received an unusually large dioxin dose in Vietnam; all Ranch Hands with high dioxin levels are treated similarly.
	“Background” Ranch Hand category is probably a mixture of exposed and unexposed Ranch Hands. Analysis may be biased toward the null hypothesis of no dioxin effect.
	“Low” and “high” Ranch Hand categories are based on the initial dioxin model, which is based on valid half-life and first-order dioxin elimination. Bias is possible if model is incorrect. Also, a conditional null hypothesis is tested using these categories (“Is there a dioxin effect, given a specified level of exposure?”).

An assumption of Model 3 is that dioxin is eliminated following a first-order model. As in Model 2, the adequacy of the first-order model can be questioned. The use of a common elimination rate to determine the cutpoint separating the low and high dioxin categories may induce misclassification because current data suggests that the rate is not constant and varies inversely with body mass index. The body mass index at the time of the blood measurement of dioxin was included in Models 2 and 3 to account for this variation, but the adequacy of this adjustment is unknown. Model 3 loses statistical power by collapsing the continuously distributed dioxin measure to a discrete measure.

A disadvantage of Model 3 is that it fails to give sufficient weight to Ranch Hands with very high doses. Another disadvantage of Model 3 is that the contrast between the Background category and Comparisons is not directly interpretable because the exposure status of individuals in the Background category is unknown. This fact was highlighted in the 1987 report by naming this category the “Unknown” category. Since 1992, the category has been named the “Background” category to simply reflect the dioxin cutpoint of 10 ppt. Another disadvantage is that some Comparisons were employed by U.S. industries, received substantial dioxin doses, are experiencing first-order elimination, and have dioxin pharmacokinetics and associations between dioxin and health.

7.2.2.4 Model 4: Health Versus 1987 Dioxin in Ranch Hands

The relation between 1987 dioxin and health was assessed using the statistical model described in Table 7-4. This measure of dioxin is termed “1987 dioxin” because most Ranch Hands were assayed for dioxin initially at the 1987 follow-up examination. This table also describes the assumptions, advantages, and disadvantages for the unadjusted analysis of a continuously distributed health variable, y .

Ranch Hands with a dioxin measurement may have had their blood collected at the pilot study in April 1987, at the 1987 physical examination, at the 1992 physical examination, at the 1997 physical examination, or at the 2002 physical examination. If an individual had measurements at more than one of these points in time, the measurement closest to the time of duty in SEA was used. If only a 1992 serum dioxin measurement was available, the level was extrapolated to the date of the 1987 physical examination. The model

$$C_{1987} = 4 + (C_{1992} - 4) \cdot \exp(rt)$$

was used for extrapolation of lipid-adjusted dioxin to 1987 levels (C_{1987}), where C_{1992} is the lipid-adjusted dioxin level in 1992, 4 ppt is considered the median background level for lipid-adjusted dioxin, $r = \log(2)/h$ is the elimination rate, h is the estimated half-life (7.6 years) of dioxin, and t is the length of time between the physical examination in 1987 and the physical examination in 1992. This model was

used only if the lipid-adjusted dioxin level in 1992 was greater than 10 ppt; otherwise, the 1992 measurement was used. A similar strategy was used for participants who had only a 1997 or a 2002 serum dioxin measurement.

The estimate of exposure in Model 4 (1987 dioxin) was based on extrapolation to the date of the 1987 physical examination for only a small percentage (3.5%) of Ranch Hands. Most measurements were based on 1987 dioxin measurements and extrapolation to 1987 levels was not needed for these measurements. Therefore, few of the 1987 dioxin values were estimated using the half-life of dioxin, which is dependent on the body mass index of the participant. Consequently, body mass index at the time of the blood measurement of dioxin was not used as a covariate in Model 4, which was different from the strategy used for Models 2 and 3.

1987 dioxin results below the limit of detection were calculated as the limit of detection divided by the square root of 2 (17). Dioxin results below the limit of quantitation were calculated as the limit of quantitation divided by the square root of 2 (17).

The relation between current health and dioxin was assessed using a statistical model, termed “Model 4,” with lipid-adjusted 1987 dioxin as the estimate of exposure. Model 4 used the logarithm (base 2) of lipid-adjusted 1987 dioxin, as described in Table 7-4.

Table 7-4. Model 4: Assessing Health Versus 1987 Dioxin in Ranch Hands: Assumptions, Advantages, and Disadvantages

Model 4: $y = b_0 + b_1 \log_2(W_{ppt}) + e$	
where	
	y = health variable
	b_0 = intercept of the y-axis in the statistical model
	b_1 = slope parameter in the statistical model, corresponding to the variable $\log_2(W_{ppt})$
	W_{ppt} = lipid-adjusted 1987 dioxin = $W_{ppq} \cdot 102.6 / W_{lipid}$, where W_{ppq} = whole weight of 1987 dioxin in the sample in femtograms (102.6 corrects for the average density of serum) and W_{lipid} = total lipid weight of the sample
	e = zero mean error.
Assumptions:	Ranch Hands received a single dioxin dose in Vietnam and background exposure thereafter.
	The error variance does not change with health status or 1987 dioxin.
Advantages:	Uses the dioxin measurement.
	The logarithm (base 2) of (1987 dioxin) presents the dioxin data as a more symmetric distribution than the distribution of 1987 dioxin in its original units. In addition, the relative risk based on the logarithm (base 2) of (1987 dioxin) is more meaningful than on the original scale (i.e., a doubling of 1987 dioxin, rather than a 1 ppt increase in dioxin).
Disadvantages:	1987 dioxin may not be a good surrogate for exposure if elimination rate differs among individuals.
	Individuals with measurements in 1992 only or 1997 only or 2002 only are extrapolated to 1987, and variation is increased with estimation using a first-order elimination model.

As in the other statistical models, the assumption that Ranch Hands received a single dioxin dose in Vietnam is a simplification of a complex and unknown exposure scenario.

The advantage that Model 4 uses the dioxin measurement is counterbalanced by the disadvantage that dioxin measure may not reflect the initial dose received by Ranch Hand veterans in Vietnam because the elimination rate appears to vary with body fat.

7.3 ANALYSIS METHODOLOGIES

7.3.1 Methods for Analyzing Continuous and Discrete Variables

For analyses of continuous dependent variables, the general linear models approach was used for applying such techniques as simple and multiple linear regression, analysis of variance, and analysis of covariance. This approach permitted model fitting of the dependent variable as a function of group or dioxin and specified covariates. Continuous dependent variables were examined to ensure that assumptions underlying appropriate statistical methods were met. Transformations (e.g., square root, logarithmic) were used to enhance normality for specific continuous health variables. A further discussion of general linear models and other methods used for the statistical analyses in this report are presented in Table 7-5.

For these continuous analyses, the SAS^{®1} general linear models analysis (PROC GLM) (18) was used. After a statistical model was fitted, tests of significance for a group or dioxin effect were developed. Associations with a p-value less than or equal to 0.05 were described as significant.

The SAS[®] procedures PHREG and LIFETEST (18) were used for the time to diabetes onset variable in the endocrinology clinical assessment (see Sections 18.2.2.1.6 and 18.2.2.1.7 in Chapter 18, Endocrinology Assessment). Statistical methods used to analyze measures of this type can be implemented using a proportional hazards model (19). Table 7-5 presents a further discussion of the proportional hazards model.

For dichotomous discrete dependent variables, logistic regression was performed using SAS[®] PROC GENMOD (18). For dependent variables with more than two categories, polytomous logistic regression was performed using SAS[®] PROC CATMOD (18). Parameter estimation and model selection for polytomous logistic regression and ordinary logistic regression are similar. Both forms of regression use the maximum likelihood principle to obtain parameter estimates. For a model with k parameters for two equations, 2k parameters are estimated, k for each logit function. If ordinary logistic regression is applied twice (e.g., once for abnormal low versus normal and then for abnormal high versus normal), 2k parameters are estimated; however, ordinary logistic regression maximizes two likelihood equations, each with k parameters, while polytomous logistic regression estimates all 2k parameters simultaneously with one likelihood equation. Polytomous logistic regression also can be used for dependent variables that have more than three levels and require more than two contrasts with a normal category. A further discussion of logistic regression and polytomous logistic regression is found in Table 7-5.

A chi-square statistic, adjusted for the continuity of the chi-square distribution, was used when a test of the relative frequency of abnormal measurements between Ranch Hands and Comparisons was performed, and the relative frequency of either the Ranch Hand or the Comparison group was zero. This test statistic yields p-values approximately equal to Fisher's exact test (20) for a two-sided alternative hypothesis.

Table 7-5. Summary of Statistical Procedures

Chi-Square Contingency Table Test

The chi-square test of independence (20) is calculated for a contingency table by the following formula:

$$\chi^2 = \sum \frac{(f_O - f_E)^2}{f_E}$$

where the sum is taken over all cells of the contingency table and

f_O = observed frequency in a cell

f_E = expected frequency under the hypothesis of independence.

Large values indicate deviations from the null hypothesis and are tested for significance by comparing the calculated χ^2 to the tables of the chi-square distribution.

For 2x2 tables, the chi-square statistic above can be adjusted for the continuity of the χ^2 distribution. This test statistic yields p-values approximately equal to Fisher's exact test (20) for a two-sided alternative and is as follows:

$$\chi^2 = \sum \frac{\max(0, (|f_O - f_E| - \frac{1}{2}))^2}{f_E}.$$

Correlation Coefficient (Pearson's Product-Moment)

The population correlation coefficient ρ (21) measures the strength of the linear relation between two random variables X and Y. A commonly used sample-based estimate of this correlation coefficient is

$$\rho = \frac{\sum (x_i - \bar{x})(y_i - \bar{y})}{\sqrt{[\sum (x_i - \bar{x})^2 \sum (y_i - \bar{y})^2]}}$$

where the sum is taken over all (x, y) pairs in the sample. A student's t-test based on this estimator is used to test for a significant correlation between the two random variables of interest.

General Linear Models Analysis

The form of the general linear model (21) for two independent variables is

$$Y = \alpha + \beta_1 X_1 + \beta_2 X_2 + \varepsilon$$

where

Y = dependent variable (continuous)

α = level of Y at $X_1 = 0$ and $X_2 = 0$ (i.e., the intercept)

X_1, X_2 = measured value of the first and second independent variables, respectively, which may be continuous or discrete (e.g., group status and age)

β_1, β_2 = coefficient indicating linear association between Y and X_1 , Y and X_2 , respectively; each coefficient reflects the effect on the model of the corresponding independent variable adjusted for the effect of the other independent variable

ε = error term.

This statistical model assumes that the error terms are independent and normally distributed with a mean of 0 and a constant variance. Extension to more than two independent variables is immediate. Simple linear regression, multiple linear regression, analysis of variance, and analysis of covariance are all examples of a general linear models analysis.

Table 7-5. Summary of Statistical Procedures (Continued)

Logistic Regression Analysis	
The logistic regression model (22) enables a dichotomous dependent variable to be modeled in a regression framework with continuous and discrete independent variables. For two risk factors, such as dioxin and age, the logistic regression model is	
$\text{logit } P = \alpha + \beta_1 X_1 + \beta_2 X_2 + \varepsilon$	
where	
P	= probability of disease for an individual with risk factors X_1 and X_2
logit P	= $\ln (P/(1-P))$ (i.e., the log odds for disease)
X_1	= first risk factor (e.g., dioxin)
X_2	= second risk factor (e.g., age).
The parameters are interpreted as follows:	
α	= log odds for the disease when $X_1 = 0$ and $X_2 = 0$
β_1	= coefficient indicating the dioxin effect adjusted for age
β_2	= coefficient indicating the age effect adjusted for dioxin
ε	= error term.
For a dichotomous measure, the term $\exp(\beta_1)$ equals the adjusted odds ratio of abnormal versus normal for Ranch Hands ($X_1 = 1$) compared to Comparisons ($X_1 = 0$). If the probability of being abnormal is small compared to being normal for both the Ranch Hand and Comparison groups, the odds ratio is approximately equal to the relative risk of being abnormal between the two groups. If X_1 is a continuous covariate, $\exp(\beta_1)$ represents the adjusted odds ratio of outcome 1 versus outcome 0 for a unit increase in X_1 . If the risk factor is expressed in logarithmic (base 2) form, $\exp(\beta_1)$ reflects the adjusted odds ratio for a twofold increase in the risk factor.	
Polytomous Logistic Regression Analysis	
Polytomous logistic regression (22, 23) allows a categorical dependent variable with more than two outcomes to be modeled in a regression environment with continuous and discrete independent variables. For polytomous logistic regression, the model equation depends on the scale of the dependent variable. This discussion focuses on nominal scaled dependent variables.	
Suppose Y is a nominal scaled dependent variable with three outcomes labeled 0, 1, or 2 (normal, low, or high). Polytomous logistic regression models two logit functions, one for $Y = 1$ versus $Y = 0$ and the other for $Y = 2$ versus $Y = 0$. The zero outcome for Y is called the reference category. To model Y with two covariates such as group status and age, the polytomous regression model would be	
$\text{logit } P_1 = \alpha_1 + \beta_{1(1)} X_1 + \beta_{1(2)} X_2 + \varepsilon_1$	
$\text{logit } P_2 = \alpha_2 + \beta_{2(1)} X_1 + \beta_{2(2)} X_2 + \varepsilon_2$	
where	
P_i	= probability that $Y = i$ (outcome i) with covariates X_1 and X_2 , $i = 0, 1, 2$
logit P_i	= $\ln (P_i/P_0)$ (i.e., the log odds of outcome i versus outcome 0, $i = 1, 2$)
X_1	= first effect (e.g., group status)
X_2	= second effect (e.g., age).

Table 7-5. Summary of Statistical Procedures (Continued)

Polytomous Logistic Regression Analysis (continued)	
The parameters are interpreted as follows:	
α_i	= log odds of outcome i versus outcome 0 when $X_1 = 0$ and $X_2 = 0$, $i = 1, 2$
$\beta_{i(1)}$	= coefficient indicating the group status effect on the logit P_i , adjusted for age; $i = 1, 2$
$\beta_{i(2)}$	= coefficient indicating the age effect on the logit P_i , adjusted for group status; $i = 1, 2$
ϵ_i	= error term for logit P_i , $i = 1, 2$.
This model assumes independent multinomial sampling.	
Because the interpretation of each logistic modeling function is similar, consider the logit P_1 and suppose X_1 is a binary covariate ($X_1 = 1$ for Ranch Hands or $X_1 = 0$ for Comparisons). The term $\exp(\beta_{1(1)})$ equals the adjusted odds ratio of low versus normal for Ranch Hands ($X_1 = 1$) compared to Comparisons ($X_1 = 0$). If the probability of being low is small compared to being normal for both the Ranch Hand and Comparison groups, the odds ratio of low versus normal is approximately equal to the relative risk of being low between the two groups. If X_1 is a continuous covariate, $\exp(\beta_{1(1)})$ represents the adjusted odds ratio of outcome 1 versus outcome 0 for a unit increase in X_1 .	
Proportional Hazards Model	
The Cox proportional hazards model (19) permits regression analysis of censored survival data and explains the effect of explanatory variables, or risk factors, on survival times. A proportional hazards model allows a nonconstant hazard rate, $h(t)$ (e.g., rate at which diabetes is developed, which can vary with time), to be modeled as a function of either discrete or continuous risk factors. The proportional hazards model makes the assumption that the hazard functions in the cohorts of interest remain proportional to each other across time, and so the ratio of the hazard function in the groups is independent of time. The natural logarithm of the ratio of the hazard functions can be expressed as a linear combination of the risk factors.	
Using the example of time to diabetes onset, for those participants who have developed diabetes, time to onset is defined as the time from the end of the participant's last qualifying tour to the date of diagnosis of diabetes. This time is known as the event time. If a participant has not developed diabetes, the time from the end of the participant's last qualifying tour to the date of the 2002 physical examination is known as the censoring time. The proportional hazards model accounts for both event times and censoring times to calculate the hazard ratio.	
The parameters of the proportional hazards model can be estimated by partial likelihood methodology (24). These computations are performed using SAS [®] PROC PHREG (18), which accounts for censored survival times. PROC PHREG provides estimates, standard errors, and p-values from a chi-squared test on the parameter associated with each risk factor in the model. These statistics are used to test the significance of group (Model 1) or estimates of dioxin exposure (Models 2, 3, and 4) in the unadjusted and adjusted models.	
For the example of time to diabetes onset, the summary statistic provided in this report is the 10 th percentile of the hazard function. Because approximately 20 percent of the participants at the 2002 follow-up examination are diabetic, the 10 th percentile is being used in this report to represent an estimate of the approximate median time to diabetes onset. Percentile estimates can be made for different cohorts, such as group, as given in Table 18-9(a) (Ranch Hand, Comparison), or a covariate such as race (Black, non-Black), as given in Appendix Table F-10. This observed time represents an estimate of the number of years that have elapsed since the end of the last qualifying tour until 10 percent of participants in the cohort of interest were diagnosed as diabetic.	

Table 7-5. Summary of Statistical Procedures (Continued)

Proportional Hazards Model (continued)	
In general, for the time to onset of a condition, the p^{th} percentile is defined by the time period t such that p percent of the observations in the data have been diagnosed with the condition on or before the time period t . That is, for a random variable T , $P(T \leq t) = 0.10$. The 10 th percentile of time to onset of diabetes was estimated using the SAS [®] procedure PROC LIFETEST (18). PROC LIFETEST computes nonparametric estimates of the survivor function via the Kaplan-Meier product-limit estimation procedure (25), where the survivor function is the probability that a participant has not developed diabetes by time t .	

7.4 FACTORS DETERMINING THE STATISTICAL ANALYSIS METHOD

For a specified questionnaire-based or clinical measurement determined from the physical or laboratory examination, the selection of an analytical method depended on each of the following:

- Dependent Variable Form: Continuous or discrete
- Exposure Estimate and Analysis Cohort:
 - Model 1: Group—All Ranch Hands and Comparisons
 - Model 2: Initial dioxin—Ranch Hands having a dioxin body burden of greater than 10 ppt of lipid-adjusted dioxin, based on 1987 dioxin levels as defined in Section 7.2.2.4
 - Model 3: Categorized dioxin—Comparisons and all Ranch Hands with a lipid-adjusted dioxin measurement
 - Model 4: 1987 dioxin—All Ranch Hands with a lipid-adjusted dioxin measurement
- Analysis Type: Unadjusted or adjusted.

Table 7-6 specifies 16 separate analysis types based on dependent variable form, exposure estimate, analysis cohort, and analysis type. For each of the 16 types, the statistical method is specified. For example, linear regression models were used for adjusted analyses of initial dioxin for continuous dependent variables.

Table 7-6. Summary of Statistical Analysis Situations by Dependent Variable Form, Exposure Estimate, Analysis Cohort, and Analysis Type

Exposure Estimate	Analysis Cohort	Analysis Type	Statistical Methods	Independent Variables
Continuous				
Model 1: Group (Ranch Hands vs. Comparisons)	All Ranch Hands and Comparisons	Unadjusted	Analysis of Variance	Group
		Adjusted	Analysis of Covariance	Group; Covariates

Table 7-6. Summary of Statistical Analysis Situations by Dependent Variable Form, Exposure Estimate, Analysis Cohort, and Analysis Type (Continued)

Exposure Estimate	Analysis Cohort	Analysis Type	Statistical Methods	Independent Variables
Model 2: Log ₂ (Initial Dioxin)	Ranch Hands >10 ppt lipid-adjusted 1987 dioxin	Unadjusted	Linear Regression	Log ₂ (Initial Dioxin); Body Mass Index at the Time of the Blood Measurement of Dioxin
		Adjusted	Linear Regression	Log ₂ (Initial Dioxin); Body Mass Index at the Time of the Blood Measurement of Dioxin; Covariates
Model 3: Categorized Dioxin	All Ranch Hands with a lipid-adjusted dioxin measurement, all Comparisons	Unadjusted	Analysis of Covariance	DXCAT; Body Mass Index at the Time of the Blood Measurement of Dioxin
		Adjusted	Analysis of Covariance	DXCAT; Body Mass Index at the Time of the Blood Measurement of Dioxin; Covariates
Model 4: Log ₂ (1987 Dioxin)	All Ranch Hands with a lipid-adjusted dioxin measurement	Unadjusted	Linear Regression	Log ₂ (1987 Dioxin)
		Adjusted	Linear Regression	Log ₂ (1987 Dioxin); Covariates
Discrete				
Model 1: Group (Ranch Hands vs. Comparisons)	All Ranch Hands and Comparisons	Unadjusted	Chi-Square Contingency Table, Logistic Regression	Group
		Adjusted	Logistic Regression	Group; Covariates
Model 2: Log ₂ (Initial Dioxin)	Ranch Hands >10 ppt lipid-adjusted 1987 dioxin	Unadjusted	Logistic Regression	Log ₂ (Initial Dioxin); Body Mass Index at the Time of the Blood Measurement of Dioxin
		Adjusted	Logistic Regression	Log ₂ (Initial Dioxin); Body Mass Index at the Time of the Blood Measurement of Dioxin; Covariates
Model 3: Categorized Dioxin	All Ranch Hands with a lipid-adjusted dioxin measurement, all Comparisons	Unadjusted	Chi-Square Contingency Table; Logistic Regression	DXCAT; Body Mass Index at the Time of the Blood Measurement of Dioxin
		Adjusted	Logistic Regression	DXCAT; Body Mass Index at the Time of the Blood Measurement of Dioxin; Covariates
Model 4: Log ₂ (1987 Dioxin)	All Ranch Hands with a lipid-adjusted dioxin measurement	Unadjusted	Logistic Regression	Log ₂ (1987 Dioxin)
		Adjusted	Logistic Regression	Log ₂ (1987 Dioxin); Covariates

Note: Log₂ (Initial Dioxin) = Logarithm (base 2) of estimated initial dioxin level.

DXCAT = Categorized dioxin (incorporating group membership—three categories for Ranch Hands, one category for Comparisons).

Log₂ (1987 Dioxin) = Logarithm (base 2) of 1987 dioxin level.

7.4.1 Modeling Strategy

In general, based on one of the adjusted analysis statistical models described in Table 7-6, a model for dependent variables was based on the exposure effect (group or dioxin) and medically relevant covariates, as identified in Chapters 9 through 20 for each clinical category. As described previously, body mass index at the time of the blood measurement of dioxin was included in Models 2 and 3 as a covariate because these statistical models depended on the estimated initial dioxin and the estimate appears to vary with body fat. The adequacy of the adjustment for the body mass index is unknown.

The general modeling strategy did not remove any covariates from the model; however, the modeling strategy for the adjusted analysis of dependent variables in certain clinical areas was modified as necessary because of the large number of covariates or sparse number of participants with abnormal measurements. Stepwise elimination of covariates was conducted to allow for proper estimation of model parameters. When this strategy of removing covariates was necessary, the covariates removed from (or retained in) a model for a given health endpoint and statistical model were specified in footnotes to the tables in Chapters 9 through 20.

For Chapter 12, Psychology Assessment, 55 participants did not provide information for current total household income. Most of these participants refused to answer this question. For Chapter 15, Cardiovascular Assessment, 52 participants did not provide information for family history of heart disease before age 45. Most of these participants did not know the answer to this question. In an attempt not to exclude a substantial number of participants in these two chapters, a limited version of a stepwise procedure was used. If current total household income or family history of heart disease before age 45 was not significant ($p > 0.05$) in Chapters 12 and 15, respectively, for the adjusted analysis of a dependent variable for a particular model, the covariate was excluded from the analysis. Excluding current total household income and family history of heart disease from the statistical model, where appropriate, allowed the participants who did not provide information for these variables to be included in the analysis of the model and thus increased the sample size. The parameters of the statistical model were then re-estimated; the statistics from the re-estimated models were shown in the chapter tables. A footnote to the table specifies when current total household income or family history of heart disease before age 45 was deleted as a covariate.

7.5 STUDY LIMITATIONS, STRENGTHS, AND STATISTICAL POWER

This study was limited by the sample size (preventing the study of rare diseases), imperfect exposure metrics, and the possible existence of other confounding factors that we have not measured. Study strengths included complete record verification of all statistically analyzed health conditions, rigorous quality control, good compliance, complete population ascertainment, many years of follow-up, and adjustment for many known confounding factors.

Although many covariates were considered in this report, there are others that may be unknown and some that were measured but not used in this report. Some of the analyses in this report, therefore, may be biased due to lack of adjustment for an important confounding covariate. Recent studies of cancer in Ranch Hand veterans indicate that the calendar period and length of service in the Ranch Hand unit is an important covariate, for example, but this fact was discovered after the analytical plan for this report was already in place.

The study benefited from a two-tiered management structure based on separate but parallel program management and technical teams, an independently appointed and administered Advisory Committee, periodic review by the Institute of Medicine, and collaboration through interagency agreements between the Air Force and the Centers for Disease Control making the dioxin measurements possible. The

management structure, oversight, carefully managed funding and contracting and outstanding contractors all contributed to uniformly rigorous quality assurance, attention to detail, and timely task completion.

7.5.1 Power

A type I error is making a false conclusion that an association (group or dioxin effect) exists when there is no association. The other possible inference error, a type II error, is the failure to detect an association when one actually exists. The power of a statistical test is 1 minus the probability of a type II error. The power of the test is the probability that the test will reject the hypothesis of no group or dioxin effect when an effect does in fact exist.

The fixed size of the Ranch Hand cohort limits the ability of this study to detect some group or dioxin associations if they exist. This limitation is most obvious for specific types of cancer, such as soft tissue sarcoma and non-Hodgkin's lymphoma. These conditions are so uncommon that fewer than two cases were expected in this study, indicating that there is virtually no statistical power to detect low-to-moderate associations between dioxin and cancer. In an attempt to overcome the lack of power to detect group differences for specific types of systemic cancer, for example, all types of systemic cancer were combined into a single variable. It is still possible, however, that an increased risk could exist for a particularly rare type of cancer, allowing that increased risk to be missed in this study.

Table 7-7 and Appendix Tables E-1 through E-3 contain the approximate power at a significance level of 0.05 to detect specified relative risks for a given prevalence rate of a discrete dependent variable. Table 7-7 presents power calculations for Model 1 (group) and Appendix Tables E-1 through E-3 present power calculations for Model 2 (initial dioxin), Model 3 (categorized dioxin—low and high Ranch Hand dioxin categories combined versus Comparison contrast), and Model 4 (lipid-adjusted 1987 dioxin). Power calculations were performed using the logarithm (base 2) of dioxin in Models 2 and 4. Consequently, the relative risk is for a twofold increase in dioxin in Models 2 and 4. The power of a test for a discrete variable depends on the significance level, actual relative risk, prevalence of the condition, and the Ranch Hand and Comparison sample sizes (for Models 1 and 3) or the distribution of the dioxin data (for Models 2 and 4). As an example, Table 7-7 shows a power of 0.20 to detect a relative risk of 2.0 for a disease with a prevalence of 0.005. For a disease with a prevalence of 0.05, the power to detect a relative risk of 1.5 would be 0.50.

Table 7-7. Approximate Power to Detect a Group Effect at a 5-Percent Level of Significance (Discrete Dependent Variable)

Prevalence of Condition	Relative Risk								
	1.10	1.20	1.30	1.40	1.50	1.75	2.00	10.00	20.00
0.005	0.05	0.06	0.07	0.08	0.10	0.14	0.20	0.91	0.97
0.01	0.05	0.07	0.09	0.12	0.15	0.24	0.34	1.00	1.00
0.02	0.06	0.09	0.13	0.18	0.24	0.42	0.59	1.00	1.00
0.03	0.06	0.10	0.17	0.25	0.34	0.57	0.76	1.00	1.00
0.04	0.07	0.12	0.21	0.31	0.42	0.69	0.86	1.00	1.00
0.05	0.07	0.14	0.24	0.37	0.50	0.78	0.92	1.00	1.00
0.10	0.10	0.22	0.41	0.61	0.77	0.96	1.00	1.00	1.00
0.15	0.11	0.30	0.54	0.75	0.89	0.99	1.00	1.00	1.00
0.20	0.13	0.36	0.63	0.84	0.95	1.00	1.00	1.00	1.00

Table 7-8 and Appendix Tables E-4 through E-6 provide the same information on power as Table 7-7 and Appendix Tables E-1 through E-3 for a continuous dependent variable at a significance level of 0.05. The power calculations are defined in terms of the coefficient of variation (100 times the standard deviation of the dependent variable divided by the mean of the dependent variable) and the proportion mean change. The coefficient of variation relates the spread of the data relative to the magnitude of the data. In general, the power of a test is greater when the coefficient of variation is smaller. Table 7-8 presents power calculations for Model 1 (group) and Appendix Tables E-4 through E-6 present power calculations for Model 2 (initial dioxin), Model 3 (categorized dioxin—low and high Ranch Hand dioxin categories combined versus Comparison contrast), and Model 4 (lipid-adjusted 1987 dioxin). Power calculations were performed using the logarithm (base 2) of dioxin in Models 2 and 4. Consequently, the relative risk is for a twofold increase in dioxin. The power of a test for a continuous variable depends on the significance level, actual difference in the true dependent variable means or slope of the dioxin coefficient, variation in the dependent variable data, sample size, and the distribution of the dioxin data if dioxin is the exposure estimate.

The proportion mean change in Table 7-8 and Appendix Table E-5 is defined as the difference in the true Ranch Hand and Comparison means, relative to the combined average of the two groups, assuming no transformation of the dependent variable. The proportion mean change in Appendix Tables E-4 and E-6 is defined as the change in the expected value (mean) of the dependent variable for a twofold increase in initial dioxin, relative to the dependent variable mean. The proportion mean change in Appendix Tables E-4 and E-6 corresponds mathematically to the slope of initial or 1987 dioxin divided by the dependent variable mean, assuming no transformation of the dependent variable. Analogous quantities can be derived based on transformed statistics. As an example, white blood cell (WBC) count (on the natural logarithm scale) for all participants has a coefficient of variation of approximately 15 percent. With this coefficient of variation, for the 777 Ranch Hands and 1,174 Comparisons in Model 1, the power is approximately 0.82 for detecting a 2-percent increase in the mean WBC count of Ranch Hands relative to the mean WBC count of Comparisons (mean change = 0.02).

Table 7-8. Approximate Power to Detect a Group Effect at a 5-Percent Level of Significance (Continuous Dependent Variable)

Mean Change	Coefficient of Variation ($100\sigma/\mu$)					
	5	10	15	25	50	75
0.005	0.58	0.19	0.11	0.07	0.06	0.05
0.01	0.99	0.58	0.30	0.14	0.07	0.06
0.02	1.00	0.99	0.82	0.41	0.14	0.09
0.03	1.00	1.00	0.99	0.74	0.25	0.14
0.04	1.00	1.00	1.00	0.93	0.41	0.21
0.05	1.00	1.00	1.00	0.99	0.58	0.30
0.10	1.00	1.00	1.00	1.00	0.99	0.82

In summary, this study has good power to detect relative risks of 2.0 or more with respect to diseases, such as heart disease and basal cell carcinoma, occurring at a prevalence of at least 5 percent in unexposed populations. In addition, the study size is sufficient to detect small mean shifts in the continuously distributed variables. The detection of significant mean shifts without a corresponding indication of increased Ranch Hand abnormalities or disease may be an artifact of multiple testing, could represent a subclinical effect, or could be of little or no medical importance.

7.6 EXPLANATION OF TABLES

This section explains the contents of the tables used to report the results of the analyses for continuous and discrete dependent variables (two levels and more than two levels). Selected tables from the General Health Assessment (Chapter 9) and the Hematology Assessment (Chapter 16) will be referenced throughout this discussion. The contents of each table depend on the form of the health status endpoint (i.e., whether the dependent variable under analysis is a continuous or discrete variable).

The results of the exposure analysis are displayed in subpanels within each table as specified in Table 7-9. The specification of the subpanels is applicable whether the dependent variable is continuous or discrete.

Table 7-9. Location of Table Results from Different Exposure Analysis Models

Model	Exposure Estimate	Analysis Cohort	Subpanel in Table	Type of Analysis
1	Group	All Ranch Hands and Comparisons	a	Unadjusted
			b	Adjusted
2	Initial Dioxin	Ranch Hands >10 ppt lipid-adjusted 1987 dioxin	c	Unadjusted
			d	Adjusted
3	Categorized Dioxin	All Ranch Hands with a lipid-adjusted dioxin measurement, all Comparisons	e	Unadjusted
			f	Adjusted
4	1987 Dioxin	All Ranch Hands with a lipid-adjusted dioxin measurement	g	Unadjusted
			h	Adjusted

7.6.1 Continuous Variables

Table 16-3 in the Hematology Assessment chapter presents an example of the results of the analysis when the dependent variable was continuous. Subpanels (a) and (b) show the results of unadjusted and adjusted Model 1 analyses that compared the Ranch Hand and Comparison means of a dependent variable. Contrasts between Ranch Hands and Comparisons also are presented within each military occupational category (i.e., officer, enlisted flyer, and enlisted groundcrew).

For the unadjusted analysis in subpanel (a), a sample size (n) and a mean are presented for all military occupational categories combined and separately for each occupational category. If the dependent variable was transformed for the analysis, the means of the transformed values were converted to the original scale and the column heading is footnoted. For each contrast of Ranch Hands versus Comparisons, the difference of means on the original scale and the associated 95-percent confidence interval are reported. The 95-percent confidence interval was constructed by adding and subtracting 1.96 multiplied by the standard error (for the upper and lower bounds, respectively) to the estimated mean. If the analysis was performed on a transformed scale, the 95-percent confidence interval on the differences of means is not presented and the column is footnoted. When presenting results from analyses of means based on log-transformed (or square root-transformed) data, means were converted back to original units. Conversion of the standard deviation from log units to original units is not recommended (26); therefore, confidence intervals for mean differences in original units are not presented when the variable is analyzed on the logarithmic or square root scale. A p-value also is reported to determine whether a difference in means on the scale used for analysis for a specified contrast was equal to zero. The confidence interval and p-value for each military occupational category were determined using analysis of variance techniques from a group-by-occupation interaction in the statistical model. The group-by-occupation interaction was used to determine the model coefficients and standard errors simultaneously for officers,

enlisted flyers, and enlisted groundcrew. The respective coefficients and standard errors from the group and group-by-interaction terms in the model, along with the covariances between the estimates, were combined as appropriate to construct the confidence intervals and p-values for the three military occupational strata.

For an adjusted Model 1 analysis, subpanel (b) includes a sample size, an adjusted mean, a difference of Ranch Hand and Comparison adjusted means on the original scale, the associated 95-percent confidence interval (if the analysis was performed on the original scale), and a p-value for each contrast. Sample sizes for corresponding panels of unadjusted and adjusted analyses may differ because of missing covariate information. The confidence interval and p-value for each military occupational category were determined using analysis of covariance techniques from a group-by-occupation interaction in the statistical model.

Subpanel (c) of Table 16-3 reports summary statistics from the analysis that assessed the association between the continuous dependent variable and initial dioxin (Model 2) without adjusting for covariate information. The sample size and mean of the dependent variable (transformed to the original units, if necessary) are presented for low, medium, and high categories of initial dioxin. The low, medium, and high categories were determined by dividing all Ranch Hands with initial dioxin estimates into three approximately equally sized categories based on their initial dioxin estimate. The numerical values defining these categories are specified in a table subpanel footnote. Means of the dependent variable, adjusted for body mass index at the time of the blood measurement of dioxin, also are presented for the low, medium, and high categories of initial dioxin. Based on a linear regression analysis adjusted for body mass index at the time of the blood measurement of dioxin, the coefficient of determination (R^2), the estimated slope, and its associated standard error are reported. If the dependent variable was transformed for the regression analysis, the transformation is identified in the footnote. The p-value associated with testing whether the slope was equal to zero also is presented. The summary statistics that are reported were based on initial dioxin divided into three categories, whereas the R^2 , slope, standard error, and p-value were based on \log_2 (initial dioxin) in its continuous form.

Based on analyses that incorporate covariate information, subpanel (d) reports summary statistics from the analysis that assessed the association between the continuous dependent variable and initial dioxin (Model 2). Similar to the unadjusted analysis, a sample size and adjusted mean of the dependent variable (transformed to the original units, if necessary) are presented for low, medium, and high categories of initial dioxin. The numerical values defining these categories are specified in a table subpanel footnote. Sample sizes for corresponding panels of unadjusted and adjusted analyses may differ because of missing covariate information. Based on the multiple linear regression of the dependent variable on \log_2 (initial dioxin) and covariate effects, including body mass index at the time of the blood measurement of dioxin, the R^2 , the adjusted slope for \log_2 (initial dioxin), and its associated standard error are reported. If the dependent variable was transformed for the regression analysis, the adjusted means, adjusted slope, and standard error are footnoted and the transformation is identified in the footnote. The p-value for testing whether the slope was equal to zero also is presented.

Subpanels (e) and (f) of Table 16-3 show the results of unadjusted and adjusted Model 3 analyses that contrasted the means of a continuous dependent variable for Ranch Hands with background, low, high, and low plus high dioxin levels with all Comparisons. The low and high Ranch Hand categories were determined by dividing all Ranch Hands with lipid-adjusted dioxin estimates greater than 10 ppt into two approximately equally sized categories based on their initial dioxin estimate. The note at the bottom of the table subpanels defines the dioxin categories. The low plus high Ranch Hand category is a combination of the low and high categories. The mean for the low plus high category is a weighted average (transformed to the original units, if necessary) of the low Ranch Hand and high Ranch Hand

category means on the scale used for transformation, where the weights were based on the low and high Ranch Hand category sample sizes. Sample sizes for corresponding panels of unadjusted and adjusted analyses may differ because of missing covariate information.

For the unadjusted analysis in subpanel (e), a sample size and dependent variable mean are presented for each category. If the dependent variable was transformed for the analysis, the means of the transformed values were converted to the original scale and the column heading is footnoted. The mean of the dependent variable adjusted for body mass index at the time of the blood measurement of dioxin also is presented for each dioxin category. For each individual contrast of the Ranch Hand category versus the Comparison category, the difference of means on the original scale and the associated 95-percent confidence interval are reported. If the analysis was performed on a transformed scale, the 95-percent confidence interval on the differences of means is not presented and the column is footnoted. A p-value also is reported to determine whether a difference in means for a specified contrast was equal to zero. The p-value was based on the difference of means on the scale used for analysis. The adjusted mean, confidence interval, and p-value for each contrast were determined from an analysis of covariance statistical model with adjustment for body mass index at the time of the blood measurement of dioxin.

For the adjusted analysis in subpanel (f), the table includes a sample size, an adjusted mean (adjusted for body mass index at the time of the blood measurement of dioxin and covariates), a difference in adjusted means on the original scale, and a 95-percent confidence interval on the difference in adjusted means (if the analysis was performed on the original scale). The p-value for testing whether the difference in adjusted means for a specified contrast was equal to zero also is presented.

Subpanel (g) of Table 16-3 reports summary statistics from Model 4 analyses, which assessed the association between the continuous dependent variable and 1987 dioxin without adjusting for covariate information. The sample size and mean of the dependent variable (transformed to the original units, if necessary) are presented for low, medium, and high categories of 1987 dioxin. The low, medium, and high categories were determined by dividing all Ranch Hands with 1987 dioxin levels into three approximately equally sized categories based on their 1987 dioxin measurement and are defined in a table subpanel footnote. Based on a linear regression of the dependent variable on \log_2 (1987 dioxin), the R^2 , the estimated slope, and its associated standard error are reported for each model. If the dependent variable was transformed for the regression analysis, the means, slope, and standard error are footnoted and the transformation is identified in the footnote. The p-value associated with testing whether the slope was equal to zero also is presented.

Based on analyses that incorporate covariate information, subpanel (h) reports summary statistics for Model 4 analyses that assessed the association between the continuous dependent variable and 1987 dioxin. The sample size and adjusted mean of the dependent variable (transformed to the original units, if necessary) are presented for low, medium, and high categories of 1987 dioxin. The numerical values defining these categories are specified in a table subpanel footnote. Sample sizes for corresponding panels of unadjusted and adjusted analyses may differ because of missing covariate information. Based on the multiple linear regression of the dependent variable on \log_2 (1987 dioxin) and covariates, the R^2 , the adjusted slope for \log_2 (1987 dioxin), and its associated standard error are reported for each model. If the dependent variable was transformed for the regression analysis, the adjusted means, adjusted slope, and standard error are footnoted and the transformation is identified in the footnote. The p-value for testing whether the slope was equal to zero also is presented.

7.6.2 Discrete Variables

7.6.2.1 Discrete Variable with Two Categories

Table 9-3 in the General Health Assessment chapter presents an example of the results of analysis when the dependent variable is discrete and dichotomous. Subpanels (a) and (b) display the results of unadjusted and adjusted Model 1 analyses that compared the percentage of Ranch Hands and Comparisons that were considered abnormal for the dependent variable of interest (the abnormal classification for self-perception of health in Table 9-3 is “fair or poor”). Contrasts between Ranch Hands and Comparisons also are presented within each military occupational category (i.e., officer, enlisted flyer, and enlisted groundcrew). For the unadjusted analysis in subpanel (a), a sample size and the number and percentage of participants considered abnormal are presented for each group within each military occupational category. For the contrasts of Ranch Hands versus Comparisons, an unadjusted relative risk, an associated 95-percent confidence interval on the relative risk, and a p-value for testing whether the risk was equal to 1.0 are presented. The normal distribution was used to calculate an approximate 95-percent confidence interval. Results for each military occupational category were determined from a group-by-occupation interaction that was included in the statistical model.

For the adjusted analysis of Model 1, as presented in subpanel (b), the table presents a sample size, an adjusted relative risk, a 95-percent confidence interval on the relative risk, and a p-value for testing whether the risk was equal to 1.0 for all military occupational categories combined and separately for each occupational category. The sample size, adjusted relative risk, confidence interval, and p-value were determined from a multiple logistic regression model that used the appropriate covariates for the clinical area and dependent variable of interest. Results for each military occupational category were determined from a group-by-occupation interaction that was included in the statistical model. Sample sizes for corresponding panels of unadjusted and adjusted analyses may differ because of missing covariate information.

Subpanel (c) of Table 9-3 reports summary statistics for analyses that assessed the association between the dependent variable and initial dioxin (Model 2) without adjusting for covariate information. Sample sizes are presented for low, medium, and high categories of initial dioxin. The numerical values defining these categories are specified in a table footnote. The number and percentage of Ranch Hands considered abnormal are presented for the low, medium, and high initial dioxin categories. Based on a logistic regression model, adjusted for body mass index at the time of the blood measurement of dioxin, an unadjusted relative risk and its 95-percent confidence interval are reported. The p-value associated with testing whether the relative risk was equal to 1.0 also is presented. The normal distribution was used to determine an approximate 95-percent confidence interval. The summary statistics that are reported were based on initial dioxin divided into three categories, whereas the relative risk, confidence interval, and p-value were based on \log_2 (initial dioxin) in its continuous form.

Subpanel (d) of Table 9-3 reports summary statistics for analyses that assessed the association between the discrete dependent variable and initial dioxin (Model 2), adjusted for body mass index at the time of the blood measurement of dioxin and covariate information. The sample size given is based on a multiple logistic regression of the discrete dependent variable on \log_2 (initial dioxin), body mass index at the time of the blood measurement of dioxin, and covariates. Total sample sizes for corresponding panels of unadjusted and adjusted analyses may differ because of missing covariate information. The adjusted relative risk for \log_2 (initial dioxin) and its associated 95-percent confidence interval are reported and are based on this multiple logistic regression model. The normal distribution was used to determine an approximate 95-percent confidence interval. The p-value for testing whether the relative risk was equal to 1.0 also is presented.

Subpanels (e) and (f) of Table 9-3 show the results of unadjusted and adjusted Model 3 analyses that contrasted Ranch Hands having background, low, high, and low plus high dioxin levels with all Comparisons. The percentage of participants that were considered abnormal for the dependent variable of interest was contrasted between the four categories of Ranch Hands and Comparisons. The low and high Ranch Hand categories were determined by dividing all Ranch Hands with lipid-adjusted dioxin estimates greater than 10 ppt into two approximately equally sized categories based on their initial dioxin estimate. The low plus high Ranch Hand category is a combination of the low and high Ranch Hand categories. The footnote at the bottom of the table subpanel defines the dioxin categories. The percentage of Ranch Hands in the low plus high category is a weighted average of the low Ranch Hand and high Ranch Hand category percentages, where the weights are based on the low category and high category sample sizes. Sample sizes for corresponding panels of unadjusted and adjusted analyses may differ because of missing covariate information.

For the Model 3 unadjusted analysis in subpanel (e), the sample size and the number and percentage of participants considered abnormal is presented for each dioxin category. For the individual contrasts of the Ranch Hand categories versus Comparisons, an unadjusted relative risk, a 95-percent confidence interval for the relative risk, and a p-value associated with testing whether the risk was equal to 1.0 are presented. The relative risk, confidence interval, and p-value were determined from a logistic regression model, adjusted for body mass index at the time of the blood measurement of dioxin. The normal distribution was used to determine an approximate 95-percent confidence interval.

For the Model 3 adjusted analysis, subpanel (f) of the table presents sample size, an adjusted relative risk, a 95-percent confidence interval for the relative risk, and a p-value associated with testing whether the risk was equal to 1.0 for the individual contrasts of the Ranch Hand categories with Comparisons. The relative risk, confidence interval, and p-value were determined from a logistic regression model, adjusted for body mass index at the time of the blood measurement of dioxin and covariates. The normal distribution was used to determine an approximate 95-percent confidence interval.

Subpanels (g) and (h) of Table 9-3 present summary statistics from Model 4, which assessed the association between the dependent variable and 1987 dioxin. For the unadjusted analysis in subpanel (g), the sample size and the number and percentage of participants considered abnormal is presented for each 1987 dioxin category. The low, medium, and high categories were determined by dividing all Ranch Hands with 1987 dioxin levels into three approximately equally sized categories. The numerical values defining these categories are specified in a table footnote. Based on a logistic regression model, an unadjusted relative risk and its 95-percent confidence interval are reported. The p-value associated with testing whether the relative risk was equal to 1.0 also is presented. The normal distribution was used to determine an approximate 95-percent confidence interval. The summary statistics are reported for 1987 dioxin divided into three categories, whereas the relative risk, confidence interval, and p-value were based on \log_2 (1987 dioxin) in its continuous form.

Incorporating covariate information, subpanel (h) reports summary statistics from analyses that assessed the association between the dichotomous dependent variable and 1987 dioxin. The sample size is presented for a multiple logistic regression of the discrete dependent variable on \log_2 (1987 dioxin) including covariates in the final adjusted model. Total sample sizes for corresponding panels of unadjusted and adjusted analyses may differ because of missing covariate information. Based on the multiple logistic regression model, the adjusted relative risk for \log_2 (1987 dioxin) and its associated 95-percent confidence interval are reported. The normal distribution was used to determine an approximate 95-percent confidence interval. The p-value for testing whether the relative risk was equal to 1.0 also is presented.

7.6.2.2 Discrete Variable with More Than Two Categories

Polytomous regression techniques were used to analyze discrete dependent variables having more than two levels (e.g., abnormal low, normal, abnormal high—see Table 16-4 in the Hematology Assessment chapter). Results were presented in a similar fashion to discrete variables with only two categories; however, the number and percentage of participants for each dependent variable category (including normal) are given. Therefore, the relative frequencies sum to 100 percent across the dependent variable categories and the number of participants in each of the dependent variable categories adds to the total number of participants in each exposure group or dioxin category. In addition, a relative risk, a 95-percent confidence interval, and a p-value were presented for each contrast with the normal level of the dependent variable (e.g., abnormal low versus normal and abnormal high versus normal).

In Table 16-4, subpanels (a) and (b) display the results of unadjusted and adjusted Model 1 analyses that compared Ranch Hands and Comparisons on the relative frequencies of each abnormal level for a specified discrete dependent variable. For example, the percentage of participants with an abnormally high red blood cell (RBC) count was contrasted to participants with a normal RBC count, and the percentage of participants with an abnormally low RBC count was contrasted to participants with a normal RBC count. Contrasts between Ranch Hands and Comparisons also are presented within each military occupational category (i.e., officer, enlisted flyer, and enlisted groundcrew). For the unadjusted analysis in subpanel (a), a sample size is presented for each exposure group (Ranch Hand, Comparison) across all military occupational categories and within each occupational category. For the contrasts of Ranch Hands versus Comparisons, an unadjusted relative risk, a 95-percent confidence interval for the relative risk, and a p-value associated with testing whether the risk was equal to 1.0 are presented for each contrast against the normal level of the dependent variable (e.g., abnormal low versus normal and abnormal high versus normal). The normal distribution was used to calculate an approximate 95-percent confidence interval. Results for each military occupational category were determined from the group-by-occupation interaction that was included in the statistical model.

For a Model 1 analysis adjusted for covariate information and shown in subpanel (b), the table presents an adjusted relative risk, a 95-percent confidence interval on the relative risk, and a p-value associated with testing whether the risk was equal to 1.0 for each military occupational category and each contrast. The normal distribution was used to calculate an approximate 95-percent confidence interval. Results for each military occupational category were determined from the group-by-occupation interaction that was included in the statistical model. Sample sizes for corresponding panels of unadjusted and adjusted analyses may differ because of missing covariate information.

Subpanels (c) and (d) of Table 16-4 summarize the unadjusted and adjusted Model 2 analyses relating initial dioxin to discrete dependent variables having more than two categories. Both unadjusted and adjusted analyses are adjusted for body mass index at the time of the blood measurement of dioxin. In subpanel (c), the sample size and the number and percentage of Ranch Hands in each category of the dependent variable are presented for each initial dioxin category (i.e., low, medium, and high initial dioxin), which are defined in a footnote to the subpanel. The relative risk, the 95-percent confidence interval for the relative risk, and the p-value associated with testing whether the risk was equal to 1.0 are presented for each abnormal level of the dependent variable (e.g., abnormal low versus normal and abnormal high versus normal). The summary statistics that are reported were based on initial dioxin divided into three categories, whereas the relative risk, confidence interval, and p-value were based on \log_2 (initial dioxin) in its continuous form.

In subpanel (d), after adjustment for covariate information, the sample size, the adjusted relative risk, the 95-percent confidence interval for the relative risk, and the p-value associated with testing whether the risk was equal to 1.0 are presented for each abnormal level of the dependent variable. Total sample sizes

for corresponding panels of unadjusted and adjusted analyses may differ because of missing covariate information.

Subpanels (e) and (f) of Table 16-4 present unadjusted and adjusted Model 3 analyses of categorized dioxin versus a discrete dependent variable having more than two categories. Both unadjusted and adjusted analyses are adjusted for body mass index at the time of the blood measurement of dioxin. Results are presented in a similar fashion to the dichotomous analysis, except that contrasts other than abnormal versus normal are presented (e.g., abnormal high versus normal, along with abnormal low versus normal). For the unadjusted analysis, a sample size is presented for each dioxin category. The low plus high Ranch Hand category is a combination of the low and high Ranch Hand categories. The percentage of Ranch Hands in the low plus high category is a weighted average of the low Ranch Hand and high Ranch Hand category percentages, where the weights are based on the low category and high category sample sizes. Sample sizes for corresponding panels of unadjusted and adjusted analyses may differ because of missing covariate information.

The total sample size and the number and percentage of participants for each level of the dependent variable are presented for each dioxin category in subpanel (e). For each contrast of a Ranch Hand category versus the Comparison group, an unadjusted relative risk, a 95-percent confidence interval for the relative risk, and a p-value associated with testing whether the risk was equal to 1.0 are presented. These results are given for each contrast against the normal level of the dependent variable (e.g., abnormal low versus normal and abnormal high versus normal). For an adjusted Model 3 analysis in subpanel (f), the table presents sample sizes and an adjusted relative risk, a 95-percent confidence interval on the relative risk, and a p-value for each contrast of Ranch Hands versus Comparisons for each abnormal level of the dependent variable.

Unadjusted and adjusted analyses of discrete dependent variables with more than two categories were performed using 1987 dioxin in Model 4. In Table 16-4, summaries of the analyses are given in subpanels (g) and (h). Results are presented in a similar fashion to the dichotomous analysis, except that contrasts other than abnormal versus normal are presented (e.g., abnormal high versus normal, along with abnormal low versus normal). For the unadjusted analysis in subpanel (g), sample sizes are presented for each 1987 dioxin category (i.e., low, medium, and high 1987 dioxin). The number and percentage of Ranch Hands for each dependent variable category for each 1987 dioxin category are presented. An unadjusted relative risk, a 95-percent confidence interval on the relative risk, and an associated contrast p-value are reported for each abnormal level of the dependent variable (e.g., abnormal low versus normal and abnormal high versus normal). The summary statistics that are reported were based on 1987 dioxin divided into three categories, whereas the relative risk, confidence interval, and p-value were based on \log_2 (1987 dioxin) in its continuous form.

Adjusted analysis results in subpanel (h) include a total sample size and an adjusted relative risk, a 95-percent confidence interval on the relative risk, and an associated contrast p-value for each contrast of the dependent variable. Sample sizes for corresponding panels of unadjusted and adjusted analyses may differ because of missing covariate information.

8 COVARIATE ASSOCIATIONS WITH ESTIMATES OF DIOXIN EXPOSURE

8.1 INTRODUCTION

The associations between the covariates used throughout this report and four estimates of dioxin exposure are evaluated in this chapter. The purpose of studying these associations was to determine if these covariates, which have been determined to be associated with one or more of the health endpoints considered in this study, were associated with an estimate of dioxin exposure, and, therefore, could potentially be confounding variables in subsequent statistical analyses in this report. These covariates and estimates of dioxin exposure are used extensively in the statistical analyses in Chapters 9 through 20. Specific definitions of the covariates are contained in those chapters. The results contained in this chapter are associations and should not be interpreted as indicating causal relations between the estimates of dioxin exposure and covariate levels.

Some of the relations between covariates and estimates of dioxin exposure may have been confounded with military occupation. In this report, the unadjusted relations between dioxin exposure and all covariates were evaluated, as were the relations when military occupation was considered.

Four models were examined for each covariate. The analyses of these models are presented below. Further details on dioxin and the modeling strategy are found in Chapters 2 and 7, respectively. Model 1 examined the relation between the covariate and group (i.e., Ranch Hand or Comparison). In this model, exposure was defined as “yes” for Ranch Hands and “no” for Comparisons without regard to the magnitude of the exposure.

During the 1987, 1992, 1997, and 2002 examinations, serum dioxin levels were measured by the Centers for Disease Control and Prevention (CDC) using high-resolution gas chromatography and high-resolution mass spectrometry and were reported in parts per trillion (ppt) on a lipid weight basis (1). These dioxin measurements are referred to as “lipid-adjusted.” All measures of dioxin used in this report were based on lipid-adjusted dioxin measurements.

Model 2 examined the relation between the covariate and an extrapolated initial dioxin measure for Ranch Hands who had a 1987 dioxin measurement greater than 10 ppt. The initial dioxin was calculated by extrapolating the 1987 dioxin level back in time to the end of the tour of duty that qualified a Ranch Hand veteran for inclusion in this study. If a Ranch Hand did not have a 1987 dioxin level, then the first dioxin measured, either at 1992, 1997, or 2002, was used to estimate the initial dioxin level. Regardless of when the dioxin was measured, Ranch Hand veterans with a level less than or equal to 10 ppt were excluded from statistical analyses based on Model 2.

Model 3 divided the Ranch Hands examined in Model 2 into two categories based on their initial dioxin measures. These two categories were referred to as “low Ranch Hand” and “high Ranch Hand.” Two additional categories—Ranch Hands with serum dioxin levels at or below 10 ppt and Comparisons—were formed and included in the model. Ranch Hands with serum dioxin levels at or below 10 ppt were assigned to the “background Ranch Hand” category. If a Ranch Hand did not have a 1987 dioxin measurement, the first measured dioxin level was used. These four categories—Comparisons, background Ranch Hands, low Ranch Hands, and high Ranch Hands—were used in Model 3 analyses. The relation between the covariate in each of the three Ranch Hand categories and the covariate in the

Comparison category was examined. Ranch Hands with no dioxin measurements were excluded from statistical analyses based on Model 3.

Model 4 examined the relation between the covariate and 1987 dioxin levels in all Ranch Hands with a dioxin measurement. If a Ranch Hand did not have a 1987 dioxin measurement, the first dioxin level obtained, either in 1992, 1997, or 2002, was extrapolated to the date of the 1987 physical examination. If the first dioxin level was not obtained in 1987 and was less than or equal to 10 ppt, it was not extrapolated to 1987 level, but was used at the measured value. One Ranch Hand without a dioxin measurement was excluded from statistical analyses based on Model 4.

The summary statistics listed in the tables in this chapter are percentages, correlation coefficients (r), or means. For Models 1 and 3, if a covariate is discrete, the percentage of Ranch Hands and Comparisons is shown for each of the covariate categories and the equality of percentages in each covariate category is tested. If a covariate is continuous, the mean of the covariate is given separately for Ranch Hands and Comparisons and the equality of means is tested.

Because the measure of dioxin is continuous for the analyses of Models 2 and 4, if a covariate is also continuous, a correlation coefficient between initial or 1987 dioxin and the covariate is provided and a test is performed to see if the correlation coefficient is significantly different from zero. If a covariate is discrete, dioxin means for each of the covariate categories are displayed and the equality of dioxin means among each covariate category is tested.

Consistent with the methodology used in each of the clinical chapters, the means presented in the tables were transformed from the logarithmic (base 2) scale for initial dioxin in Model 2 and for 1987 dioxin in Model 4. For each of the sections below, a written description of the findings is given. A table displaying all the statistics and p-values is given at the end of the section.

8.2 MATCHING DEMOGRAPHIC VARIABLES (AGE, RACE, AND MILITARY OCCUPATION)

Age, race, and military occupation were used in the design of the Air Force Health Study to match Ranch Hand participants with Comparisons to reduce the association between these variables and group status (Model 1). It was impossible, however, to eliminate the possible confounding associations between these variables and serum dioxin in Models 2 through 4 through study design, because the matched design accounted for the possible confounding associations between age, race, and military occupation and group, but not dioxin. Results of tests of association between age, race, and military occupation and the four estimates of dioxin exposure are given in Table 8-1.

Examining the association between age in its continuous form and dioxin revealed significant relations in the unadjusted analyses of Models 2, 3, and 4 ($p < 0.001$ for each model). After adjusting for military occupation, however, the association was not significant in Models 2 or 4 ($p = 0.333$ and $p = 0.645$, respectively) but was significant in Model 3 ($p = 0.023$). The highest mean age (64.5 years) was observed in the low Ranch Hand dioxin category and the youngest average age was observed for Ranch Hands in the high dioxin category, with a mean age of 60.1 years. No significant association was seen between group and age in unadjusted and adjusted Model 1 analyses ($p \geq 0.72$ for each analysis).

Dichotomized age (i.e., born before 1942, born in or after 1942) and dioxin exposure showed relations similar to age in its continuous form. Models 2, 3, and 4 were significant in the unadjusted analyses ($p < 0.001$ for each analysis). When the relation was adjusted for military occupation, however, the results were no longer significant in Models 2 and 4 ($p = 0.080$ and $p = 0.712$, respectively), but were significant in Model 3 ($p = 0.014$). More Ranch Hands in the low dioxin category (64.9%) were in the older age

category than Ranch Hands in the background category (61.4%), Comparisons (54.1%), or Ranch Hands in the high dioxin category (33.8%). In unadjusted and adjusted Model 1 analyses, no significant difference in age was seen between Ranch Hands and Comparisons ($p>0.78$) due to the matched study design.

The association between race and dioxin was significant only for Model 2 in the unadjusted analyses ($p=0.032$). After adjusting for military occupation, however, Models 2, 3, and 4 showed significant results ($p<0.001$, $p=0.013$, and $p=0.009$, respectively). Blacks had lower mean initial and 1987 dioxin levels than did non-Blacks in Models 2 and 4. The mean initial dioxin level in Blacks was 97.1 ppt compared to 140.5 ppt in non-Blacks. Likewise, the 1987 dioxin level was lower in Blacks (12.5 ppt) than in non-Blacks (13.3 ppt). In Model 3, the percentage of Blacks varied among Comparisons (6.5%) and Ranch Hands in the background dioxin category (5.1%), the low dioxin category (10.0%), and the high dioxin category (4.7%). Because participants were matched according to race, no difference in race was seen between exposure groups in unadjusted and adjusted Model 1 analyses ($p>0.92$ for each analysis).

A significant association was found between military occupation and dioxin in Models 2, 3, and 4 ($p<0.001$ for each model). In Models 2 and 4, the mean dioxin levels were lowest among officers, followed by enlisted flyers and enlisted groundcrew. As expected, the percentages of officers, enlisted flyers, and enlisted groundcrew were similar between Ranch Hands and Comparisons in Model 1 ($p=0.679$), but the percentages varied considerably among the three Ranch Hand dioxin categories in Model 3. In Model 3, 61.7 percent of Ranch Hands in the background dioxin category were officers, but only 39.8 percent of Ranch Hands in the low dioxin category and 2.8 percent of Ranch Hands in the high dioxin category were officers. The mean initial dioxin level was 61.8 ppt among officers compared to 125.1 ppt among enlisted flyers and 189.1 ppt among enlisted groundcrew. Similarly the mean 1987 dioxin level was lowest in officers (7.0 ppt), followed by enlisted flyers (15.3 ppt) and enlisted groundcrew (22.5 ppt).

Table 8-1. Associations Between Matching Demographic Variables (Age, Race, and Military Occupation) and Estimates of Herbicide or Dioxin Exposure

		Model 1

^aAnalyses are adjusted for military occupation.

**: Statistically significant (p-value≤0.010).

Note: Means for discrete covariates were transformed from the logarithmic (base 2) scale for initial dioxin in Model 2 and for 1987 dioxin in Model 4.

8.3 ALCOHOL USE

Results of tests of association between alcohol use and the estimates of dioxin exposure are shown in Table 8-2. No significant association was found between dioxin and current alcohol use in unadjusted or adjusted Model 1, 2, or 3 analyses using the continuous form of alcohol use ($p > 0.10$ for each analysis). Model 4 analysis showed a significant unadjusted association between current alcohol use and 1987 dioxin ($p = 0.016$), but this association was not significant when adjusted for military occupation ($p = 0.254$).

The relation between the dichotomized form of current alcohol use and dioxin exposure mirrored the relation between the continuous form of current alcohol use and dioxin exposure. No significant relations were seen between the discrete form of current alcohol use and dioxin in the unadjusted or adjusted analyses of Models 1 through Model 3 ($p > 0.09$ for all analyses). The unadjusted analysis of Model 4 was significant ($p = 0.041$), but the relation was no longer significant after adjustment for military occupation ($p = 0.294$).

The adjusted and unadjusted associations between lifetime alcohol history in its continuous form and dioxin exposure were not significant in Models 1, 3, and 4 ($p > 0.29$ for all analyses). Model 2 showed a significant positive correlation ($r = 0.106$) between lifetime alcohol history and initial dioxin in the unadjusted and adjusted analyses ($p = 0.030$ unadjusted, $p = 0.009$ adjusted).

Similar results were seen in the analysis of the discrete form of lifetime alcohol use. Model 2 unadjusted and adjusted analyses showed a significant relation between lifetime alcohol use and initial dioxin ($p = 0.030$ unadjusted, $p = 0.019$ adjusted). The mean initial dioxin level was higher for nondrinkers (207.6 ppt) than for drinkers with less than 40 drink-years (129.1 ppt) or drinkers with a lifetime alcohol history of more than 40 drink-years (139.4 ppt). No significant associations between lifetime alcohol use and initial dioxin were observed in the unadjusted and adjusted analyses of Models 1, 3, and 4 ($p > 0.08$ for all analyses).

Statistically significant associations were found in the unadjusted analysis of dioxin and current wine use in its continuous form for Model 3 ($p = 0.009$) and Model 4 ($p < 0.001$). Neither of these associations, however, was significant when the models were adjusted for military occupation ($p > 0.67$ for all analyses). No significant associations were seen between current wine use in its continuous form and dioxin in Model 1 or Model 2 for the unadjusted and adjusted models ($p > 0.05$ for all analyses).

Current wine use in its discrete form showed significant association with dioxin exposure in the unadjusted analyses of Model 2 ($p = 0.001$), Model 3 ($p < 0.001$), and Model 4 ($p < 0.001$). None of these associations was significant when military occupation was taken into consideration ($p > 0.09$ for all analyses). No difference in current wine use was observed between Ranch Hands and Comparisons in the unadjusted and adjusted analyses for Model 1 ($p > 0.31$ for both analyses).

Lifetime wine history, in its continuous form, showed significant relations with dioxin in the unadjusted analyses of Model 2, Model 3, and Model 4 ($p = 0.002$, $p < 0.001$, $p < 0.001$, respectively). None of these results was significant when adjusted for military occupation ($p > 0.15$ for all analyses). Unadjusted and adjusted analyses of Model 1 revealed no significant difference in lifetime wine use between Ranch Hands and Comparisons ($p > 0.31$ for each analysis).

The discrete form of lifetime wine use showed significant association with dioxin in the unadjusted analyses of Models 2, 3, and 4 ($p < 0.001$, $p = 0.014$, and $p = 0.002$, respectively). After adjusting for military occupation, the relations were significant for Model 1 and Model 3 ($p = 0.049$ and $p = 0.047$,

respectively) but not significant for Models 2 and 4 ($p > 0.11$ for each analysis). Of all Ranch Hands, 71.5 percent were wine drinkers, as compared to 75.3 percent of Comparisons who were wine drinkers. A higher percentage of Comparisons (75.3%) were wine drinkers than Ranch Hands in the background (75.0%), low (72.9%), and high (64.8%) dioxin categories.

**: Statistically significant (p-value≤0.010).

Note: Means for discrete covariates were transformed from the logarithmic (base 2) scale for initial dioxin in Model 2 and for 1987 dioxin in Model 4.

8.4 CIGARETTE SMOKING

Results of tests of association between cigarette smoking and the estimates of dioxin exposure are given in Table 8-3. The mean number of cigarettes smoked per day was significantly higher in Ranch Hands than Comparisons in the unadjusted and adjusted analyses of Model 1 (p=0.011 unadjusted, p=0.010 adjusted). Ranch Hands smoked an average of 3.22 cigarettes per day and Comparisons smoked an average of 2.30 cigarettes per day. No significant associations between the current cigarette smoking in its continuous form and initial dioxin were observed in Model 2 analyses (p>0.17 for both analyses). In Model 3, a significant difference was noted for current cigarette smoking in its continuous form among the dioxin categories in the unadjusted and adjusted analyses (p=0.033 unadjusted, p=0.024 adjusted). The mean number of cigarettes smoked per day was 3.92 for Ranch Hands in the high dioxin category followed by Ranch Hands in the background and low dioxin categories (2.91 cigarettes per day for each) and Comparisons (2.30 cigarettes per day). While the unadjusted analysis of Model 4 showed no

significant association ($p=0.376$), the adjusted analyses showed current cigarette smoking increasing with increasing 1987 dioxin levels ($p=0.030$).

Using the discrete form of current cigarette smoking, the results were not significant in the unadjusted analyses of Model 1 through Model 4 ($p>0.06$ for each analysis). After considering military occupation, significant associations were revealed in Model 3 ($p=0.019$) and Model 4 ($p<0.001$), but not in Model 1 or Model 2 ($p>0.05$ for each analysis). The distribution of smokers was relatively similar among Comparisons, Ranch Hands in the background category, and Ranch Hands in the low dioxin category. Ranch Hands in the high dioxin category had more nonsmokers (32.4%) and fewer former smokers (47.0%), but more participants smoking up to 20 cigarettes per day (16.9%), than Comparisons or Ranch Hands in the other dioxin categories.

No significant associations were observed between lifetime cigarette smoking in its continuous form and dioxin exposure in Model 1, Model 2, and Model 3 for unadjusted or adjusted analyses ($p>0.36$ for all analyses). In the Model 4 unadjusted analysis, no significant relation was seen between 1987 dioxin levels and lifetime cigarette smoking ($p=0.629$). After adjusting Model 4 for military occupation, 1987 dioxin levels decreased with increasing lifetime cigarette smoking ($p=0.019$).

No significant associations between the cigarette smoking in its discrete form and dioxin were observed in Model 1 or Model 3 unadjusted and adjusted analyses ($p>0.07$ for all analyses). The unadjusted analyses of Model 2 and Model 4 revealed no significant associations between lifetime cigarette smoking and dioxin exposure ($p>0.23$ for each analysis). After adjusting for military occupation, however, the results of both analyses were significant ($p=0.046$ for Model 2; $p<0.001$ for Model 4). The mean initial and 1987 dioxin levels decreased with increasing lifetime cigarette smoking. The mean initial dioxin was 125.9 ppt in heavy smokers (greater than 10 pack-years), 142.4 ppt in moderate smokers (up to 10 pack-years), and 149.4 ppt in nonsmokers. Mean 1987 dioxin levels were 12.7 ppt in heavy smokers, 12.9 ppt in moderate smokers, and 14.3 ppt in nonsmokers.

Note: Means for discrete covariates were transformed from the logarithmic (base 2) scale for initial dioxin in Model 2 and for 1987 dioxin in Model 4.

8.5 EXPOSURE TO CARCINOGENS

Results of tests of association between reported exposure to ionizing radiation, industrial chemicals, herbicides, insecticides, and degreasing chemicals and the estimates of dioxin exposure are presented in Table 8-4. These variables were constructed based on responses given by participants and were intended to indicate only post-Southeast Asia (SEA) exposures to these suspected carcinogens.

The association between reported degreasing chemical exposure and dioxin was significant in the unadjusted analyses of Models 2, 3, and 4 (p<0.001 for each model), but not significant in Model 1 (p=0.098). After adjusting for military occupation, however, the association between reported degreasing chemical exposure and dioxin exposure was not significant in any of the models (p>0.05 for all analyses).

Significant associations between group or dioxin levels and reported exposure to herbicides were observed in Models 1, 3, and 4 unadjusted and adjusted analyses (p<0.001 for each analysis). In Model 1, more than twice as many Ranch Hands (97.4%) than Comparisons (44.6%) reported herbicide exposure. Model 3 results showed a similar relation between Ranch Hands and Comparisons, where more than 95 percent of the Ranch Hands in each category reported herbicide exposure. In Model 4, Ranch Hands who reported exposure to herbicides had a mean 1987 dioxin level of 13.5 ppt, as compared to a mean 1987 dioxin level of 5.8 ppt for Ranch Hands not reporting herbicide exposure. In Model 2, unadjusted and

adjusted analyses showed no significant association between reported herbicide exposure and initial dioxin levels ($p>0.47$ for both analyses).

The association between industrial chemical exposure and dioxin exposure was significant in the analysis of Models 2, 3, and 4 ($p=0.045$ for Model 2 and $p<0.001$ for Models 3 and 4). After adjusting for military occupation, however, these associations were no longer significant ($p>0.44$ for all analyses). No significant difference in industrial chemical exposure was seen between Ranch Hands and Comparisons in Model 1 unadjusted and adjusted analyses ($p>0.68$ for all analyses).

Significant associations were observed between insecticide exposure and group in Model 1 unadjusted and adjusted analyses ($p<0.001$), as well as between insecticide exposure and categorized dioxin in Model 3 unadjusted and adjusted analyses ($p<0.001$). In Model 1, 81.7 percent of Ranch Hands reported exposure to insecticides, in contrast to 66.9 percent of Comparisons. In Model 3, the percentage of participants exposed to insecticides was similar among the Ranch Hand dioxin categories (81.8% for Ranch Hands in the background dioxin category, 81.5% for Ranch Hands in the low dioxin category, and 81.7 % for Ranch Hands in the high dioxin category) and lower for Comparisons (66.9%). No significant relation was seen between insecticide exposure and dioxin in Model 2 or Model 4 unadjusted and adjusted analyses ($p>0.12$ for all analyses).

A significant difference between the percentage of participants who have been exposed to ionizing radiation was seen between Ranch Hands (22.3%) and Comparisons (26.7%) in Model 1 unadjusted and adjusted analyses ($p=0.032$ unadjusted, $p=0.024$ adjusted). No significant associations were seen between dioxin exposure estimates and ionizing radiation exposure in Models 2 through 4 unadjusted and adjusted analyses ($p>0.05$ for all analyses).

^aAnalyses are adjusted for military occupation.

** : Statistically significant (p-value≤0.010).

Note: Means for discrete covariates were transformed from the logarithmic (base 2) scale for initial dioxin in Model 2 and for 1987 dioxin in Model 4.

8.6 HEALTH VARIABLES

Results of tests of association between numerous measures related to a participant's health and the estimates of dioxin exposure are presented in Table 8-5.

No significant relations between body mass index in its continuous form and dioxin were demonstrated in the unadjusted and adjusted analyses of Model 1 and Model 2 ($p > 0.15$ for all analyses). In Model 3 unadjusted and adjusted analyses, body mass index differed significantly between Comparisons and Ranch Hands categorized by dioxin levels ($p < 0.001$ for all analyses). The mean body mass index was 29.0 kg/m^2 for Comparisons, 27.8 kg/m^2 for Ranch Hands in the background category, 29.9 kg/m^2 for Ranch Hands in the low category, and 30.3 kg/m^2 for Ranch Hands in the high category. Likewise, Model 4 results showed that body mass index was positively correlated with 1987 dioxin levels ($r = 0.256$) in the unadjusted and adjusted analyses ($p < 0.001$ for each analysis).

The discrete form of body mass index showed results similar to those of the continuous form. No association was detected in the unadjusted or adjusted analyses of Model 1 and Model 2 ($p > 0.51$ for all analyses). Model 3 results were significant for both the unadjusted and adjusted analyses ($p < 0.001$ for each analysis). The percent of Ranch Hands who were classified as obese rose with the dioxin level (23.1% of background Ranch Hands were categorized as obese compared to 44.1% of Ranch Hands in the low dioxin category and 47.0% of Ranch Hands in the high dioxin category). In contrast, 35.4 percent of Comparisons were classified as obese. Obese Ranch Hands had significantly higher 1987 dioxin levels (18.0 ppt) in Model 4 unadjusted and adjusted analyses than participants who were not obese (11.2 ppt) ($p < 0.001$ for all analyses).

No association was seen between dioxin and cholesterol levels in the discrete or continuous form, either with or without adjustment for military occupation in Model 1 through Model 4 ($p > 0.07$ for all analyses).

High-density lipoprotein (HDL) cholesterol in its continuous form showed significant associations with dioxin in Model 2 ($p = 0.003$), Model 3 ($p < 0.001$), and Model 4 ($p < 0.001$). When adjusted for military occupation, the association became nonsignificant in Model 2 ($p = 0.094$). The adjusted association remained significant in Model 3 ($p = 0.044$) and Model 4 ($r = -0.180$; $p = 0.003$), with HDL levels decreasing as the mean dioxin levels increased. In Model 3, the mean HDL level was 46.1 mg/dL for Comparisons, 48.2 mg/dL for background Ranch Hands, 46.0 mg/dL for Ranch Hands in the low dioxin category, and 42.6 mg/dL for Ranch Hands in the high dioxin category.

In the analysis of the discrete form of HDL, no significant results were seen in the unadjusted or adjusted analyses of Model 2 or Model 4 ($p > 0.06$ for all analyses). In Model 1, no significant associations between HDL and dioxin were noted in the unadjusted analyses ($p = 0.058$), but the results were significant after adjusting for military occupation ($p = 0.049$). HDL values greater than 35 mg/dL were seen in 78.6 percent of Ranch Hands versus 82.2 percent of Comparisons. A significant association was seen between HDL in its discrete form and dioxin in the unadjusted analysis of Model 3 ($p = 0.020$). The association was not significant after adjusting for military occupation ($p = 0.153$).

Statistically significant unadjusted associations were found between the cholesterol-HDL ratio in its continuous form and dioxin for Model 2 ($p = 0.011$), Model 3 ($p < 0.001$), and Model 4 ($p < 0.001$). These associations were not significant when adjusted for military occupation ($p > 0.11$ for all analyses). Neither the unadjusted nor the adjusted Model 1 analyses were significant ($p > 0.80$ for both analyses).

Dichotomizing the cholesterol-HDL ratio using a cutpoint of 5.0 revealed significant associations with dioxin for Models 3 and 4 ($p=0.008$ for Model 3; $p<0.001$ for Model 4). The associations between the categorized cholesterol-HDL ratio and dioxin levels were no longer significant after adjusting for military occupation ($p>0.26$ for both analyses). Unadjusted and adjusted analyses of Model 1 and Model 2 showed no significant findings ($p\geq 0.13$ for all analyses).

The examination of the physical activity index showed a significant association with dioxin in the unadjusted Model 1 through Model 4 analyses ($p=0.037$ for Model 1; $p<0.001$ for Model 2; $p=0.005$ for Model 3; $p<0.001$ for Model 4). More Comparisons were classified as sedentary (51.6%) than Ranch Hands (46.6%). The percent of sedentary Ranch Hands increased as the dioxin levels increased in the dioxin categories of Model 3. In the background dioxin category, 41.2% of Ranch Hands were sedentary versus 46.0% of Ranch Hands in the low dioxin category and 56.3% of Ranch Hands in the high dioxin category. In Model 2, the mean initial dioxin level was lower in moderately active participants (111.2 ppt) and very active participants (111.4 ppt) than sedentary participants (166.4 ppt). Model 4 results were similar to Model 2, with mean 1987 dioxin levels being lowest in the moderately active category (11.3 ppt), followed by very active participants (11.5 ppt) and sedentary participants (15.6 ppt). With the exception of Model 3, these associations remained significant after adjusting for military occupation ($p=0.038$ for Model 1; $p<0.001$ for Model 2; $p=0.078$ for Model 3; $p=0.011$ for Model 4).

A significant association between diabetic class and dioxin was revealed in the unadjusted Model 3 and Model 4 analyses ($p=0.003$ for Model 3; $p<0.001$ for Model 4), and the results remained significant after adjusting for military occupation ($p=0.009$ for Model 3; $p<0.001$ for Model 4). More participants were classified as diabetic as the dioxin levels increased in Model 3. For Ranch Hands in the background dioxin category, 11.9 percent of participants were classified as diabetic. In the low dioxin category, 22.8 percent of Ranch Hands were classified as diabetic; 24.4 percent of Ranch Hands in the high dioxin category were classified as diabetic. In Model 4, participants classified as diabetic had higher mean 1987 dioxin levels (18.9 ppt) than participants whose diabetic status was classified as impaired (11.8 ppt) or normal (12.4 ppt). Model 2 showed a significant association between diabetic class and initial dioxin levels only after adjusting for military occupation ($p=0.285$ unadjusted, $p=0.048$ adjusted). The mean initial dioxin level was 136.1 ppt for normal participants compared to 122.8 ppt for participants with impaired diabetic status and 152.0 ppt for diabetics. No difference in diabetic class was seen between Ranch Hands and Comparisons in Model 1 unadjusted and adjusted analyses ($p>0.70$ for all analyses).

The analysis of family history of diabetes revealed no significant associations with dioxin levels in Models 1 through Model 4 in the unadjusted or adjusted analyses ($p>0.05$ for all analyses).

Participants who were not diagnosed as diabetic prior to the 2002 physical examination, but were suspected to be diabetic based on glucose levels, were recommended to seek follow-up tests. Those participants who were subsequently confirmed to be diabetic were assigned a value of 0 years for duration of diabetes. Nondiabetic participants were also assigned a value of 0 years for duration of diabetes. Significant associations were observed between duration of diabetes in its continuous form and dioxin exposures in Model 2, Model 3, and Model 4; the associations remained significant after adjusting for military occupation ($p<0.03$ for all analyses). The duration of diabetes increased as initial dioxin levels increased in Model 2 ($r=0.104$) and as 1987 dioxin levels increased in Model 4 ($r=0.146$). Likewise, the mean duration of diabetes in Ranch Hands increased with increasing dioxin categories in Model 3. Ranch Hands in the high dioxin category had diabetes for an average of 2.48 years compared to Ranch Hands in the low dioxin category (2.14 years), Ranch Hands in the background category (1.05 years), and Comparisons (1.42 years). No significant difference in duration of diabetes was seen between Ranch

Hands and Comparisons in Model 1 unadjusted and adjusted analyses ($p=0.141$ unadjusted, $p=0.145$ adjusted).

The dichotomized form of duration of diabetes showed results similar to the continuous form. Model 3 and Model 4 demonstrated significant associations between duration of diabetes and dioxin exposure in the unadjusted and adjusted analyses ($p<0.001$ for each analysis). The analysis of Model 2 showed significant results in the adjusted analysis ($p=0.014$), but not the unadjusted analysis ($p=0.167$). No difference in duration of diabetes was seen between Ranch Hands and Comparisons in Model 1 unadjusted and adjusted analyses ($p>0.86$ for all analyses). Higher initial and 1987 dioxin levels were seen for participants who were previously diagnosed as diabetic than for nondiabetics or newly diagnosed diabetics (154.2 ppt versus 132.4 ppt for initial dioxin; 20.1 ppt versus 12.2 ppt for 1987 dioxin). Among Ranch Hands, the percentage of participants who were previously diagnosed as diabetic increased with increasing dioxin level categories (9.1%, 19.4%, and 22.5% in the background, low, and high dioxin categories, respectively).

No significant associations were observed between family history of heart disease or family history of heart disease before age 45 and any of the estimates of dioxin exposure in Model 1 through Model 4 unadjusted and adjusted analyses ($p>0.20$ for all analyses).

Mean uric acid levels differed significantly between Ranch Hands and Comparisons in Model 1 unadjusted and adjusted analyses ($p=0.026$ for all analyses) and between Comparisons and Ranch Hands in the various dioxin categories in Model 3 ($p=0.019$ unadjusted, $p=0.010$ adjusted). The mean uric acid level was 5.85 mg/dL for Comparisons and 5.72 mg/dL for all Ranch Hands. When Ranch Hands were categorized by dioxin levels in Model 3, mean uric acid levels increased with increasing dioxin levels. The mean uric acid level for Ranch Hands in the background category was 5.61 mg/dL compared to 5.79 mg/dL for Ranch Hands in the low dioxin category and 5.85 mg/dL for Ranch Hands in the high dioxin category. No significant differences in mean uric acid levels were seen in Model 2 or Model 4 unadjusted and adjusted analyses ($p>0.12$ for all analyses).

When uric acid levels were dichotomized, Model 1, Model 2, and Model 4 showed no significant associations between dioxin and uric acid in unadjusted or adjusted analyses ($p>0.07$ for all analyses). In Model 3, significant differences in the percent of participants with uric acid levels greater than 5.5 mg/dL were seen between Comparisons and Ranch Hands in the various dioxin categories in the unadjusted analysis ($p=0.016$) and the adjusted analysis ($p=0.009$). Ranch Hands in the low dioxin category were more likely to have had a high uric acid level (57.8%) than Comparisons (55.7%), Ranch Hands in the high dioxin category (54.0%), or Ranch Hands in the background category (46.6%).

Significant relations were noted between waist-to-hip ratio measurements in the continuous form and dioxin for Model 3 and Model 4 before and after adjustment for military occupation ($p<0.001$ for all analyses). The mean waist-to-hip ratio varied from 0.99 for Ranch Hands in the background category to 1.00 for Comparisons, 1.01 for Ranch Hands in the low dioxin category, and 1.02 for Ranch Hands in the high dioxin category. In Model 4 analysis, the waist-to-hip ratio was increased with increasing 1987 dioxin levels ($r=0.200$). Model 2 analysis showed no significant results in the unadjusted analysis ($p=0.108$), but was significant when adjusted for military occupation ($p=0.006$). Initial dioxin levels were positively correlated ($r=0.078$) with waist-to-hip ratios. No difference in waist-to-hip ratios was seen between Ranch Hands and Comparisons in Model 1 unadjusted and adjusted analyses ($p>0.80$ for each).

Significant relations were also seen between waist-to-hip ratio measurements in the discrete form and dioxin for Model 3 and Model 4 before and after adjustment for military occupation ($p<0.001$ for all

analyses). The percentage of participants with a waist-to-hip ratio greater than 1.0 increased as dioxin levels increased in Model 3. Ranch Hands in the high dioxin category were more likely to have a waist greater than their hip circumference (59.6%) than Ranch Hands in the low dioxin category (53.1%), Ranch Hands in the background category (37.6%), or Comparisons (49.8%). Mean 1987 dioxin levels were higher in participants with a waist greater than the hip circumference (16.5 ppt) than in participants with a waist-to-hip ratio less than or equal to 1.0 (10.8 ppt). Model 2 analysis also showed significant results in the unadjusted ($p=0.018$) and adjusted results ($p=0.008$). The mean initial dioxin was 121.2 ppt for participants with a waist less than or equal to the hip circumference. For those participants with a waist-to-hip ratio greater than 1.0, the mean initial dioxin was 150.1 ppt. No difference in the waist-to-hip ratio was seen between Ranch Hands and Comparisons in Model 1 unadjusted and adjusted analyses ($p>0.35$ for each analysis).

When examining the relation between current blood pressure medication use and dioxin exposure, no significant relation was observed in Model 1, Model 2, or Model 3, whether or not adjustment was made for military occupation ($p>0.06$ for all analyses). In Model 4, the unadjusted analysis was significant ($p=0.037$), as was the adjusted analysis ($p=0.025$). Mean 1987 dioxin levels were higher in participants currently taking medication for high blood pressure (14.5 ppt) than for those not taking medication (12.3 ppt).

No significant relations between current use of alpha- or beta-adrenergic blocking agents and dioxin exposure were seen in the unadjusted or adjusted analyses of Model 1 through Model 4 ($p>0.27$ for all analyses).

The relation between current angiotensin-converting enzyme (ACE) inhibitor use and dioxin exposure was not significant in Model 1, Model 2, or Model 3 unadjusted and adjusted analyses ($p>0.10$ for all analyses). The unadjusted analysis of Model 4 showed a significant association between 1987 dioxin levels and current ACE inhibitor use ($p=0.028$). After adjusting for military occupation, however, the results were no longer significant ($p=0.055$).

No significant associations were noted between dioxin exposure and current calcium channel blocker use in any of the unadjusted and adjusted analyses using the four models ($p>0.14$ for all analyses) or between dioxin exposure and current diuretic use ($p>0.12$ for all analyses).

^aAnalyses are adjusted for military occupation.

^bDiabetic Class:

Diabetic: past history of diabetes, as diagnosed previously by a physician, or ≥ 200 mg/dL 2-hour postprandial glucose on two separate occasions, or ≥ 126 mg/dL fasting glucose on two separate occasions, or one 2-hour postprandial glucose measurement ≥ 200 mg/dL and one fasting glucose ≥ 126 mg/dL on two separate occasions.

Impaired: not diabetic; ≥ 140 mg/dL 2-hour postprandial glucose or ≥ 110 mg/dL fasting glucose at the 2002 physical examination.

Normal: not diabetic or impaired; < 140 mg/dL 2-hour postprandial glucose and < 110 mg/dL fasting glucose at the 2002 physical examination.

^cNondiabetics and participants who were diagnosed as diabetic subsequent to the 2002 physical examination were assigned the value of 0 years for duration of diabetes.

*: Statistically significant ($0.010 < p\text{-value} \leq 0.050$).

**: Statistically significant ($p\text{-value} \leq 0.010$).

Note: Means for discrete covariates were transformed from the logarithmic (base 2) scale for initial dioxin in Model 2 and for 1987 dioxin in Model 4.

8.7 SUN-EXPOSURE VARIABLES

Results of tests of association between a participant's reaction to sun exposure and the estimates of dioxin exposure are shown in Table 8-6. These statistics are based on non-Black participants because the sun-exposure covariates were used in only adjusted analyses of skin neoplasms and Blacks were excluded from those analyses.

No significant associations were seen between skin color and group in Model 1 or between skin color and initial dioxin in Model 2 unadjusted and adjusted analyses ($p > 0.06$ for all analyses). In Model 3, the percentage of participants with peach skin color differed significantly among the Ranch Hands categorized by dioxin levels and Comparisons with or without adjustment for military occupation ($p = 0.034$ unadjusted, $p = 0.018$ adjusted). For Ranch Hands in the low dioxin category, 83.2 percent had peach skin color compared to 76.4 percent of Ranch Hands in the high dioxin category, 74.3 percent of Ranch Hands in the background category, and 73.3 percent of Comparisons. Participants with peach skin color had significantly higher mean 1987 dioxin levels (13.8 ppt) than participants with nonpeach skin color (11.7 ppt) in Model 4 only after adjustment for military occupation ($p = 0.103$ unadjusted, $p = 0.008$ adjusted).

A significant association between hair color and dioxin levels was observed in unadjusted Model 2 ($p = 0.002$) and Model 3 ($p = 0.005$) analyses, but was not seen in the unadjusted analyses of Model 1 ($p = 0.729$) and Model 4 ($p = 0.056$). After adjusting for military occupation, however, all associations in Model 1 through Model 4 analyses were not significant ($p > 0.07$ for all analyses).

Eye color differed significantly between Ranch Hands and Comparisons in Model 1, before and after adjustment for military occupation ($p = 0.026$ unadjusted, $p = 0.025$ adjusted). Brown eyes and blue eyes were more prevalent in Comparisons than Ranch Hands (31.9 percent versus 27.5 percent for brown eyes; 42.6 percent versus 41.8 percent for blue eyes), but hazel and green eyes were less common in Comparisons than Ranch Hands (25.5 percent versus 30.8 percent). No other significant associations were seen in the unadjusted or adjusted analyses of Models 2, 3, and 4 ($p > 0.05$ for all analyses).

No significant associations were observed between group or dioxin exposure estimates and reaction of skin to sun after at least 2 hours, reaction of skin to sun after repeated exposures, or the composite sun-reaction index for either the adjusted or unadjusted analyses ($p > 0.12$ for all analyses).

Unadjusted and adjusted analyses of average lifetime residential latitude revealed significant associations with dioxin exposure in Model 1 ($p = 0.025$ unadjusted, $p = 0.020$ adjusted) and Model 2 ($p = 0.010$ unadjusted, $p = 0.002$ adjusted) unadjusted and adjusted analyses. In Model 1, significantly more Comparisons lived closer to the equator (53.6%), on average, than Ranch Hands (48.1%). In Model 2, the mean initial dioxin levels were greater for participants living closer to the equator (159.3 ppt) than for those living farther from the equator (125.0 ppt). No difference in average lifetime residential latitude was seen between Comparisons and the Ranch Hand dioxin categories in Model 3 unadjusted and adjusted analyses ($p > 0.06$ for all analyses). While no significant association was seen in the unadjusted analysis of Model 4 ($p = 0.238$), the association between latitude was significant when adjusting for military occupation ($p = 0.026$). Participants living closer to the equator, on average, had higher mean 1987 dioxin levels (14.0 ppt) than participants living farther from the equator (12.7 ppt).

^aAnalyses are adjusted for military occupation.

*: Statistically significant (0.010<p-value≤0.050).

**: Statistically significant (p-value≤0.010).

Note: Means for discrete covariates were transformed from the logarithmic (base 2) scale for initial dioxin in Model 2 and for 1987 dioxin in Model 4.

8.8 OTHER MISCELLANEOUS COVARIATES

Results of tests of association between other miscellaneous covariates and the estimates of dioxin exposure are shown in Table 8-7. Examining the association between current total household income in its continuous form and dioxin yielded significant results in the analysis of Models 2 through 4 ($p < 0.001$ for all analyses). When adjusted for military occupation, the association between income and dioxin levels was not significant for any of the models ($p > 0.15$ for each analysis). The current income of Ranch Hands was not significantly different than Comparisons in Model 1 unadjusted and adjusted analyses, even after adjustment for military occupation ($p > 0.41$ for all analyses).

When income was categorized, significant associations were seen between current income and dioxin exposure in the unadjusted analysis of Model 2, Model 3, and Model 4 ($p = 0.005$ for Model 2; $p = 0.007$ for Model 3; $p = 0.013$ for Model 4). Model 2 and Model 3 results were not significant after adjustment for military occupation ($p > 0.25$ for each analysis). Model 4 results, however, remained significant after adjusting for military occupation ($p = 0.022$). The mean 1987 dioxin level was higher in participants making less than \$65,000 per year (14.8 ppt) than in participants with higher incomes (12.1 ppt). No significant difference in current income was seen between Ranch Hands and Comparisons in Model 1 analyses ($p > 0.36$ for all analyses).

The relation between education and group was not significant in Model 1 unadjusted and adjusted analyses ($p > 0.24$ for all analyses). A significant relation between education and dioxin was revealed for Models 2 through 4 ($p \leq 0.001$ for each model). After adjusting for military occupation, however, no significant relations were observed in Models 2, 3, or 4 ($p > 0.28$ for all analyses).

No significant relation between current employment status and dioxin exposure was seen in Model 1, Model 2, or Model 3 unadjusted and adjusted analyses ($p > 0.05$ for all analyses). Significant relations were seen between 1987 dioxin levels and current employment status in Model 4 in the unadjusted analysis ($p = 0.031$), but the relations were no longer significant when adjusted for military occupation ($p = 0.271$).

In the analysis of the relation between current marital status and dioxin exposure, no significant association was observed in Model 1, Model 2, or Model 3 unadjusted and adjusted analyses ($p > 0.08$ for all analyses). A significant relation between current marital status and 1987 dioxin levels was seen in the unadjusted analysis of Model 4 ($p = 0.049$). After adjusting for military occupation, however, the relation was no longer significant ($p = 0.527$).

Current parental status (having a child younger than 18 years old at home) was not significantly related to dioxin exposure estimates in Model 1 through Model 4 unadjusted and adjusted analyses ($p > 0.09$ for all analyses).

The analysis of participants who reported having worked with vibrating power equipment or tools for 30 days or more revealed a significant association with 1987 dioxin ($p = 0.019$) in Model 4. After adjustment for military occupation, however, this association was not significant ($p = 0.581$). All tests of association in Model 1 through Model 3 were not significant for this covariate ($p \geq 0.07$ for all analyses).

Tests of the association between reported exposure to heavy metals (worked for 30 days or more with lead, mercury, chromium, nickel, copper, cadmium, manganese, arsenic, selenium, or molybdenum) and dioxin were significant for categorized dioxin in Model 3 ($p = 0.011$) and 1987 dioxin in Model 4 ($p = 0.011$). After adjustment for military occupation, the association was not significant in Model 3 ($p = 0.321$) or in Model 4 ($p = 0.621$). All tests of association between reported exposure to heavy metals

and group in Model 1 unadjusted and adjusted analyses were not significant ($p>0.09$ for all analyses), as were tests of association between reported exposure to heavy metals and initial dioxin in Model 2 unadjusted and adjusted analyses ($p>0.23$ for all analyses).

No significant associations were seen between dioxin exposure and the length of exercise prior to peripheral blood pressure measurements in the continuous or discrete forms for Model 1 through Model 4 unadjusted and adjusted analyses ($p>0.46$ for all analyses).

Note: Means for discrete covariates were transformed from the logarithmic (base 2) scale for initial dioxin in Model 2 and for 1987 dioxin in Model 4.

8.9 SUMMARY

This chapter investigates whether the covariates used throughout this report were associated with the estimates of herbicide or dioxin exposure. Military occupation, being associated with education, may have influenced the associations between covariates and dioxin estimates. Therefore, associations between covariates and the estimates of exposure in this chapter were adjusted for military occupation but not for other known or suspected confounders. Associations between covariates and dioxin estimates should be interpreted with caution and do not necessarily reflect a causal relation.

The demographic variables of age, race, and military occupation were used as matching variables in the original study design. As expected because of the matching, there were no significant differences between Ranch Hands and Comparisons for these three variables. As exhibited in previous reports, dioxin was significantly associated with military occupation. Officers had the lowest levels, followed by enlisted flyers and enlisted groundcrew. Because the Ranch Hand enlisted groundcrew tended to be younger on average than the Ranch Hand officers and enlisted flyers and were more likely to have been exposed to dioxin, a strong inverse association was seen between dioxin levels and age. When military occupation was taken into consideration, however, initial and 1987 dioxin levels did not appear to be related to age. Race exhibited significant associations with dioxin in that Black participants appeared to have lower dioxin levels than non-Black participants. The association between race and serum dioxin levels was strengthened when military occupation was considered.

Lifetime alcohol consumption had a positive association with initial dioxin. A greater percentage of Comparisons than Ranch Hands were wine-drinkers and the percentage of wine-drinkers within the Ranch Hand group decreased as dioxin increased.

Significant associations were observed between current cigarette smoking and lifetime cigarette smoking history and 1987 dioxin after adjustment for military occupation.

Questions posed to the participants regarding exposure to known carcinogens were intended to indicate post-SEA exposures; however, the data suggest that the participants may have included SEA exposures as well. A greater percentage of Ranch Hands reported herbicide and insecticide exposure, which may indicate that Ranch Hands were more likely to report SEA or pre-SEA exposures than Comparisons. Significant associations were seen between dioxin and both degreasing chemicals and industrial chemicals, but adjusted analysis showed that these associations were related to military occupation. It is believed that fewer officers were exposed to industrial chemicals and degreasing chemicals than enlisted personnel. The percentage of Comparisons exposed to ionizing radiation was greater than the percentage of Ranch Hands exposed and did not appear to be related to military occupation.

The significant associations between dioxin and health measurements, such as body mass index, HDL cholesterol, physical activity level, diabetic class, duration of diabetes, and waist-to-hip ratios are likely to be explained by body fat. Higher body fat measurements are known to correspond to higher dioxin levels, lower levels of HDL cholesterol, and higher cholesterol-HDL ratios. In addition, higher body fat is more likely to occur with sedentary lifestyles and a higher waist-to-hip ratio. The relation between measures associated with diabetes and dioxin exposure is analyzed in detail in Chapter 18, Endocrinology Assessment.

Of covariates related to sun exposure, the relation between dioxin and hair color was significant, but could be explained by military occupation. Eye color differed between Ranch Hands and Comparisons in that more Comparisons had brown eyes, but no difference between groups was seen in 1987 or initial dioxin levels. More Ranch Hands had peach skin color than Comparisons and Ranch Hands with peach skin color had higher 1987 dioxin levels than Ranch Hands with a nonpeach skin color. On average, a greater percentage of Comparisons lived in latitudes closer to the equator than did Ranch Hands and higher levels of dioxin were seen for those Ranch Hands who live in latitudes closer to the equator. No significant associations were observed with the reaction to sun-exposure covariates.

Any relation between dioxin and current total household income, education, current employment status, current marital status, and having a child younger than 18 years old living at home appeared to be directly related to military occupation. Participants who were officers at the time of service in SEA were more likely to have higher current incomes than participants who were enlisted at the time of service in SEA. Officers had the lowest dioxin levels (Table 8-1); consequently, there was an inverse association between income and dioxin. A greater percentage of officers tended to be college graduates than enlisted personnel, and, consequently, college graduates had lower dioxin levels than participants with at most a high school diploma. Current marital and parental status may be related to military occupation directly or indirectly through the relation between military occupation and socioeconomic factors. No associations were seen between dioxin exposure and working with vibrating power equipment, exposure to heavy metals, or length of exercise prior to blood pressure measurements.

8.10 CONCLUSION

This chapter investigates whether the covariates used throughout this report were associated with herbicide or dioxin exposure and, therefore, could potentially be confounding variables in subsequent statistical analyses. Military occupation, being associated with education, may have influenced the associations between covariates and dioxin estimates. The associations between covariates and the estimates of dioxin exposure in this chapter were adjusted for military occupation, but not for other

known or suspected confounders. Therefore, associations between covariates and dioxin estimates should be interpreted with caution.

In general, the Ranch Hand and Comparison groups were similar for the majority of the covariates, with the following exceptions: current cigarette smoking, lifetime wine use, physical activity levels, uric acid levels, herbicide exposure, insecticide exposure, ionizing radiation exposure, eye color, and average lifetime residential latitude. A greater percentage of Ranch Hands than Comparisons reported herbicide exposure. Although the questionnaire had been structured to indicate post-SEA exposure only, a possible explanation for this association between group and herbicide exposure may have been the tendency of Ranch Hands to report their exposure to dioxin during their time of duty in SEA. A greater percentage of Ranch Hands reported exposure to insecticides than did Comparisons, and more Comparisons reported ionizing radiation exposure. More Comparisons had a history of wine use than Ranch Hands. Ranch Hands had a higher average level of current cigarette use than Comparisons. More Comparisons than Ranch Hands lived in latitudes closer to the equator. Ranch Hands who lived closer to the equator had a higher average initial and 1987 dioxin level than Ranch Hands living farther from the equator.

Most of the significant associations between dioxin and the covariates in the Ranch Hand group can be explained at least partially by the associations between dioxin and military occupation or body mass index. Of the three military occupational cohorts, enlisted groundcrew had the highest levels of 1987 and initial dioxin. Adjusted analyses in the clinical chapters fully account for group, age, military occupation, and other potential confounders to further investigate significant associations between covariates and dioxin. Body mass index and the half-life of dioxin are known to be related; consequently, the Models 2 and 3 analyses in the clinical chapters were adjusted for body mass index. In addition, body mass index was used as a risk factor where appropriate. The reader is referred to the clinical chapters for a more complete assessment of the associations between dioxin and relevant medical endpoints.

9 GENERAL HEALTH ASSESSMENT

9.1 INTRODUCTION

9.1.1 Background

9.1.1.1 *Organs/Diseases*

Four variables were included in the Air Force Health Study (AFHS) general health assessment: self-perception of health, appearance of illness or distress during the examination, relative age, and body mass index. For the evaluation of self-perception of health, each participant was asked to rate his health (excellent, good, fair, poor) compared to other people his age. In addition, a board-certified internist examined the participants for the appearance of acute illness or distress (yes or no). The internist assessed whether each subject appeared younger than, older than, or the same as his stated age to determine relative age. Body mass index was computed based on height and weight recorded at the physical examination. Erythrocyte sedimentation rate had been discussed under the general health assessment for previous AFHS examination reports, but this laboratory parameter is in the hematology assessment (see Chapter 16).

9.1.1.2 *Toxicology*

The assessment of the risk of dioxin exposure to human health is in large part based on the molecular and cellular mechanisms of dioxin toxicity in animals and has been the subject of numerous review articles (1-8). In laboratory animals, dioxin toxicity is species- and strain-specific and appears to correlate with the presence of a stereospecific protein receptor, the aryl hydrocarbon (Ah) receptor, found in the cytosol of selected organs and capable of binding aromatic hydrocarbons (9-12). Ah receptors have been isolated in the tissue of several human organs (12-17), and the comparative properties of animal and human Ah receptors have been studied (18, 19). A recent literature review concluded that toxicological data continue to support the role of the Ah receptor in dioxin toxicity, and the biological plausibility of endpoints of toxicity in humans similar to those found in animals (20). The exact mechanistic basis of the differences in toxicity found across species and tissue types, however, is not known (20). Nevertheless, these studies of animal toxicology and the presence of the Ah receptor in humans form the basis for several epidemiologic studies that evaluate the association between dioxin exposure and numerous health outcomes.

9.1.1.3 *Epidemiology*

Although the potentially lethal consequences of acute phenoxy herbicide toxication in humans have been well-defined (21, 22), the long-term effects of herbicide exposure on human health remain controversial. Epidemiologic studies of such long-term health effects published in scientific literature have focused on target organ effects defined in animal models, including immunotoxicity, carcinogenicity, hepatotoxicity, and neurotoxicity. These epidemiologic studies were based on cohorts of Vietnam veterans (23-47), civilian populations occupationally exposed to dioxins (48-79), or consequences of industrial accidents (68, 80-90). Such studies were reviewed comprehensively (20, 91-97), and were considered in detail in subsequent chapters of this report.

Exposure assessments in early investigations of human health effects of herbicides relied on job titles or production processes from work history records, occupations from death certificates, cancer registries or hospital records, job tasks or exposure status based on self-reports, or residential locations. The lack of an accurate measure of exposure is recognized as the most important methodological limitation common to all of these studies (91).

Assay techniques developed in 1987 by the Centers for Disease Control and Prevention (CDC) (98) permitted the accurate detection and quantitative measurement of trace amounts of dioxin in blood and adipose tissue and the identification of subjects with prior exposure to dioxin. The CDC's study of serum dioxin levels demonstrated that there was no significant difference in the current body burden of dioxin between most Vietnam and non-Vietnam veterans of the same era (99, 100). Nevertheless, it has been shown that of all veterans who served in Vietnam, the Air Force Ranch Hand personnel were among those exposed most highly to dioxin and that, within this group, the enlisted groundcrew responsible for handling the herbicides and for maintaining the spray equipment were at the greatest risk for exposure (26, 27, 101).

Analyses of serum dioxin data from the AFHS (102, 103) and several other epidemiologic studies (67, 104-106) were published and have contributed to a better understanding of the pharmacokinetics of dioxin in humans. The reliability and reproducibility of the serum dioxin assay were established (107) and the potential effects of age, body fat, and time since exposure on the rate of dioxin elimination were explored (102). These recent analyses confirmed an earlier report (108) that an increase in body fat is associated with prolongation of the dioxin half-life, a finding that may be relevant to the development of clinical endpoints related to obesity. Based on the pharmacokinetic analyses of serial serum dioxin levels taken from Ranch Hand veterans and subjects exposed to dioxin after an industrial accident, the half-life of dioxin in humans is estimated to be 7.6 years (45). Dioxin was observed to be more rapidly eliminated within the first few months of exposure among individuals who were briefly exposed (44).

The importance of the serum dioxin assay is reflected in the number of publications reporting serum dioxin levels in exposed populations around the world, including the United States (49, 77, 101, 103, 109-114), Asia (78, 79, 115, 116), Germany (117-119), Russia (76, 120, 121), New Zealand (122), Austria (123), Australia (124), and Italy (86, 106, 125).

In response to unanswered questions and ongoing concerns that Vietnam veterans may have been harmed by herbicide defoliants, Congress passed the Agent Orange Act of 1991 in February 1991. Under this legislation, Public Law 102-4, the National Academy of Sciences, Institute of Medicine (IOM), was mandated to conduct an independent review of all scientific evidence relevant to the issue of health effects of Agent Orange, and to make recommendations for the directions of future research. The first IOM report (91), *Veterans and Agent Orange*, was published in 1994, with biennial updates published in 1996, 1998, 2000, and 2002 (20, 92, 96, 97). These reports provide a comprehensive resource of information on the potential health consequences of exposure to herbicides and, particularly, to the contaminant dioxin. Among the valuable contributions of the IOM reports (20) is the assessment of the scientific evidence for and against a statistical association with herbicide or dioxin exposure according to four categories: (1) sufficient evidence of an association, (2) limited or suggestive evidence of an association, (3) inadequate or insufficient evidence to determine whether an association exists, and (4) limited or suggestive evidence of no association. The committee established by the IOM concentrated its efforts on epidemiologic studies to evaluate the statistical association (20).

The committee in 1994 emphasized the merits of the model of the AFHS and proposed that a similar methodology be applied to a study of the only other veteran group with significant herbicide exposure—

the Army Chemical Corps (91). In the first IOM report (91), the committee endorsed the continued follow-up of the Air Force Ranch Hand and Comparison cohorts.

In the 1982, 1985, 1992, and 1997 AFHS examinations, dioxin-exposed cohort members perceived themselves to be in poorer health than unexposed participants (23, 24, 27, 34). No differences were noted in the appearance of illness or relative age (34). In the 1987, 1992, and 1997 examinations, a positive association was observed between obesity and the serum dioxin level (26, 27, 34). Apart from the AFHS examinations, only a few published reports related clinical and laboratory indices other than those described above to serum or adipose dioxin levels (49, 66, 68, 87, 126-129). These studies, which related specific health outcomes with evidence of prior exposure to dioxin, are discussed in subsequent chapters.

9.1.2 Summary of Previous Analyses of the AFHS

9.1.2.1 1982 Baseline Examination Summary Results

General health variables for the 1982 baseline examination included self-perception of health, appearance of illness or distress, relative age, and body fat. A statistically significant difference in self-perception of health was found between the Ranch Hand and Comparison groups, with a greater percentage of Ranch Hands reporting their health as fair or poor than Comparisons (20.6% versus 14.2%). This was true in both the younger and older age groups. Because only 9 (8 Ranch Hands) of 1,811 individuals were reported by the examining physician as appearing ill or distressed, this designation was apparently reserved for only very ill or distressed individuals. Conversely, more Ranch Hands than Comparisons were reported by the examiners as appearing younger than their actual ages (4.9% versus 2.5%, $p=0.029$). No overall differences in body fat were found.

9.1.2.2 1985 Follow-up Examination Summary Results

General physical health was evaluated by the same measures used in the baseline examination (self-perception of health, appearance of illness or distress, relative age, and body fat). The Ranch Hands again rated their health as fair or poor more often than the Comparisons (9.1% versus 7.3%, respectively), although this difference was not statistically significant. Further analysis revealed a significant group-by-occupation interaction. Differences were largely confined to the enlisted groundcrew category where the adjusted relative risk was 1.90 ($p=0.003$).

Ten individuals were reported as appearing acutely ill or distressed at the 1985 follow-up examination. In contrast to the baseline examination, four were Ranch Hands and six were Comparisons; thus, no group difference was suggested. Relative age, as determined by the examining physician, was not significantly different in the two groups.

The mean body fat of the Ranch Hands was significantly lower than the Comparisons (21.10 percent versus 21.54 percent, $p=0.037$), and the difference was of nearly the same magnitude after adjustment for age, race, and occupation.

Longitudinal differences between the 1982 baseline and the 1985 follow-up examination were assessed by analyses of self-perception of health. Analysis of self-perception of health showed no significant group differences in the change over time, with the Ranch Hand and Comparison groups reporting symmetrical improvements in their perceptions over the 3-year period.

9.1.2.3 1987 Follow-up Examination Summary Results

The general health in the Ranch Hand and Comparison groups was assessed by the same measures used in previous AFHS examinations: self-perception of health, appearance of illness or distress, relative age, and body fat. There were no significant group differences nor were there any significant group-by-covariate interactions for self-perception of health, appearance of illness or distress, relative age, or percent body fat. Longitudinal analyses revealed a similar decline in both groups over time in the percentage of individuals reporting their health as fair or poor.

9.1.2.4 Serum Dioxin Analysis of 1987 Follow-up Examination Summary Results

Body fat exhibited a significant positive association with initial dioxin. The adjusted analysis of relative age appearance exhibited significant interactions between dioxin and time since tour of duty. For Ranch Hands with 18.6 years or less since the end of duty in Southeast Asia (SEA), the associations between relative age and dioxin were positive and significant for the adjusted analysis under the minimal exposure assumption (i.e., Ranch Hands with less than or equal to 10 ppt of dioxin, as measured in 1987, were not used). For the other variables, the dioxin-by-time analyses generally displayed nonsignificant but positive associations with dioxin.

In general, the adjusted analyses for the four dioxin categories overall exhibited significant contrasts for body fat, with Ranch Hands exceeding Comparisons for the high versus background contrast and the low versus background contrast. The body fat results of dioxin in its categorized form displayed an increasing association with dioxin within the Ranch Hands (i.e., unknown [termed as “background” in subsequent reports], low, and high categories); however, the background category for Comparisons exceeded the unknown category for Ranch Hands.

The longitudinal analyses of self-perception of health demonstrated significant positive associations with dioxin. The percentage of participants who reported fair or poor health decreased by more than 50 percent from 1982 to 1987.

9.1.2.5 1992 Follow-up Examination Summary Results

In the assessment of general health, significant differences between Ranch Hands and Comparisons—the enlisted groundcrew in particular—were evident for self-perception of health. Significant associations between negative self-perception of health and levels of dioxin also were evident. These results were consistent with the 1985 and 1987 follow-up examinations. In contrast to self-perception of health, no significant results were found for the appearance of illness or distress and relative age appearance, which were recorded by the examining physicians. The analyses of body fat displayed a significant positive association with dioxin, whether calculated on a whole-weight or lipid-adjusted basis.

In the longitudinal analysis, the increase in the percentage of Ranch Hands who perceived their health to be poor in 1992 from those that were normal in 1982 was significantly associated with initial dioxin levels. Relative age appearance also displayed a significant positive association with initial dioxin. The change in body fat from 1982 to 1992 was significantly associated with initial dioxin, and a significant difference between Ranch Hands and Comparisons also was found, especially in enlisted groundcrew.

9.1.2.6 1997 Follow-up Examination Summary Results

The self-perception of health analysis revealed significant differences among Ranch Hands and Comparisons, with more Ranch Hands than Comparisons indicating their health as fair or poor. As in previous examinations, the difference was most apparent in enlisted groundcrew, who had the highest

median dioxin level. This observation also was confirmed in the categorized dioxin analysis, where Ranch Hands with the highest dioxin levels perceived their health as fair or poor more often than Comparisons. Also, among Ranch Hands, those with the higher 1987 dioxin levels reported fair or poor health more often than Ranch Hands with lower levels. These results were consistent with the 1985, 1987, and 1992 examinations. No group differences were noted in the appearance of illness or relative age, as recorded by examining physicians, nor were these variables correlated with serum dioxin levels in the Ranch Hand cohort.

The analysis of body fat indicated positive associations with dioxin levels. The results of the 1997 examination confirmed those of the 1992 examination and appear consistent with a difference in dioxin pharmacokinetics in obese versus lean individuals.

In conclusion, fair or poor self-perception of health displayed an adverse association with dioxin. Increased body fat was associated with increased levels of dioxin exposure, a finding most likely related to the pharmacokinetics of dioxin elimination. Other measures of general health revealed no association with levels of dioxin.

9.1.3 Parameters for the 2002 General Health Assessment

9.1.3.1 Dependent Variables

The general health assessment was based on data from the 2002 questionnaire and physical examination.

9.1.3.1.1 Questionnaire Variable

During the health interview administered through the 2002 National Opinion Research Center (NORC) questionnaire, each AFHS participant was asked the following: “Compared to other people your age, would you say your health is excellent, good, fair, or poor?” This self-reported perception was analyzed as a measure of the general health status of each participant, although it was recognized that the perception was susceptible to varying degrees of conscious and subconscious bias (e.g., most participants were aware of their serum dioxin levels). This variable was dichotomized as “excellent or good” and “fair or poor” for statistical analyses. No participants were excluded for medical reasons from the analysis of this variable.

9.1.3.1.2 Physical Examination Variables

Three variables derived from the 2002 Scripps Clinic physical examination were analyzed in the assessment of general health. For the first variable, the board-certified internist at the examination recorded the appearance of acute illness or distress (yes, no) of the AFHS participant. For the second variable, the internist noted the appearance of the subject as younger than, older than, or the same as his stated age. This variable was dichotomized as “older than” and “same as or younger than” for statistical analyses. Because the examining internist was kept blind to the participant’s group membership, these assessments were less subject to bias than the self-perception of health.

The third variable, body mass index, was calculated as $\text{weight}/(\text{height})^2$, where the weight was measured in kilograms and the height was measured in meters at the physical examination (130). This variable was analyzed in both the discrete and continuous forms. For purposes of discrete analyses, body mass index was dichotomized as “not obese” ($\leq 30 \text{ kg/m}^2$) and “obese” ($> 30 \text{ kg/m}^2$). Underweight participants ($< 18.5 \text{ kg/m}^2$) and participants with a normal body mass index (131) were combined into one category because only four participants (two Ranch Hand, two Comparison) fit this definition. This variable does not

reflect changes in weight since time of duty in SEA. No participants were excluded for medical reasons from the analyses of these three variables.

9.1.3.2 Covariates

The effects of the covariates age (in years), race (Black, non-Black), military occupation (officer, enlisted flyer, enlisted groundcrew), current cigarette smoking (cigarettes/day), lifetime cigarette smoking history (pack-years), current alcohol use (drinks/day), and lifetime alcohol history (drink-years) were used for analyses with all dependent variables.

Age, race, and military occupation were determined from military records. Lifetime alcohol history was based on information from the 2002 questionnaire and combined with similar information gathered at the 1987, 1992, and 1997 follow-up examinations. Each participant was asked about his drinking patterns throughout his lifetime. When a participant's drinking pattern changed, he was asked to describe how his alcohol consumption differed and the duration of time that the drinking pattern lasted. The participant's average daily alcohol consumption was determined for each of the reported drinking pattern periods throughout his lifetime, and an estimate of the corresponding total number of drink-years was derived. One drink-year was the equivalent of drinking 1.5 ounces of an 80-proof alcoholic beverage, one 12-ounce beer, or one 5-ounce glass of wine per day for 1 year. Current alcohol use was defined as the average number of drinks per day during the 2 weeks prior to completing the physical examination.

Current cigarette smoking and lifetime cigarette smoking history were based on questionnaire data. For lifetime cigarette smoking history, the respondent's average smoking was estimated over his lifetime based on his responses to the 2002 questionnaire, with 1 pack-year defined as 365 packs of cigarettes smoked during a single year.

9.1.4 Statistical Methods

Table 9-1 summarizes the statistical analysis performed for the 2002 general health assessment. The first part of this table lists the dependent variables analyzed, source of the data, form of the data, cutpoints, covariates, exclusions, and statistical methods. The second part of the table further describes the covariates. A covariate was used in its continuous form whenever possible for all adjusted analyses. If the covariate was inherently discrete (e.g., military occupation), or if a categorized form was needed to develop measures of association with the dependent variables, the covariate was categorized as shown in Table 9-1.

Table 9-1. Statistical Analysis for the General Health Assessment

Dependent Variables

Variable (Units)	Data Source	Data Form	Cutpoints	Covariates ^a	Exclusions	Statistical Analysis and Methods
Self-perception of Health	Q-SR	D	Fair or Poor Excellent or Good	(1)	None	U:LR,CS A:LR

Four models were examined for each dependent variable given in Table 9-1. The analyses of these models are presented below. Further details on dioxin and the modeling strategy are found in Chapters 2 and 7, respectively. These analyses were performed both unadjusted and adjusted for covariates. These covariates are given in Table 9-1. Model 1 examined the relation between the dependent variable and group (i.e., Ranch Hand or Comparison). In this model, exposure was defined as “yes” for Ranch Hands and “no” for Comparisons without regard to the magnitude of the exposure. In an attempt to quantify exposure, three contrasts of Ranch Hands and Comparisons were performed along with the overall Ranch Hand versus Comparison contrast. These three contrasts compared Ranch Hands and Comparisons within each military occupational category (i.e., officers, enlisted flyers, and enlisted groundcrew). As described in previous reports and Table 2-4, the median level of exposure to dioxin was highest for enlisted groundcrew, followed by enlisted flyers, then officers.

During the 1987, 1992, 1997, and 2002 examinations, serum dioxin levels were measured by the CDC using high-resolution gas chromatography and high-resolution mass spectrometry and were reported in parts per trillion (ppt) on a lipid weight basis (132). These dioxin measurements are referred to as “lipid-adjusted.” All measures of dioxin used in this report were based on lipid-adjusted dioxin measurements.

Model 2 examined the relation between the dependent variable and an extrapolated initial dioxin measure for Ranch Hands who had a 1987 dioxin measurement greater than 10 ppt. The initial dioxin was calculated by extrapolating the 1987 dioxin level back in time to the end of the tour of duty that qualified a Ranch Hand veteran for inclusion in this study. If a Ranch Hand did not have a 1987 dioxin level, then the first dioxin measured, either at 1992, 1997, or 2002, was used to estimate the initial dioxin level. Regardless of when the dioxin was measured, Ranch Hand veterans with a level less than or equal to 10 ppt were excluded from statistical analyses based on Model 2. A statistical adjustment for body mass index at the time of the participant’s blood measurement of dioxin was included in this model to account for body mass index-related differences in elimination rate (45). This adjustment was accomplished for the unadjusted and adjusted analyses of all dependent variables except body mass index in 2002. The use of body mass index at the time of the participant’s blood measurement of dioxin as a covariate may mask the relation between body mass index in 2002 and the dioxin measure.

Model 3 divided the Ranch Hands examined in Model 2 into two categories based on their initial dioxin measures. These two categories were referred to as “low Ranch Hand” and “high Ranch Hand.” Two additional categories—Ranch Hands with serum dioxin levels at or below 10 ppt and Comparisons—were formed and included in the model. Ranch Hands with serum dioxin levels at or below 10 ppt were assigned to the “background Ranch Hand” category. If a Ranch Hand did not have a 1987 dioxin measurement, the first measured dioxin level was used. Another category was examined by combining the low and high Ranch Hand categories. This combination is referred to in the tables as the “low plus high Ranch Hand” category. These five categories—Comparisons, background Ranch Hands, low Ranch Hands, high Ranch Hands, and low plus high Ranch Hands—were used in Model 3 analyses. The relation between the dependent variable in each of the four Ranch Hand categories and the dependent variable in the Comparison category was examined. As in Model 2, a statistical adjustment for body mass index at the time of the participant’s blood measurement of dioxin was included in this model for the unadjusted and adjusted analyses of all dependent variables except body mass index in 2002. One Ranch Hand without a dioxin measure was excluded from statistical analyses based on Model 3.

Model 4 examined the relation between the dependent variable and 1987 dioxin levels in all Ranch Hands with a dioxin measurement. If a Ranch Hand did not have a 1987 dioxin measurement, the first dioxin level obtained, either in 1992, 1997, or 2002, was extrapolated to the date of the 1987 physical examination. If the first dioxin level was not obtained in 1987 and was less than or equal to 10 ppt, it was

not extrapolated to 1987 level, but was used at the measured value. One Ranch Hand without a dioxin measurement was excluded from statistical analyses based on Model 4.

The term “unadjusted” was used in the text and tables as follows: Models 1 and 4 did not adjust for any covariates. Models 2 and 3 adjusted only for body mass index at the time of the blood measurement for dioxin, although no such adjustment was made when the dependent variable was body mass index at the time of the 2002 physical examination.

The term “adjusted” was used in the text and tables as follows: Models 1 and 4 adjusted for the covariates shown in Table 9-1 unless otherwise specified by a footnote to the table. Models 2 and 3 additionally adjusted only for body mass index at the time of the blood measurement for dioxin, although no such adjustment was made when the dependent variable was body mass index at the time of the 2002 physical examination.

Table 9-2 provides a summary of the number of participants with missing dependent variable and covariate data.

Table 9-2. Number of Participants with Missing Data for the General Health Assessment

Variable	Variable Use	Group ^a		Dioxin (Ranch Hands Only) ^b		Categorized Dioxin ^c	
		Ranch Hand	Comparison	Initial Dioxin	1987 Dioxin	Ranch Hand	Comparison

^a777 Ranch Hands and 1,174 Comparisons for group.

^b424 Ranch Hands for initial dioxin; 776 Ranch Hands for 1987 dioxin.

^c776 Ranch Hands and 1,174 Comparisons for categorized dioxin.

Note: COV = Covariate.

DEP = Dependent variable.

9.2 RESULTS

9.2.1 Dependent Variable-covariate Associations

The dependent variables in the general health assessment were tested for associations with each of the covariates used in the adjusted analyses. The complete results are presented in Appendix F, Table F-1. These associations were pairwise between the dependent variable and the covariate and were not adjusted

for any other covariates. A brief summary of the pattern of significant ($p \leq 0.05$) dependent variable-covariate associations is described in the following paragraphs.

Age was associated with appearance of illness or distress, as well as body mass index in its continuous form. A higher percentage of older participants appeared ill or distressed than the younger participants. Body mass decreased with age.

All dependent variables were associated with military occupation, except for appearance of illness or distress. Enlisted personnel had a higher percentage of abnormal results for self-perception of health and relative age appearance than officers. Officers were classified as obese less often and had a lower mean body mass index than enlisted personnel.

Current cigarette smoking was associated with all dependent variables. The percentage of abnormal results for self-perception of health, appearance of illness or distress, and relative age appearance increased with current cigarette smoking. Body mass decreased as current cigarette smoking levels increased.

Lifetime cigarette smoking was associated with self-perception of health, appearance of illness or distress, and relative age appearance. In each of these dependent variables, the heaviest smokers (in terms of pack-years) had the highest percentage of abnormalities.

Current alcohol use was associated with body mass index in its continuous form. Body mass decreased as current alcohol use increased.

Both self-perception of health and body mass index in its continuous form were associated with lifetime alcohol history. The highest percentage of participants who perceived their health as fair or poor was among nondrinkers, followed by heavy lifetime drinkers and moderate lifetime drinkers. Body mass decreased as lifetime alcohol use increased.

9.2.2 Exposure Analysis

The following section presents results of the statistical analyses of the dependent variables shown in Table 9-1. Dependent variables are grouped into two sections: (1) the questionnaire variable self-perception of health, derived from the questionnaire that was administered in the 2002 follow-up examination, and (2) the physical examination variables, obtained during the 2002 physical examination.

9.2.2.1 Questionnaire Variable

9.2.2.1.1 Self-perception of Health

The unadjusted and adjusted analyses for Models 1 through 4 showed no significant results (Table 9-3(a-d): $p > 0.05$ for each analysis).

Table 9-3. Analysis of Self-perception of Health

(a) MODEL 1: RANCH HANDS VS. COMPARISONS – UNADJUSTED					
Occupational Category	Group	n	Number (%) Fair or Poor	Unadjusted Relative Risk (95% C.I.)	p-Value

9.2.2.2.2 Relative Age Appearance as Assessed by Physician

The unadjusted and adjusted analyses in Models 1 and 2 showed no significant results (Table 9-5(a-d): p>0.15 for each analysis).

The unadjusted Model 3 analysis of relative age appearance as assessed by a physician revealed significant differences between Ranch Hands in the high dioxin category and Comparisons (Table 9-5(e): Unadjusted Relative Risk [RR]=2.01, p=0.016), as well as between Ranch Hands in the low and high dioxin categories combined and Comparisons (Table 9-5(e): Unadjusted RR=1.73, p=0.023). The

percentages of participants appearing older among Ranch Hands in the high dioxin category, Ranch Hands in the low and high categories combined, and Comparisons were 8.5, 7.3, and 4.1, respectively. After adjusting for covariates, neither difference was significant (Table 9-5(f): $p=0.223$ for high Ranch Hands versus Comparisons; $p=0.116$ for low and high Ranch Hands combined).

A significant relation between relative age appearance and 1987 dioxin was seen in the unadjusted Model 4 analysis (Table 9-5(g): Unadjusted RR=1.34, $p=0.002$). The percentages of Ranch Hands who appeared older than their stated age were 2.3, 4.3, and 9.3 for the low, medium, and high 1987 dioxin categories. After adjusting for covariates, the relation was not significant ($p=0.061$).

Note: Results were not adjusted for race because of the sparse number of Ranch Hands who appear older than their stated age.

9.2.2.2.3 Body Mass Index (Continuous)

No significant associations with dioxin were shown in all Model 1 and 2 unadjusted and adjusted analyses of body mass index in its continuous form (Table 19-6(a-d): p>0.20 for each analysis).

All four contrasts were significant in the unadjusted Model 3 analyses of body mass index (Table 9-6(e): difference of means=-1.20 kg/m², p<0.001 for Ranch Hands in the background category versus Comparisons; difference of means=0.81 kg/m², p=0.010 for Ranch Hands in the low dioxin category; difference of means=1.20 kg/m², p<0.001 for Ranch Hands in the high dioxin category; and difference of means=1.00 kg/m², p<0.001 for Ranch Hands in the low and high dioxin categories combined).

Adjusting for covariates revealed similar results (Table 9-6(f): difference of adjusted means=-1.04 kg/m², p<0.001 for Ranch Hands in the background category versus Comparisons; difference of adjusted means=0.87 kg/m², p=0.006 for Ranch Hands in the low dioxin category; difference of means=1.15 kg/m², p<0.001 for Ranch Hands in the high dioxin category; and difference of means=1.01 kg/m², p<0.001 for Ranch Hands in the low and high dioxin categories combined).

Both unadjusted and adjusted analyses showed Comparisons had a significantly higher mean body mass index than did Ranch Hands in the background dioxin category (28.85 kg/m² versus 27.81 kg/m² for the adjusted analysis). Conversely, the adjusted mean body mass index of Ranch Hands in each of the low

(29.72 kg/m²), high (30.00 kg/m²), and low and high dioxin categories combined (29.86 kg/m²) was significantly greater than Comparisons (28.85 kg/m²).

The Model 4 unadjusted and adjusted analyses each revealed a significant association between 1987 dioxin levels and body mass index (Table 9-6(g): Slope=0.024, p<0.001 and (h): Adjusted Slope=0.026, p<0.001). Body mass index increased as dioxin levels increased. Adjusted mean body mass index values for the low, medium, and high 1987 dioxin categories were 26.93 kg/m², 28.88 kg/m², and 29.65 kg/m², respectively.

9.2.2.2.4 Body Mass Index (Discrete)

All Model 1 and 2 unadjusted and adjusted analyses of body mass index in its discrete form were nonsignificant (Table 9-7(a-d): p>0.65 for each analysis).

The unadjusted Model 3 analysis of body mass index revealed significant results in all four contrasts (Table 9-7(e): Unadjusted RR=0.55, p<0.001 for Ranch Hands in the background dioxin category; Unadjusted RR=1.44, p=0.016 for the Ranch Hands in the low dioxin category; Unadjusted RR=1.62, p=0.001 for Ranch Hands in the high dioxin category; and Unadjusted RR=1.53, p<0.001 for Ranch Hands in the low and high dioxin categories combined). The percentage of obese participants was higher for Comparisons (35.3%) than for Ranch Hands in the background dioxin category (23.1%). The percentage of obese participants, however, was lower for Comparisons than for Ranch Hands in the low, high, and low and high dioxin categories combined (44.1%, 46.9%, and 45.5%, respectively).

Similarly, all contrasts were significant after adjusting for covariates in Model 3 (Table 9-7(f): Adjusted RR=0.59, p<0.001 for Ranch Hands in the background dioxin category; Adjusted RR=1.48, p=0.011 for the Ranch Hands in the low dioxin category; Adjusted RR=1.52, p=0.009 for Ranch Hands in the high dioxin category; and Adjusted RR=1.50, p=0.001 for Ranch Hands in the low and high dioxin categories combined).

The Model 4 unadjusted and adjusted analyses revealed significant positive associations between body mass index and 1987 dioxin levels (Table 9-7(g): Unadjusted RR=1.31, p<0.001, and (h): Adjusted RR=1.31, p<0.001). The percentages of obese participants in the low, medium, and high 1987 dioxin categories were 21.6, 38.0, and 46.5, respectively.

9.3 DISCUSSION

The following four factors were considered when assessing the overall state of participant health in the 2002 AFHS: self-perception of health, appearance of illness, relative age, and body mass index. Clinicians often employ such measures to assess an overall state of health rather than a specific organ system. While these measures may be imperfect and were no doubt influenced by many variables, they do reflect overall health impressions from both self and observer perspectives.

The covariates included in the analysis were age, race, military occupation, current and lifetime cigarette smoking, and current and lifetime alcohol consumption. Such covariates gave insight into the factors having the most impact on general health measurements and helped to clarify whether findings of associations with herbicides or measures of dioxin were due to dioxin exposure or to factors that may not have been matched between groups in the design of the AFHS.

The relation between covariates and the general health endpoints were consistent with findings that are well established in clinical practice. Older participants were more likely to appear ill than younger participants. Analysis of body mass index also showed that age was inversely associated with body mass index. This result was consistent with other studies showing that adults older than 55 tend to lose weight (133).

Officers more often perceived their health to be in the “excellent” or “good” categories than did enlisted personnel. Many factors could have contributed to this observed association, such as the various levels of

education among the groups. Some studies have revealed that a higher level of formal education has a major impact on health status and the outcomes of most chronic diseases (134). Enlisted flyers appeared older than officers or enlisted groundcrew.

The association of smoking with ill appearance in this study underscores the pervasive effects of smoking on health. Both lifetime and current cigarette smoking were significantly associated with the perception of overall health, appearance of illness, and relative age appearance. In all cases, the more cigarettes smoked, the greater the likelihood the participants perceived themselves as ill or appeared ill. These results concur with the vast amount of literature that implicates smoking exposure as a major risk to overall health (135).

Former smokers perceived a level of health that approximates the “never smoker” level. This effect was consistent with other studies showing that some of the deleterious effects of smoking are reversible, such as the improvement of bronchial dysfunction commonly associated with active smoke exposure (136).

Current smoking also was associated with a decrease in body mass index. As the amount of cigarettes smoked increases, the percentage of obese participants decreased. This result was consistent with the common association made between smoking and weight loss.

General health, as measured in terms of self-perception, showed no significant differences in the studied populations by herbicide or dioxin exposure. Although some participants know their exposure levels and may have had concerns, such information did not appear to have had a significant effect on their perceived overall health at the 2002 follow-up examination.

During the course of the AFHS, however, self-perception of general health has shown mixed results since 1982. For example, the 1982 baseline study indicated that a greater percentage of Ranch Hands than Comparisons reported fair or poor health (20.6% for Ranch Hands versus 14.2% for Comparisons), as did the 1992 and 1997 follow-up examinations (10.4% of Ranch Hands versus 7.4% of Comparisons and 14.3% versus 10.4%, respectively). But in the 1985, 1987, and 2002 studies, no appreciable differences were seen between Ranch Hands and Comparisons. Thus, no persistent or emergent impact of herbicide or dioxin exposure on this general health measure has been observed, raising the possibility that participant concern regarding exposure decreased over time.

In 2002, the appearance of illness or distress as assessed by the examining physicians disclosed no differences between the Ranch Hand and Comparison groups, a finding similar to results reported in previous AFHS examinations. The appearance of illness classification was reserved for a relatively low percentage (approximately 4%) of participants who had significant manifestations of illness, such as cachexia and frailty.

The Ranch Hand and Comparison groups did not show any significant differences in appearing older than expected. Likewise, analysis did not suggest any association between appearing older than expected and dioxin levels. These results were generally consistent with previous AFHS results that showed no association between herbicide or dioxin exposure and relative age appearance.

The body mass index, a measurement of relative weight that adjusts for height, serves as a valuable clinical clue to the presence of disease and helps define obesity—an important health risk factor. Contrasts on body mass index showed no statistically significant difference between the Ranch Hand and Comparison groups or in initial dioxin levels within the Ranch Hands; however, in the categorized dioxin analyses, there was a detectable increase in the mean body mass index compared to the Comparison group for the low and high Ranch Hand dioxin categories. Likewise, 1987 dioxin levels were associated with

increased obesity in the analyses. Increased percentages of obesity were observed in relation to increasing dioxin exposure.

The 2002 body mass index results were similar to previous AFHS follow-up examinations in that obesity was highly correlated with dioxin levels. This association appears to be due to slower dioxin elimination pharmacokinetics in obese participants relative to participants who were lean or not obese. In part, participants with the highest dioxin levels retain dioxin due to their higher body fat content. A remarkable finding was that the prevalence of obesity in the participant population approaches 35 percent, which was somewhat greater than the national average of approximately 30 percent (137). Therefore, more than one-third of AFHS participants are at risk for health complications associated with obesity.

9.4 SUMMARY

The general health assessment was based on perception of health, as reported in the questionnaire by the participant, and physical examination data. Associations with herbicide exposure (i.e., group – Model 1), initial dioxin (Model 2), categorized dioxin (Model 3), and 1987 dioxin levels (Model 4) were examined for each variable in the general health assessment. The significant adjusted results are discussed in the sections below.

9.4.1 Model 1: Group Analysis

All group analyses (Ranch Hands versus Comparisons) revealed no significant differences between Ranch Hands and Comparisons overall or within each occupation. The results are summarized in Table 9-8.

Table 9-8. Summary of Group Analysis (Model 1) for General Health Variables (Ranch Hands vs. Comparisons)

Variable	UNADJUSTED			
	All	Officer	Enlisted Flyer	Enlisted Groundcrew
Questionnaire				
Self-perception of Health (D)	NS	NS	ns	NS
Physical Examination				
Appearance of Illness or Distress (D)	ns	NS	NS	ns
Relative Age Appearance (D)	NS	NS	NS	NS
Body Mass Index (C)	ns	NS	ns	NS
Body Mass Index (D)	NS	NS	ns	NS

Note: NS or ns: Not significant ($p>0.05$).

C: Continuous form of dependent variable.

D: Discrete form of dependent variable.

A capital “NS” denotes a nonsignificant positive association. A lowercase “ns” denotes a nonsignificant inverse association.

Table 9-8. Summary of Group Analysis (Model 1) for General Health Variables (Ranch Hands vs. Comparisons) (Continued)

Variable	ADJUSTED			
	All	Officer	Enlisted Flyer	Enlisted Groundcrew
Questionnaire				
Self-perception of Health (D)	NS	NS	ns	NS
Physical Examination				
Appearance of Illness or Distress (D)	ns	NS	NS	ns

Note: NS or ns: Not significant ($p>0.05$).

C: Continuous form of dependent variable.

D: Discrete form of dependent variable.

A capital “NS” denotes a nonsignificant positive association. A lowercase “ns” denotes a nonsignificant inverse association.

9.4.2 Model 2: Initial Dioxin Analysis

Each variable examined in the analyses of initial dioxin showed no significant findings. Results are displayed in Table 9-9.

Table 9-9. Summary of Initial Dioxin Analysis (Model 2) for General Health Variables (Ranch Hands Only)

Variable	Unadjusted	Adjusted
Questionnaire		
Self-perception of Health (D)	NS	NS
Physical Examination		
Appearance of Illness or Distress (D)	ns	NS
Relative Age Appearance (D)	NS	NS
Body Mass Index (C)	NS	NS
Body Mass Index (D)	NS	NS

Note: NS or ns: Not significant ($p>0.05$).

C: Continuous form of dependent variable.

D: Discrete form of dependent variable.

A capital “NS” denotes a nonsignificant positive association. A lowercase “ns” denotes a nonsignificant inverse association.

9.4.3 Model 3: Categorized Dioxin Analysis

Table 9-10 summarizes the results of the categorized dioxin analyses. The analyses of categorized dioxin yielded similar results for body mass index in its continuous form. The mean body mass index in the background Ranch Hand category was significantly lower than the Comparison mean, and the means in the low, high, and low and high combined Ranch Hand dioxin categories were significantly higher than the Comparison mean.

Analyses of body mass index in its discrete form revealed a significantly lower percentage of obese Ranch Hands in the background dioxin category, and a significantly higher percentage of obese Ranch Hands in the low, high, and low and high Ranch Hand categories combined, than Comparisons.

Table 9-10. Summary of Categorized Dioxin Analysis (Model 3) for General Health Variables (Ranch Hands vs. Comparisons)

Variable	UNADJUSTED			
	Background Ranch Hands vs. Comparisons	Low Ranch Hands vs. Comparisons	High Ranch Hands vs. Comparisons	Low plus High Ranch Hands vs. Comparisons
Questionnaire				
Self-perception of Health (D)	ns	NS	NS	NS
Physical Examination				
Appearance of Illness or Distress (D)	NS	NS	ns	ns
Relative Age Appearance (D)	ns	NS	p=0.016 (2.01)	p=0.023 (1.73)
Body Mass Index (C)	p<0.001 (-1.20)	p=0.010 (0.81)	p<0.001 (1.20)	p<0.001 (1.00)
Body Mass Index (D)	p<0.001 (0.55)	p=0.016 (1.44)	p=0.001 (1.62)	p<0.001 (1.53)

Note: NS or ns: Not significant ($p>0.05$).

C: Continuous form of dependent variable.

D: Discrete form of dependent variable.

The p-value was given if $p\leq 0.05$. The relative risk was given in parentheses for a significant result from the analysis of a discrete dependent variable. The difference in means was given in parentheses for a significant result from the analysis of a continuous dependent variable.

A capital “NS” denotes a nonsignificant positive association. A lowercase “ns” denotes a nonsignificant inverse association.

Appearance of Illness or Distress (D)	NS	ns	ns	ns
Relative Age Appearance (D)	ns	NS	NS	NS
Body Mass Index (C)	p<0.001 (-1.04)	p=0.006 (0.87)	p<0.001 (1.15)	p<0.001 (1.01)
Body Mass Index (D)	p<0.001 (0.59)	p=0.011 (1.48)	p=0.009 (1.52)	p=0.001 (1.50)

Table 9-10. Summary of Categorized Dioxin Analysis (Model 3) for General Health Variables (Ranch Hands vs. Comparisons) (Continued)

Note: NS or ns: Not significant ($p>0.05$).

C: Continuous form of dependent variable.

D: Discrete form of dependent variable.

The p-value was given if $p\leq 0.05$. The relative risk was given in parentheses for a significant result from the analysis of a discrete dependent variable. The difference in means was given in parentheses for a significant result from the analysis of a continuous dependent variable.

A capital “NS” denotes a nonsignificant positive association. A lowercase “ns” denotes a nonsignificant inverse association.

9.4.4 Model 4: 1987 Dioxin Level Analysis

The associations between the measures of general health studied in this assessment and the 1987 dioxin levels are presented in Table 9-11. The adjusted analysis showed that body mass index in both the continuous and discrete forms was significant.

Table 9-11. Summary of 1987 Dioxin Analysis (Model 4) for General Health Variables (Ranch Hands Only)

Variable	Unadjusted	Adjusted
Questionnaire		
Self-perception of Health (D)	NS	NS
Physical Examination		
Appearance of Illness or Distress (D)	ns	NS
Relative Age Appearance (D)	$p=0.002$ (1.34)	NS
Body Mass Index (C)	$p<0.001$ (0.024)	$p<0.001$ (0.026)
Body Mass Index (D)	$p<0.001$ (1.31)	$p<0.001$ (1.31)

Note: NS or ns: Not significant ($p>0.05$).

C: Continuous form of dependent variable.

D: Discrete form of dependent variable.

The p-value was given if $p\leq 0.05$. The relative risk was given in parentheses for a significant result from the analysis of a discrete dependent variable. The slope was given in parentheses for a significant result from the analysis of a continuous dependent variable.

A capital “NS” denotes a nonsignificant positive association. A lowercase “ns” denotes a nonsignificant inverse association.

9.4.5 Summary of Significant Results

Table 9-12 summarizes the significant results ($p\leq 0.05$) for the adjusted analyses that were performed for the general health assessment. The dependent variable and its table reference are listed along with the model and the contrast or description of the model. The p-value is provided along with analysis statistics

that correspond to the type of analysis that was performed (either continuous or discrete). A description of the analysis and the statistics that are presented is referenced under the “Note” column and is explained in footnotes.

Table 9-12. Summary of Results from Significant Adjusted Analyses in the General Health Assessment

Dependent Variable (Table Reference)	Model	Contrast or Description	p-Value	Analysis Statistics	Adjusted Mean or Percent Abnormal	Note
Body Mass Index (9-6)	3	Background RH vs. C	<0.001	-1.04	RH: 27.81 kg/m ² C: 28.85 kg/m ²	(a)
	3	Low RH vs. C	0.006	0.87	RH: 29.72 kg/m ² C: 28.85 kg/m ²	(a)
	3	High RH vs. C	<0.001	1.15	RH: 30.00 kg/m ² C: 28.85 kg/m ²	(a)
	3	Low plus High RH vs. C	<0.001	1.01	RH: 29.86 kg/m ² C: 28.85 kg/m ²	(a)
	4	All RH: 1987 dioxin	<0.001	0.026 (0.004)	Low: 26.93 kg/m ² Medium: 28.88 kg/m ² High: 29.65 kg/m ²	(b)
Body Mass Index (9-7)	3	Background RH vs. C	<0.001	0.59 (0.45,0.79)	RH: 23.1% C: 35.3%	(c)
	3	Low RH vs. C	0.011	1.48 (1.09,2.01)	RH: 44.1% C: 35.3%	(c)
	3	High RH vs. C	0.009	1.52 (1.11,2.07)	RH: 46.9% C: 35.3%	(c)
	3	Low plus High RH vs. C	0.001	1.50 (1.19,1.89)	RH: 45.5% C: 35.3%	(c)
	4	All RH: 1987 Dioxin	<0.001	1.31 (1.17,1.47)	Low: 21.6% Medium: 38.0% High: 46.5%	(d)

- (a): Continuous variable: difference of adjusted means was presented; confidence interval was not presented because analysis was performed on natural logarithm scale; adjusted means were transformed to original scale and were presented for each dioxin category in contrast.
- (b): Continuous variable: slope and standard error were presented and were based on natural logarithm of dependent variable versus log₂ (1987 dioxin); adjusted means were transformed to original scale and were presented for each of three 1987 dioxin categories.
- (c): Discrete variable: adjusted relative risk and 95% confidence interval were presented; percent abnormal was presented for each dioxin category in contrast.
- (d): Discrete variable: adjusted relative risk and 95% confidence interval were presented for a twofold increase in 1987 dioxin; percent abnormal was presented for each of three 1987 dioxin categories.

Note: RH = Ranch Hand.
C = Comparison.

Model 3: Background (Ranch Hand): 1987 dioxin ≤ 10 ppt.
Low (Ranch Hand): 1987 dioxin > 10 ppt, 10 ppt < initial dioxin ≤ 118 ppt.
High (Ranch Hand): 1987 dioxin > 10 ppt, initial dioxin > 118 ppt.

Model 4: Low = ≤7.8 ppt; Medium = >7.8–19.2 ppt; High = >19.2 ppt (Ranch Hands only).

9.5 CONCLUSION

Self-perception of health, appearance of illness, and relative age appearance were not found to be associated with herbicide exposure (Ranch Hand versus Comparison) or dioxin level. Body mass index was positively associated with 1987 dioxin, possibly reflecting the pharmacokinetics of dioxin elimination.

10 NEOPLASIA ASSESSMENT

10.1 INTRODUCTION

10.1.1 Background

10.1.1.1 Organs/Diseases

The Air Force Health Study (AFHS) included questionnaire, clinical assessments, and chest x-ray films to ascertain benign and malignant neoplasms. Medical records review was accomplished to confirm reported neoplasms and to identify any unreported neoplasms. In addition, when chest x-ray findings were reported as needing follow-up, the AFHS made every effort to contact and encourage participants to see their physicians and to determine a final diagnosis.

The AFHS evaluation of neoplasms distinguished between skin and systemic neoplasms, and both skin and systemic neoplasms were examined according to the following behavior types: all neoplasms, malignant neoplasms, benign neoplasms, and neoplasms of an unspecified nature. Malignant systemic neoplasms were analyzed according to specific sites. Finally, the prostate-specific antigen (PSA) levels were measured to detect prostate enlargement and prostate cancer.

The neoplasia assessment was based on the occurrence of neoplasms (both benign and malignant) after service in Southeast Asia (SEA). Information on the occurrence of neoplasms at the 1982 baseline examination and at the 1985, 1987, 1992, and 1997 follow-up examinations were coded according to conventions in the International Classification of Diseases, 9th Revision, Clinical Modification (ICD-9-CM) manual. This information was combined with data collected at the 2002 follow-up examination to form a complete neoplastic history for each participant. The analyses performed in this chapter were based on the 1,951 participants who attended the 2002 follow-up examination.

Cancers are considered to be related to a complex interplay between intrinsic (i.e., inherited genes, hormones, and immunologic mechanisms) and environmental factors. A number of lifestyle factors play a primary role in the etiology of cancers, including dietary constituents, tobacco use, patterns of reproduction, and alcohol consumption. In addition, infectious agents, workplace exposures, natural physical exposures, water and air pollution, medical products and procedures, and consumer products may contribute to an increased risk of developing cancer (1). Tobacco use has long been known to be a major risk factor for lung and laryngeal cancers and is suspected in the etiology of cancers of the bladder, liver, uterine cervix, and perhaps, breast (1). Arsenic, asbestos, benzene, cadmium, and vinyl chloride are among a variety of chemicals known to be human carcinogens (1). Also, a number of viruses, such as the Epstein-Barr herpesvirus, human papillomavirus, hepatitis B and C viruses, and the human immunodeficiency virus (1), are believed to contribute to the development of cancer.

10.1.1.2 Toxicology

Between 1977 and 1988, long-term exposure studies in experimental animals established the multiorgan carcinogenicity of 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD or dioxin) (2-9). The carcinogenic response to dioxin occurs in multiple strains and species, in both sexes, and by several routes of administration: dermal (6), feeding (2, 3, 10), gavage (4, 5, 7), and intraperitoneal injection (8). Dioxin has been considered a “complete” carcinogen solely responsible for a variety of malignant tumors at multiple sites (11). The affected sites and exposure needed to induce cancer at these sites varied

substantially from species to species (12, 13), and carcinogenic response varied by exposure rate (14). In rats, dioxin produced tumors of the liver, thyroid, adrenal cortex, lung, nasopharynx, tongue, brain, kidney, and breast (2, 3, 5); in mice, tumors of the liver, thymus, breast, stomach, and skin (4-7, 14); and in the Syrian Hamster, a squamous cell carcinoma of the skin (8). The histopathologic characteristics of the neoplastic response demonstrated greater variety—more than 30 distinct malignancies were characterized microscopically (15).

The biological basis for the assessment of risk related to dioxin exposure has been discussed in several molecular, biological, and pharmacologic studies and reviews (16-30). Experimental studies support an indirect, nongenotoxic mechanism of carcinogenicity of dioxins (26). The biological mechanisms for carcinogenicity, however, have not been firmly established (12, 26). Much of the basic research into the carcinogenicity of dioxin in laboratory animals focused on the properties of the aryl hydrocarbon (Ah) receptor and the induction of the cytochrome P-450 enzyme system (16, 28, 31-36). The Ah receptor was isolated from the tissues of several human organs (37-40) and the comparative properties of animal and human receptors were studied (41, 42). These experiments demonstrated far fewer Ah receptor sites and a significant reduction in dioxin binding affinity in human cells relative to rodent cell lines (23). Experimental animal models showed that health effects mediated by the Ah receptor are similar to those found in exposed human populations, and humans and animals appear to have similar degrees of sensitivity to dioxin-induced effects (25). In a random sample of individuals from Seveso, Italy, 20 years after the Seveso accident in 1976, an analysis of the expression of dioxin-inducible genes involved in carcinogenesis showed that serum dioxin levels are associated with a disrupted regulation of the Ah receptor (43).

10.1.1.3 Epidemiology

Many of the longitudinal studies of dioxin toxicity included malignancies as clinical endpoints based on cohorts of civilian populations exposed to dioxin through environmental contamination (43-59), occupation (60-107), and in association with service in SEA during the Vietnam War (108-128). Much debate has taken place over the carcinogenicity of dioxin, and results described in these epidemiologic studies have been the subject of considerable commentary and review (129-177).

One of the most extreme human exposures to dioxin occurred consequent to the industrial explosion in Seveso, Italy, in 1976 (43-53, 59). In the area closest to the explosion, soil concentrations of dioxin ranged from 15.5 to 580.4 $\mu\text{g}/\text{m}^2$, with a median serum dioxin level of 447 parts per trillion (ppt) measured immediately among residents after the accident (45). Median serum dioxin levels were lower in study areas farther away from the accident site, ranging from 5.5 ppt in unexposed referents to 94 ppt in the second-most contaminated area (45). In a mortality follow-up of this population through 1996, some indication for an increased risk of mortality from respiratory and lymphohematopoietic cancers was found among residents in the most ($n=804$) and second-most ($n=5,941$) contaminated areas as compared to the unexposed population, but consistent exposure-response gradients with time since first exposure were not observed. Males were found to have an increased risk of mortality from cancers of the rectum and lung, whereas females showed an increased risk of lymphatic and hematopoietic cancers (45). An earlier cancer incidence study suggested evidence for an elevated risk of hepatobiliary neoplasms and cancers of the hematopoietic system among inhabitants of the second-most contaminated area as compared to the reference population (46).

Other studies of environmental contamination also indicated an elevated risk of some cancers in relation to potential dioxin exposure (54-58). An increased risk of soft tissue sarcoma, which was hypothesized to be at least, in part, related to potential dioxin exposure (54), was found among a population of about 10,000 residents living near a chemical plant in Mantua, Italy. Elevated rates of soft tissue sarcoma and

non-Hodgkin's lymphoma were also found in a population living near a French municipal solid waste incinerator with high emission levels of dioxin (57, 58). Other studies found an increased risk of developing cancer of the lung in populations living near a chemical plant in Russia (56), and of mortality from all cancers combined near a municipal solid waste incinerator in Japan (55).

Carcinogenicity of occupational exposure to dioxins was primarily evaluated in nine worker cohorts in studies conducted by the International Agency for Research on Cancer (IARC) (80-82, 90) and the National Institute for Occupational Safety and Health (NIOSH) (74, 91, 92, 107), as well as in studies of production workers at Dow Chemical Company (63-65, 70-72, 86, 87, 89, 106), Monsanto (69, 95, 104), BASF (85, 88, 93, 96-98), and in the Netherlands (66, 79), Germany (60-62, 76-78), Britain (68, 103), and Denmark (101, 102). The IARC study included the Dutch, German, British, and Danish workers, whereas the NIOSH cohort included workers studied separately in the Dow Chemical Company and Monsanto studies.

The most recent update of the IARC follow-up study, published in 1997, evaluated the mortality of 21,863 male and female workers exposed to dioxins in 12 countries from 1939 to 1992 (80). Elevated risks of cancer mortality from the kidney, bladder, female breast, respiratory organs, and connective tissue and other soft tissues were observed among workers exposed to dioxins. The risk of mortality from all malignant neoplasms, lung cancer, and non-Hodgkin's lymphoma was slightly increased, but no relation with duration of exposure was found (80). A case-control study of 11 cases and 55 controls nested within this cohort found an excess risk of soft tissue sarcoma in relation to dioxin exposure (81).

Two cohorts included in the IARC study evaluated cancer risk in relation to serum dioxin levels. In the German study of 1,189 male workers involved in the production of herbicides and insecticides, cancer mortality was evaluated from 1952 through 1992 (62, 77, 78). An average serum dioxin level of 108.6 ppt was observed. Total cancer mortality was elevated in a dose-response fashion, whereas risks were elevated for neoplasms of the lung and lymphohematopoietic system, but inconsistently related to serum dioxin levels (62, 78). In a 1998 update of the Dutch cohort of 1,167 workers from 1955 through 1991, reported average serum dioxin levels were 7.6 ppt in unexposed workers and ranged from 16.6 to 96.3 ppt in those exposed. Some indication of an exposure-related cancer risk was found (79).

As part of the NIOSH Dioxin Registry, cause-specific mortality was initially determined in 5,172 workers exposed to dioxin at 12 U.S. chemical production plants (74). Serum dioxin levels were measured among 253 members of the exposed cohort and in 79 unexposed persons; average serum dioxin levels were 233 ppt and 7 ppt, respectively (74). Updates of this cohort extended the period of follow-up by 6 years through 1993. Analyses in these studies were restricted to 3,538 workers in eight plants for whom estimated (92) or blood-measured (91) levels of dioxin exposure could be determined and co-exposure to pentachlorophenol could be ruled out. The estimated dioxin exposure that was used estimated air exposure levels and known serum dioxin levels from 170 workers based on the employment history of each worker, the estimated half-life for dioxin, and a pharmacokinetic model for the storage and excretion of dioxin (91, 107). The initial evaluation found an excess mortality from all cancers, lung cancer, and soft tissue sarcoma (74). Mortality was elevated for cancers of the larynx, lung, bladder, and connective tissue and soft tissue among workers with chloracne (92). The risk of mortality from all cancers combined and lung cancer was highest among those with the highest cumulative exposure estimates (91, 92, 107). Individual studies of workers at Dow Chemical Company and Monsanto were smaller and did not assess mortality in relation to estimated serum dioxin levels (63-65, 69-72, 86, 87, 89, 95, 104, 106).

A follow-up study (1953-1992) of 243 German factory workers exposed to dioxin during a chemical explosion in 1953 reported that median serum dioxin levels ranged from 148 ppt among workers without chloracne to 1,118 ppt among those with severe chloracne (88, 98). An exposure-related increase in

mortality from all cancers combined was observed based on a total of 31 cases. Furthermore, an increased risk of lung cancer was found among those with the highest exposure to dioxins. Little evidence was seen for an increased risk of mortality or morbidity from any other cancer site (88).

The AFHS is unique among studies that have examined the incidence of malignancy in Vietnam veterans because serial serum dioxin data have been incorporated into longitudinal analyses (115, 117, 118, 122, 125, 128, 178). During the 1987 and 1992 examinations, the median serum dioxin level in the Ranch Hand cohort was nearly three times that of the Comparison group (12.5 ppt versus 4.1 ppt) (125). Stratification of the Ranch Hand cohort by occupation revealed significantly higher median levels of serum dioxin in the enlisted groundcrew (24.1 ppt) and enlisted flyers (17.8 ppt) than in the officers (7.7 ppt) (125). Each veteran was assigned to a background, low, or high dioxin exposure category based on serum dioxin levels.

The risk of developing skin and systemic cancers was evaluated in an AFHS article based on data collected through the 1992 examination (115). No increased skin cancer risk was found in Ranch Hands with the highest levels of serum dioxin, nor was there any consistent evidence of a dose-response effect (115). Elevated but not statistically significant risks were observed for oropharyngeal neoplasms and cancers of kidney or bladder among Ranch Hands with elevated exposure. Analyses assessing cancer risk by time since end of service did not reveal any consistent patterns (115). Similar results were reported in the 1997 follow-up examination (128). Another analysis conducted in 1998 evaluating post-service mortality among Ranch Hands found little evidence for an elevated risk of mortality from any cancer (118).

An article published in 2004 that describes cancer in AFHS participants explored the effects of time spent in SEA, the calendar period of service, and the percentage of SEA service spent in Vietnam (179). The analysis included external contrasts against U.S. national cancer rates and internal analyses by dioxin exposure category (similar to the Model 3 analyses in this report). Cancer incidence and mortality were separately considered. Cancer morbidity was classified by anatomical site using definitions provided by the Surveillance, Epidemiology, and End Results (SEER) section of the National Cancer Institute. The SEER categories included all anatomical sites except basal cell and squamous cell carcinoma. External contrasts found that the incidence of melanoma and prostate cancer was significantly increased among white Ranch Hand veterans; relative risks were increased and remained significant after restriction to participants whose tour of duty occurred between 1966 and 1970, the period of heaviest Agent Orange spraying. No significant increases in cancer mortality were found relative to national rates. Two internal analyses were conducted: the first was restricted to participants who spent at most 2 years in SEA and the second to Ranch Hands who spent 100 percent of their SEA tour in Vietnam and to Comparisons who spent 0 percent of their SEA tour in Vietnam. Among Ranch Hands who spent at most 2 years in SEA, the risk of cancer at any SEER site was significantly increased in the low and high dioxin categories relative to Comparisons who spent at most 2 years in SEA. Among Ranch Hands who spent 100 percent of their SEA tour in Vietnam, the risk of cancer at any SEER site was significantly increased in the low and high dioxin categories relative to Comparisons who spent 0 percent of their SEA tour in Vietnam. Consideration of these and other factors came too late for inclusion in this report.

Studies of cancer risk among Vietnam veterans have yielded inconsistent findings. Some studies reported increased cancer risks among Vietnam veterans (109, 119-121), while others found no evidence suggesting elevated risks (108, 111-114, 116, 123).

The Institute of Medicine (IOM), as reported first in their 1994 book on the health effects of herbicides used in Vietnam (180), concluded that there is “sufficient” evidence to establish an association, although not a causal relation, between dioxin exposure and the occurrence of soft tissue sarcoma, non-Hodgkin’s

lymphoma, and Hodgkin's disease (12, 180-183). In the 2002 IOM report, the epidemiologic evidence was considered to be sufficient concerning chronic lymphocytic leukemia based primarily on studies of agricultural workers (12). The evidence for an association with respiratory cancers, prostate cancer, and multiple myeloma was considered "limited/suggestive" (12, 180-183).

10.1.2 Summary of Previous Analyses of the Air Force Health Study

10.1.2.1 1982 Baseline Examination Summary Results

Cancer received major emphasis during the AFHS baseline examination in 1982. The neoplasia assessment used data from both the in-home questionnaire and the review-of-systems questionnaire obtained during the physical examination, as well as data from the examination itself. In addition, tabulation of mortality count data from the baseline mortality report was used in conjunction with cancer morbidity information. The overall results did not show a significant difference in systemic cancer between the two groups, but did show significantly more skin cancer in the Ranch Hand group.

Of 50 reported systemic cancers from the Ranch Hand and Comparison groups, 28 (14 in each group) were verified by medical records and pathology reports. Although the number of occurrences was too small to support meaningful statistical analysis, a slight excess of genitourinary cancer and oropharyngeal cancer, but a decrease of digestive system neoplasms, were observed for Ranch Hands. A combined morbidity-mortality assessment derived from the initial 1:1 match (Ranch Hand to the Original Comparison member) disclosed similar distributions. One case of soft tissue sarcoma and one case of Hodgkin's disease were confirmed, both in the Comparison group.

Questionnaire data verified by a medical records review revealed significantly more skin cancer in Ranch Hands. Basal cell carcinoma accounted for 83.9 percent of the reported skin cancers in both groups and was concentrated anatomically on the face, head, and neck. The few melanoma and squamous cell cancers were distributed evenly between the Ranch Hand and Comparison groups. Adjustments for occupational exposures (e.g., asbestos, degreasing chemicals) did not alter the increased rate of skin cancer in the Ranch Hand group. Outdoor occupations subsequent to military service as a covariate did not account for the significant skin cancer association.

10.1.2.2 1985 Follow-up Examination Summary Results

The baseline and 1985 follow-up data were combined for the assessment of lifetime history of cancer. The adjusted group contrast between Ranch Hands and Comparisons for the sun exposure-related skin cancers, the majority of which were basal cell carcinomas, was significant. The group contrasts for all systemic cancers combined were not significant. There was one new occurrence of a soft tissue sarcoma (Ranch Hand) and one suspected cancer of the lymphatic system (Ranch Hand), in addition to the one previously reported soft tissue sarcoma and one Hodgkin's disease in the Comparison group. There were no cases of non-Hodgkin's lymphoma in either group at the time of the 1985 report.

10.1.2.3 1987 Follow-up Examination Summary Results

For non-Black participants, significantly more Ranch Hands had a skin neoplasm than did Comparisons. The majority of malignant neoplasms observed in Ranch Hands were basal cell carcinomas, a nonlife-threatening form of skin cancer. Ranch Hands exhibited a significantly increased risk for sun exposure-related malignant skin neoplasms. Approximately 90 percent of the participants with a sun exposure-related malignant skin neoplasm had a basal cell carcinoma.

After adjusting for age, residential history, sun exposure, ethnic background, and ionizing radiation exposure, the Ranch Hand risk was statistically significantly increased for verified basal cell carcinoma. Also, a significantly higher percentage of Ranch Hands had multiple verified basal cell carcinomas than did Comparisons.

No significant group differences were found in the analyses of systemic neoplasms by number, behavior (malignant, benign, or uncertain behavior or unspecified nature), or site. Thus, the increase in overall malignancy was because of elevated relative risks for skin cancer (basal cell carcinoma). The number of participants with soft tissue sarcoma and non-Hodgkin's lymphoma was comparable in the two groups.

10.1.2.4 Serum Dioxin Analysis of 1987 Follow-up Examination Summary Results

The analyses did not establish a positive association between dioxin and the presence of a skin neoplasm. Significant relative risks were found for the skin neoplasm analyses, although the relative risks were almost always inversely related to dioxin levels. For the analyses focusing on enlisted flyers with a basal cell carcinoma on sites other than the ear, face, head, or neck (and a sun exposure-related malignant skin neoplasm on sites other than the ear, face, head, or neck), relative risks were found to be significantly greater than 1.0. These differences were not noted in the enlisted groundcrew who, as a group, had higher levels of serum dioxin than enlisted flyers.

The relative risk for participants with a benign systemic neoplasm (such as lipomas) increased as the different measures of dioxin (initial, categorized, and 1987) increased. The relative risk of malignant systemic neoplasms was not significantly increased as dioxin levels increased.

The study provided no evidence of increased history of malignant neoplasms most commonly suspected as being associated with exposure to chlorophenols (Hodgkin's disease, non-Hodgkin's lymphoma, and soft tissue sarcoma). The number of participants with these specific malignancies was small; therefore, the statistical power to detect small or moderately elevated relative risks was low. The data do not support evidence of a relation between dioxin and either skin or systemic malignancies.

10.1.2.5 1992 Follow-up Examination Summary Results

Analyses of all Ranch Hands and Comparisons indicated no significant difference between the two groups with regard to benign or malignant neoplasms. All statistically significant associations between initial dioxin and benign or malignant neoplasm endpoints for Ranch Hands showed an inverse dose-response relation. After adjusting for covariates, the only significantly increased risks were for Ranch Hands in the low category for all skin neoplasms and malignancies of the colon and rectum. In contrast, the occurrence of neoplasms of any type for Ranch Hands in the high dioxin category was never significantly elevated and was often less than the occurrence for Comparisons. Parallel to analyses using initial dioxin, results observed when 1987 dioxin was used as the measure of exposure often indicated an inverse dose-response relation, although this was statistically significant in the adjusted analyses only for benign skin neoplasms. In summary, there appeared to be no overall difference between Ranch Hands and Comparisons, and there was no evidence to suggest a positive dose-response relation between dioxin and neoplastic disease.

10.1.2.6 1997 Follow-up Examination Summary Results

Several analyses showed significantly more Ranch Hands than Comparisons with a history of malignant skin or systemic neoplasms; however, no significant results were found within the enlisted groundcrew stratum, the military occupational category believed to have been, on average, the most heavily exposed.

When the association between initial dioxin and malignant neoplasms was examined within Ranch Hands, the neoplasm occurrence decreased as initial dioxin increased. A significant increase of malignant neoplasms for Ranch Hands in the low dioxin category relative to Comparisons was observed, but there was no such increase in Ranch Hands in the high dioxin category. In summary, Ranch Hands did not exhibit a significantly increased risk for neoplastic disease, nor did they show a positive dose-response relation between dioxin and malignant neoplastic conditions.

10.1.3 Parameters for the 2002 Neoplasia Assessment

10.1.3.1 Dependent Variables

The neoplasia assessment was based on the occurrence of neoplasms (both benign and malignant) after service in SEA. Information on the occurrence of neoplasms at the 1982 baseline examination and at the 1985, 1987, 1992, and 1997 follow-up examinations were coded according to conventions in the ICD-9-CM manual. This information was combined with data collected at the 2002 follow-up examination to form a complete neoplastic history for each participant. The analyses performed in this chapter were based on the 1,951 participants who attended the 2002 follow-up examination.

The neoplasia assessment was based on the number of participants with a neoplasm and not on the number of neoplasms. A participant was considered to have an adverse health condition for the neoplasia assessment if he had one or more neoplasms.

10.1.3.1.1 Medical Records Variables

During the 2002 health interview, each study participant was asked a series of questions on the occurrence of cancer since the date of his last health interview. Medical records review was accomplished to confirm reported neoplasms and to identify any unreported neoplasms. These data from the 2002 physical examination were combined with data from the 1982 baseline examination and the 1985, 1987, 1992, and 1997 follow-up examinations to form a complete neoplasia history for each participant. Only verified neoplasms were used in the neoplasia assessment.

Some possible neoplastic conditions were discovered by the physicians at the physical examination. Contingent upon participant authorization, suspicious skin lesions were biopsied and the pathology determined; no other invasive procedures were used to detect systemic neoplasms. A skin biopsy was indicated for 307 of the 1,951 (15.7%) participants at the 2002 follow-up examination; 289 of these 307 participants (94.1%) consented to the biopsy.

For chest x-ray findings that were reported as needing follow-up at the 2002 physical examination, the AFHS made every effort to contact and encourage participants to see their physicians. The participants were recontacted to determine a final diagnosis. Results that were available upon follow-up were included in the analysis of neoplasms in this chapter.

10.1.3.1.1.1 Skin Neoplasms

The analysis of skin neoplasms was divided into two sets. The first set comprised analyses of skin neoplasms by behavior. Four behavior types were examined: (1) all skin neoplasms, (2) malignant skin neoplasms only, (3) benign skin neoplasms only, and (4) skin neoplasms of uncertain behavior or unspecified nature.

The second set comprised analyses of malignant skin neoplasms by cell type and was conducted for all sites combined. The following four cell types were analyzed: (1) basal cell carcinomas, (2) squamous cell carcinomas, (3) nonmelanoma (basal cell carcinomas, squamous cell carcinomas, and malignant epithelial neoplasms not otherwise specified), and (4) melanoma.

There were relatively few Black participants in this study (6.4%). With the exception of one Black participant with a pre-SEA melanoma in a previous follow-up examination, Blacks have been observed to exhibit only benign skin neoplasms in all phases of the study to date. Consequently, skin neoplasm analyses, except for the analyses of benign skin neoplasms, were limited to non-Black participants. Both Black and non-Black participants were included in the analysis of benign skin neoplasms. Participants with a pre-SEA skin neoplasm were excluded from the analysis of the skin neoplasm variables.

10.1.3.1.1.2 Systemic Neoplasms

The systemic neoplasms were analyzed by behavior and anatomical site. As with skin neoplasms, each analysis was conducted using verified data. The analysis of the systemic neoplasms was divided into two sets, as described below.

The first set comprised analyses of systemic neoplasms by behavior type. The following four behavior types were examined: (1) all systemic neoplasms, (2) malignant systemic neoplasms, (3) benign systemic neoplasms, and (4) systemic neoplasms of uncertain behavior or unspecified nature.

The second set comprised analyses of malignant systemic neoplasms by the following sites: (1) ear, eye, head, face, and neck; (2) oral cavity, pharynx, and larynx; (3) thymus, heart, and mediastinum; (4) thyroid gland; (5) bronchus and lung; (6) colon and rectum; (7) urinary system; (8) kidney and ureter; (9) prostate; (10) penis and other male genital organs; (11) testicles; (12) bone and articular cartilage; (13) connective and other soft tissues, (14) carcinoma in situ, (15) all stomach neoplasms (malignant and benign), (16) Hodgkin's disease, (17) leukemia, (18) malignant systemic neoplasm of lymphoid and histiocytic tissue, and (19) lymphoreticular sarcoma.

Participants with a pre-SEA malignant systemic neoplasm or a pre-SEA systemic neoplasm of uncertain behavior or an unspecified nature were excluded from the analysis of the systemic neoplasm variables.

10.1.3.1.1.3 Skin and Systemic Neoplasms

Statistical analysis was performed on malignant neoplasms, which was a combination of malignant skin and malignant systemic neoplasms. In addition, statistical analysis was performed on all neoplasms, which was a combination of skin and systemic neoplasms (benign, malignant, and uncertain behavior). Participants with a pre-SEA skin neoplasm, a pre-SEA malignant systemic neoplasm, or a pre-SEA systemic neoplasm of uncertain behavior or an unspecified nature were excluded from the analysis of this variable.

10.1.3.1.2 Laboratory Variable

The PSA test was developed to detect prostate enlargement and prostate cancer. Each participant had a PSA test as a standard part of the laboratory assay. An analysis was performed on the continuous measurement, as measured in ng/mL, as well as on a discrete form of PSA. The discrete form of PSA was categorized as high or normal based on a cutpoint of 4 ng/mL. Participants with prostatectomies or radiation treatment on the prostate were excluded from the analysis of PSA.

10.1.3.2 Covariates

In the analysis of the 2002 examination results, covariates in adjusted statistical analyses assessing skin neoplasms included age, military occupation, body mass index (kg/m^2), skin color, hair color, eye color, skin reaction to sun after the first exposure, skin reaction to sun after repeated exposure, cumulative exposure to ionizing radiation (yes or no), cumulative exposure to industrial chemicals (yes or no), and average lifetime residential history. A composite skin-reaction index, which combined two individual reactions of skin to sun covariates, also was investigated.

Age, race, and military occupation were determined from military records. Body mass index was calculated as $\text{weight}/(\text{height})^2$, where the weight was measured in kilograms and the height was measured in meters at the physical examination (184). For purposes of covariate associations for discrete dependent variables, body fat was dichotomized as “not obese” ($\leq 30 \text{ kg}/\text{m}^2$) and “obese” ($> 30 \text{ kg}/\text{m}^2$).

Information on skin, hair, and eye color was obtained at the 2002 physical examination for participants who did not attend the 1985, 1987, 1992, and 1997 examinations. This information was combined with data from participants who previously provided this information. Information on the skin reaction to sun after the first exposure and after repeated exposure was reported by the participant during the questionnaire phase at the 2002 examination. Also, the participants’ cumulative exposures through 1997 to ionizing radiation, industrial chemicals, and herbicides (used in the analysis of systemic neoplasms, discussed below) were updated with information reported in the 2002 questionnaire.

The emphasis on choosing risk factors related to cancer increased during the 1985 follow-up examination and has been emphasized since that time. In particular, the interval health questionnaire was modified to collect information on each geographic location in which a participant lived for more than 12 months. Because ultraviolet light exposure has been acknowledged as the primary cause of basal cell carcinomas, this information was used to compute a cumulative sun-exposure index based on residential history. An average lifetime residential history was estimated by dividing the total degree-years (i.e., the sum of the product of latitude [degrees] and the number of years lived at each residence) from all residences by the total number of residential years reported on questionnaires since 1985. Average lifetime residential history was dichotomized as less than 37 degrees latitude (southerly) or greater than or equal to 37 degrees latitude (northerly), which was the approximate median in previous AFHS examinations.

Covariates in adjusted statistical analyses assessing systemic neoplasms and PSA included age, race, military occupation, body mass index (kg/m^2), cumulative exposure to ionizing radiation and herbicides, lifetime cigarette smoking history (in pack-years), and lifetime alcohol history (in drink-years).

Lifetime cigarette smoking history was based on questionnaire data. For lifetime cigarette smoking history, the respondent’s average smoking was estimated over his lifetime based on his responses to the 2002 questionnaire, with 1 pack-year defined as 365 packs of cigarettes smoked during a single year.

Lifetime alcohol history was based on information from the 2002 questionnaire and combined with similar information gathered at the 1987, 1992, and 1997 follow-up examinations. Each participant was asked about his drinking patterns throughout his lifetime. When a participant’s drinking pattern changed, he was asked to describe how his alcohol consumption differed and the duration of time that the drinking pattern lasted. The participant’s average daily alcohol consumption was determined for each of the reported drinking pattern periods throughout his lifetime, and an estimate of the corresponding total number of drink-years was derived. One drink-year was the equivalent of drinking 1.5 ounces of an 80-proof alcoholic beverage, one 12-ounce beer, or one 5-ounce glass of wine per day for 1 year.

Almost all Ranch Hands reported herbicide exposure at some point in their lifetime. Although the questionnaire had been structured to indicate post-SEA exposure only, a possible explanation for this reported herbicide exposure may have been the tendency of Ranch Hands to report their exposure to dioxin during their time of duty in SEA. Consequently, herbicide exposure in Ranch Hands was of limited use as a risk factor for explaining the presence of a systemic neoplasm. Therefore, many of the Model 2 and Model 4 analyses of systemic neoplasms and PSA, which were based on Ranch Hands only, did not use herbicide exposure as a covariate.

Categories of covariates and definitions are summarized below:

- Skin Color: dark, medium, pale, dark peach, and pale peach (classified for analysis purposes as (1) dark, medium, pale, or (2) dark peach, pale peach)
- Hair Color: black, dark brown, light brown, blond, red, and bald (classified for analysis purposes as (1) black, dark brown, or (2) light brown, blond, red, bald)
- Eye Color: brown, hazel, green, gray, and blue (classified for analysis purposes as (1) brown, (2) hazel, green, or (3) gray, blue)
- Skin Reaction to Sun After First Exposure: burns painfully, burns, becomes red, and no reaction
- Skin Reaction to Sun After Repeated Exposure: freckles with no tan, tans mildly, tans moderately, and tans deep brown
- Composite Skin-Reaction Index: a composite variable based on two reactions of skin to sun exposure variables was defined as follows: (1) burns painfully or freckles with no tan, (2) burns or tans mildly, and (3) all other reactions
- Average Lifetime Residential History: average latitude less than 37 degrees and average greater than or equal to 37 degrees
- Exposure to Carcinogens: ionizing radiation, industrial chemicals, and herbicides (yes or no for each); these exposures represent cumulative exposure based on self-reported questionnaire data from the 2002 examination combined with previous examinations.

10.1.4 Statistical Methods

Table 10-1 summarizes the statistical analysis performed for the 2002 neoplasia assessment. The first part of this table identifies the dependent variables, covariates, exclusions, and the statistical methods. This information is presented in the following four sections: skin neoplasms, systemic neoplasms, skin and systemic neoplasms combined, and PSA. Data source, data form, and cutpoints are summarized at the end of the table. The second part of the table describes the covariates. A covariate was used in its continuous form whenever possible for all adjusted analyses. If the covariate was inherently discrete (e.g., military occupation), or if a categorized form was needed to develop measures of association with the dependent variables, the covariate was categorized as shown in Table 10-1.

The neoplasm assessment contains many covariates for use in the adjusted analyses of skin and systemic neoplasms. In addition, the history of a neoplasm was small for many of the dependent variables. The modeling strategy for this clinical area was to include as many covariates as feasible; however, when the number of participants with a history of a particular neoplasm was too small to support analysis including all covariates, elimination of covariates was necessary to develop and support meaningful analyses.

Table 10-1. Statistical Analysis for the Neoplasia Assessment (Continued)

Dependent Variables (Except for PSA)

Data Source: Review of medical records and verification based on AFHS questionnaires and physical examinations, except for PSA, which was measured by Scripps Clinic in 2002.

Data Form: Discrete.

Cutpoints: Yes or No.

Statistical Analysis and Methods:

Unadjusted: LR: Logistic regression analysis

CS: Chi-square contingency table analysis (continuity-adjusted for 2x2 tables)

Adjusted: LR: Logistic regression analysis

^aCovariates:

- (1) age, military occupation, body mass index, skin color, hair color, eye color, skin reaction to sun after first exposure, skin reaction to sun after repeated exposure, composite skin-reaction index, residential history, cumulative ionizing radiation exposure, and cumulative industrial chemicals exposure.
- (2) age, race, military occupation, body mass index, cumulative ionizing radiation exposure, cumulative herbicide exposure, lifetime cigarette smoking history, lifetime alcohol history.
- (3) age, race, military occupation, body mass index, skin color, hair color, eye color, skin reaction to sun after first exposure, skin reaction to sun after repeated exposure, composite skin-reaction index, residential history, cumulative ionizing radiation exposure, cumulative industrial chemicals exposure, cumulative herbicide exposure, lifetime cigarette smoking history, lifetime alcohol history.

^bExclusions:

- (a) participants with a pre-SEA skin neoplasm, Blacks.
- (b) participants with a pre-SEA skin neoplasm.
- (c) participants with a pre-SEA systemic neoplasm of uncertain behavior, participants with a pre-SEA malignant systemic neoplasm.
- (d) participants with a pre-SEA skin neoplasm, participants with a pre-SEA systemic neoplasm of uncertain behavior, participants with a pre-SEA malignant systemic neoplasm.
- (e) participants with a prostatectomy or radiation treatment on the prostate gland.

Data Source:	MIL: Air Force military records PE: 2002 physical examination Q-SR: Health questionnaires (self-reported)
Data Form:	D: Discrete form of dependent variable or covariate C/D: Continuous and discrete forms of dependent variable; appropriate form for analysis (either continuous or discrete) of covariate
Statistical Analysis:	U: Unadjusted analysis A: Adjusted analysis
Statistical Methods:	CS: Chi-square contingency table analysis (continuity-adjusted for 2x2 tables) GLM: General linear models analysis LR: Logistic regression analysis TT: Two-sample t-test

Four models were examined for each dependent variable given in Table 10-1. The analyses of these models are presented below. Further details on dioxin and the modeling strategy are found in Chapters 2 and 7, respectively. These analyses were performed both unadjusted and adjusted for covariates. These covariates are given in Table 10-1. Model 1 examined the relation between the dependent variable and group (i.e., Ranch Hand or Comparison). In this model, exposure was defined as “yes” for Ranch Hands and “no” for Comparisons without regard to the magnitude of the exposure. In an attempt to quantify exposure, three contrasts of Ranch Hands and Comparisons were performed along with the overall Ranch Hand versus Comparison contrast. These three contrasts compared Ranch Hands and Comparisons within each military occupational category (i.e., officers, enlisted flyers, and enlisted groundcrew). As described in previous reports and Table 2-4, the median level of exposure to dioxin was highest for enlisted groundcrew, followed by enlisted flyers, then officers.

During the 1987, 1992, 1997, and 2002 examinations, serum dioxin levels were measured by the Centers for Disease Control and Prevention (CDC) using high-resolution gas chromatography and high-resolution mass spectrometry and were reported in ppt on a lipid weight basis (185). These dioxin measurements are referred to as “lipid-adjusted.” All measures of dioxin used in this report were based on lipid-adjusted dioxin measurements.

Model 2 examined the relation between the dependent variable and an extrapolated initial dioxin measure for Ranch Hands who had a 1987 dioxin measurement greater than 10 ppt. The initial dioxin was calculated by extrapolating the 1987 dioxin level back in time to the end of the tour of duty that qualified a Ranch Hand veteran for inclusion in this study. If a Ranch Hand did not have a 1987 dioxin level, then the first dioxin measured, either at 1992, 1997, or 2002, was used to estimate the initial dioxin level. Regardless of when the dioxin was measured, Ranch Hand veterans with a level less than or equal to 10 ppt were excluded from statistical analyses based on Model 2. A statistical adjustment for body mass index at the time of the participant’s blood measurement of dioxin was included in this model to account for body mass index-related differences in elimination rate (186).

Model 3 divided the Ranch Hands examined in Model 2 into two categories based on their initial dioxin measures. These two categories were referred to as “low Ranch Hand” and “high Ranch Hand.” Two additional categories—Ranch Hands with serum dioxin levels at or below 10 ppt and Comparisons—were formed and included in the model. Ranch Hands with serum dioxin levels at or below 10 ppt were assigned to the “background Ranch Hand” category. If a Ranch Hand did not have a 1987 dioxin measurement, the first measured dioxin level was used. Another category was examined by combining the low and high Ranch Hand categories. This combination is referred to in the tables as the “low plus high Ranch Hand” category. These five categories—Comparisons, background Ranch Hands, low Ranch Hands, high Ranch Hands, and low plus high Ranch Hands—were used in Model 3 analyses. The relation between the dependent variable in each of the four Ranch Hand categories and the dependent variable in the Comparison category was examined. As in Model 2, a statistical adjustment for body mass index at the time of the participant's blood measurement of dioxin was included in this model for the unadjusted and adjusted analyses of all dependent variables. One Ranch Hand without a dioxin measure was excluded from statistical analyses based on Model 3.

Model 4 examined the relation between the dependent variable and 1987 dioxin levels in all Ranch Hands with a dioxin measurement. If a Ranch Hand did not have a 1987 dioxin measurement, the first dioxin level obtained, either in 1992, 1997, or 2002, was extrapolated to the date of the 1987 physical examination. If the first dioxin level was not obtained in 1987 and was less than or equal to 10 ppt, it was not extrapolated to 1987 level, but was used at the measured value. One Ranch Hand without a dioxin measurement was excluded from statistical analyses based on Model 4.

The term “unadjusted” was used in the text and tables as follows: Models 1 and 4 did not adjust for any covariates. Models 2 and 3 adjusted only for body mass index at the time of the blood measurement for dioxin. The term “adjusted” was used in the text and tables as follows: Models 1 and 4 adjusted for the covariates shown in Table 10-1 unless otherwise specified by a footnote to the table. Models 2 and 3 additionally adjusted only for body mass index at the time of the blood measurement for dioxin.

Table 10-2 provides a summary of the number of participants with missing dependent variable and covariate data. In addition, the number of participants that were excluded from analyses is given.

Table 10-2. Number of Participants Excluded or with Missing Data for the Neoplasia Assessment

Variable	Variable Use	Group ^a		Dioxin (Ranch Hands Only) ^b		Categorized Dioxin ^c

EXC = Exclusion.

10.2 RESULTS

10.2.1 Dependent Variable-covariate Associations

The neoplasia dependent variables were tested for associations with each of the covariates used in the adjusted analyses. The complete results are presented in Appendix F, Table F-2. These associations were pairwise between the dependent variable and the covariate and were not adjusted for any other covariates.

A brief summary of the pattern of significant ($p \leq 0.05$) dependent variable-covariate associations is described in the following paragraphs.

Older participants were more likely than younger participants to have developed a skin neoplasm, a malignant skin neoplasm, a benign skin neoplasm, basal cell carcinoma, squamous cell carcinoma, nonmelanoma, and melanoma. The prevalence of a systemic neoplasm, a malignant systemic neoplasm, a benign systemic neoplasm, a skin or systemic neoplasm, and a malignant skin or systemic neoplasm also was greater for older participants than for younger participants. Neoplasms of the bronchus or lung, urinary system, prostate, and other neoplasms of lymphoid or histiocytic tissue were also more common in older participants than younger participants. PSA levels increased with increasing age, and abnormally high levels of PSA were more likely to be seen in older participants.

Black participants were significantly less likely to develop a skin or systemic neoplasm and a malignant skin or systemic neoplasm than non-Black participants.

Officers were more likely than enlisted personnel to have any skin neoplasm, a malignant skin neoplasm, basal cell carcinoma, squamous cell carcinoma, and nonmelanoma. In addition, officers were more likely to have developed any systemic neoplasm and a lymphoreticular sarcoma than enlisted personnel. Officers also had a higher frequency of any skin or systemic neoplasm and any malignant skin or systemic neoplasm than enlisted personnel. Abnormally high PSA levels were more frequent in officers than enlisted personnel. A malignant systemic neoplasm, a malignant systemic neoplasm of the prostate, a malignant systemic neoplasm of the penis or other male genital organs, and carcinoma in situ had a higher prevalence in enlisted flyers than in officers or enlisted groundcrew. Mean PSA levels were highest in enlisted flyers, followed by officers, then enlisted groundcrew. For all of these dependent variables, enlisted groundcrew had the lowest prevalence, and presumably many of the associations seen here were at least partially due to age. On average, officers were older than enlisted personnel.

PSA levels decreased with increasing body mass index.

Participants exposed to ionizing radiation were more likely to have developed malignant systemic neoplasms and malignant systemic neoplasms of the oral cavity, pharynx, or larynx and urinary system than participants who were not exposed.

Participants with peach skin color were more likely than participants with nonpeach skin color to develop a skin neoplasm, a malignant skin neoplasm, a benign skin neoplasm, a skin or systemic neoplasm, a malignant skin or systemic neoplasm, squamous cell carcinoma, and nonmelanoma.

Malignant skin neoplasms, basal cell carcinoma, squamous cell carcinoma, nonmelanoma, a skin or systemic neoplasm, and a malignant skin or systemic neoplasm were less prevalent in participants with black or dark-brown hair than in participants with lighter-colored hair.

Participants with gray or blue eyes were more likely to have a skin neoplasm, a malignant skin neoplasm, nonmelanoma, melanoma, and a malignant skin or systemic neoplasm than participants with hazel, green, or brown eyes. Skin neoplasms of an uncertain behavior or an unspecified nature, basal cell carcinoma, and a skin or systemic neoplasm were more prevalent in participants with green or hazel eyes than in participants with gray, blue, or brown eyes.

The prevalence of a malignant skin neoplasm, basal cell carcinoma, squamous cell carcinoma, nonmelanoma, melanoma, and a malignant skin or systemic neoplasm increased as the severity of the skin reaction to sun after first exposure increased.

Participants who freckle after repeated exposure to the sun were significantly more likely to have had a skin neoplasm, a malignant skin neoplasm, basal cell carcinoma, squamous cell carcinoma, nonmelanoma, a skin or systemic neoplasm, and a malignant skin or systemic neoplasm than those who tan with repeated exposure to the sun. Participants who tan mildly after repeated sun exposure were more likely to develop melanoma than other participants.

The prevalence of a skin neoplasm, a malignant skin neoplasm, basal cell carcinoma, squamous cell carcinoma, nonmelanoma, a skin or systemic neoplasm, and a malignant skin or systemic neoplasm increased as the reaction to sun became more severe.

Participants with an average lifetime residential history closer to the equator had a greater prevalence of a malignant skin neoplasm, basal cell carcinoma, squamous cell carcinoma, nonmelanoma, and a malignant skin or systemic neoplasm than participants living further from the equator.

Cumulative industrial chemical exposure was not significantly associated with dependent variables for neoplasia.

A malignant systemic neoplasm of the bronchus or lung, a skin or systemic neoplasm, and a malignant skin or systemic neoplasm were more likely to be seen in participants with herbicide exposure than participants who were not exposed.

The heaviest lifetime cigarette smokers (>10 pack-years) were more likely to have developed a malignant systemic neoplasm, a malignant systemic neoplasm of the bronchus or lung, and a malignant skin or systemic neoplasm.

Nondrinkers were more likely to have a malignant systemic neoplasm of the urinary system and a malignant systemic neoplasm of the penis or other male genital organs than moderate or heavy drinkers.

10.2.2 Exposure Analysis

The following section presents results of the statistical analyses of the dependent variables shown in Table 10-1. Dependent variables are grouped into two sections: (1) variables derived from the questionnaire that was administered during the 2002 follow-up and previous AFHS examinations and subsequently verified by a review of medical records, and (2) PSA, as obtained during the 2002 laboratory examination.

10.2.2.1 Medical Records Variables

10.2.2.1.1 All Skin Neoplasms

Significant group differences were found when combining all occupations in both the unadjusted and adjusted analyses of Model 1 for occurrence of skin neoplasms (Table 10-3(a,b): Unadjusted Relative Risk [RR]=1.29, $p=0.007$; Adjusted RR=1.28, $p=0.012$). The percentage of Ranch Hands with skin neoplasms was 54.2 percent versus 47.8 percent for Comparisons. Results were nonsignificant for all other Model 1 analyses (Table 10-3(a,b): $p>0.05$ for all analyses).

Results from the unadjusted Model 2 analysis indicated a significant inverse relation between initial dioxin and occurrence of skin neoplasms (Table 10-3(c): Adjusted RR=0.82, $p=0.011$). After adjusting for covariates, the results were not significant (Table 10-3(d): $p=0.313$).

The percentages of Ranch Hands with a skin neoplasm in the background dioxin category, the low dioxin category, and the low and high dioxin categories combined were all found to be significantly higher than the percentage of Comparisons with skin neoplasms (Table 10-3(e): Unadjusted RR=1.31, p=0.035 for Ranch Hands in the background dioxin category; Unadjusted RR=1.69, p=0.001 for Ranch Hands in the low dioxin category; Unadjusted RR=1.28, p=0.037 for Ranch Hands in the low and high dioxin categories combined).

After adjusting for covariates, significant differences were found when contrasting the Ranch Hands in both the low dioxin category and low and high dioxin categories combined with Comparisons (Table 10-3(f): Adjusted RR=1.56, p=0.007 for Ranch Hands in the low dioxin category; Adjusted RR=1.32, p=0.026 for Ranch Hands in the low and high dioxin categories combined). The percentages of participants with skin neoplasms were 61.0 and 54.2 for Ranch Hands in the low dioxin category and the low and high dioxin categories combined, respectively. The percentage of Comparisons with skin neoplasms was 47.8. All other Model 3 contrasts were nonsignificant (Table 10-3(e,f): p>0.10 for all analyses).

The Model 4 unadjusted and adjusted analyses did not reveal significant findings (Table 10-3(g,h): p>0.55 for both analyses).

10.2.2.1.2 Malignant Skin Neoplasms

All unadjusted and adjusted analyses of malignant skin neoplasms were nonsignificant for Model 1 (Table 10-4(a,b): p>0.05 for all analyses).

A significant inverse relation between initial dioxin levels and the occurrence of malignant skin neoplasms was revealed in the Model 2 unadjusted analysis (Table 10-4(c): Unadjusted RR=0.81, p=0.021). Results were nonsignificant after adjusting for covariates (Table 10-4(d): p=0.693).

The Model 3 unadjusted analysis showed significantly more Ranch Hands in the low dioxin category with malignant skin neoplasms than Comparisons (Table 10-4(e): Unadjusted RR=1.66, p=0.004). Of the Ranch Hands in the low dioxin category, 31.6 percent had malignant skin neoplasms versus 21.5 percent of the Comparisons. The result was also significant after adjusting for covariates (Table 10-4(f): Adjusted RR=1.52, p=0.024). All other Model 3 contrasts were nonsignificant (Table 10-4(e,f): p>0.07 for all analyses).

Both the unadjusted and adjusted Model 4 analyses were nonsignificant (Table 10-4(g,h): p>0.26 for both analyses).

^aRelative risk for a twofold increase in 1987 dioxin.

10.2.2.1.4 Skin Neoplasms of Uncertain Behavior or Unspecified Nature

A sparse number of participants exhibited skin neoplasms of uncertain behavior or unspecified nature and thus analyses were limited. All analyzed results from the Model 1 and Model 4 unadjusted and adjusted analyses of skin neoplasms of uncertain behavior or unspecified nature were nonsignificant (Table 10-6(a,b,g,h): $p \geq 0.10$ for all analyses).

The unadjusted analysis of Model 2 revealed a significant inverse relation between initial dioxin and the occurrence of skin neoplasms of uncertain behavior or unspecified nature (Table 10-6(c): Unadjusted RR=0.25, $p=0.018$). The relation remained significant after adjusting for covariates (Table 10-6(d):

Adjusted RR=0.23, p=0.033). Of the Ranch Hands in the low and medium initial dioxin categories, 2.4 percent and 0.8 percent, respectively, had skin neoplasms of uncertain behavior or unspecified nature. There were no Ranch Hands in the high initial dioxin category with skin neoplasms of uncertain behavior or unspecified nature.

In both the Model 3 unadjusted and adjusted analyses, Ranch Hands in the low dioxin category had a significantly higher occurrence of skin neoplasms of uncertain behavior or unspecified nature than Comparisons (Table 10-6(e,f): Unadjusted RR=4.51, p=0.026; Adjusted RR=4.14, p=0.041, respectively). For Ranch Hands in the low dioxin category, 2.1 percent had skin neoplasms of uncertain behavior or unspecified nature versus 0.5 percent for Comparisons.

Table 10-6. Analysis of Skin Neoplasms of Uncertain Behavior or Unspecified Nature

(a) MODEL 1: RANCH HANDS VS. COMPARISONS – UNADJUSTED					
Occupational Category	Group	n	Number (%) Yes	Unadjusted Relative Risk (95% C.I.)	p-Value

718	0.84 (0.50,1.41)		0.509

^aRelative risk for a twofold increase in 1987 dioxin.

Note: Results were not adjusted for military occupation, eye color, skin reaction to sun after first exposure, skin reaction to sun after repeated exposure, and the composite skin-reaction index because of the sparse number of Ranch Hands with a skin neoplasm of uncertain behavior or unspecified nature.

10.2.2.1.5 Basal Cell Carcinoma

The unadjusted Model 1 analysis revealed significant differences in the occurrence of basal cell carcinoma across all occupations and for officers (Table 10-7(a): Unadjusted RR=1.34, p=0.017 overall; Unadjusted RR=1.62, p=0.006 for officers). After covariate adjustment, both results remained significant (Table 10-7(b): Adjusted RR=1.33, p=0.027 overall; Adjusted RR=1.58, p=0.013 for officers). In the overall analysis, 21.4 percent of Ranch Hands had a history of basal cell carcinoma versus 16.9 percent of Comparisons. The percentage of Ranch Hand officers with basal cell carcinoma was 28.0 versus 19.4 percent for Comparison officers. All other Model 1 contrasts were nonsignificant (Table 10-7(a,b): p>0.21 for all analyses).

An inverse association between initial dioxin and occurrence of basal cell carcinoma was significant in the unadjusted Model 2 analysis (Table 10-7(c): Unadjusted RR=0.72, p=0.001). After covariate adjustment, the result was no longer significant (Table 10-7(d): p=0.309).

In the unadjusted Model 3 analyses, Ranch Hands in the background and low dioxin categories exhibited a higher occurrence of basal cell carcinoma than did Comparisons (Table 10-7(e): Unadjusted RR=1.47, p=0.012 for the background dioxin category; Unadjusted RR=1.78, p=0.002 for the low dioxin category). After covariate adjustment, the only significant difference occurred among those participants in the low dioxin category (Table 10-7(f): Adjusted RR=1.66, p=0.010). The percentages of participants with a basal cell carcinoma were 22.7 and 26.7 for Ranch Hands in the background and low dioxin categories, respectively. Among Comparisons, 16.9 percent exhibited a basal cell carcinoma.

The Model 4 unadjusted and adjusted analyses did not reveal any significant findings (Table 10-7(g,h): $p > 0.05$ for both analyses).

Table 10-7. Analysis of Basal Cell Carcinoma

^aRelative risk for a twofold increase in 1987 dioxin.

10.2.2.1.7 Nonmelanoma

The unadjusted Model 1 analyses of nonmelanoma revealed a significant overall difference between Ranch Hands and Comparisons, as well as a significant difference between Ranch Hand and Comparison officers (Table 10-9(a): Unadjusted RR=1.31, p=0.019 overall; Unadjusted RR=1.49, p=0.019 for officers). After covariate adjustment, both results remained significant (Table 10-9(b): Adjusted RR=1.31, p=0.027 overall; Adjusted RR=1.46, p=0.032 for officers). Occurrence of nonmelanoma was higher in Ranch Hands than in Comparisons (24.3% versus 19.6% overall, and 30.7% versus 23.0% among officers). All other Model 1 contrasts were nonsignificant (Table 10-9(a,b): p>0.08 for all analyses).

The Model 2 unadjusted analysis revealed a significant inverse association between initial dioxin and occurrence of nonmelanoma (Table 10-9(c): Unadjusted RR=0.77, p=0.005). After adjusting for covariates, the association was nonsignificant (Table 10-9(d): p=0.484).

The Model 3 unadjusted analysis revealed that Ranch Hands in the background dioxin category and the low dioxin category each had higher occurrences of nonmelanoma than Comparisons (Table 10-9(e): Unadjusted RR=1.42, p=0.018 for the background dioxin category; Unadjusted RR=1.73, p=0.002 for the low dioxin category). After adjusting for covariates, the only significant result occurred among the Ranch Hands in the low dioxin category (Table 10-9(f): Adjusted RR=1.60, p=0.013). The percentages of participants with nonmelanoma were 29.9 and 19.6 among Ranch Hands in the low dioxin category and Comparisons, respectively.

All results in the Model 4 unadjusted and adjusted analyses were nonsignificant (Table 10-9(g,h): p>0.11 for both analyses).

10.2.2.1.9 Systemic Neoplasms (All Sites Combined)

Results from the analyses of all systemic neoplasms in Models 1, 2, and 4, both unadjusted and adjusted, were nonsignificant (Table 10-11(a-d,g,h): $p \geq 0.16$ for all analyses).

In the unadjusted analyses for Model 3, a significant difference in the percentage of participants with a systemic neoplasm was found between Ranch Hands in the low dioxin category and Comparisons (Table 10-11(e): Unadjusted RR=1.39, $p=0.033$). After adjusting for covariates, the contrast was nonsignificant (Table 10-11(f): $p=0.174$). All other Model 3 contrasts were nonsignificant in both the unadjusted and adjusted analyses (Table 10-15(e,f): $p > 0.34$ for all analyses).

10.2.2.1.10 Malignant Systemic Neoplasms (All Sites Combined)

The unadjusted Model 1 analyses revealed significantly more Ranch Hand officers than Comparison officers with a malignant systemic neoplasm (Table 10-12(a): Unadjusted RR=1.63, p=0.023). Among Ranch Hand officers, 16.6 percent exhibited a malignant systemic neoplasm, as compared to 10.8 percent among Comparison officers. After adjusting for covariates, the contrast remained significant (Table 10-12(b): Adjusted RR=1.81, p=0.014). All other Model 1 contrasts were nonsignificant (Table 10-12(a,b): p>0.05 for all analyses).

The unadjusted Model 2 analysis of malignant systemic neoplasms revealed a significant inverse relation with initial dioxin (Table 10-12(c): Unadjusted RR=0.69, p=0.001). The association was nonsignificant after adjusting for covariates (Table 10-12(d): p=0.898).

The Model 3 contrast between Ranch Hands in the low dioxin category and Comparisons was significant in both the unadjusted and adjusted analyses (Table 10-12(e,f): Unadjusted RR=2.15, p<0.001; Adjusted RR=2.05, p=0.003, respectively). A greater percentage of participants with malignant systemic neoplasms was observed in Ranch Hands than in Comparisons (19.4% versus 10.1%, respectively). All other Model 3 results were nonsignificant (Table 10-12(e,f): p>0.07 for all analyses).

There were no significant findings in the Model 4 unadjusted and adjusted analyses (Table 10-12(g,h): p>0.16 for both analyses).

Note: Results were not adjusted for cumulative herbicide exposure because of the sparse number of Ranch Hands who did not report herbicide exposure.

10.2.2.1.13 Body Sites at Which a Sparse Number of Participants Had a Malignant Systemic Neoplasm

The analyses described below are based primarily on malignant systemic neoplasms by anatomical site. Analyses were attempted for a given site if the statistical software could compute the summary statistics without numerical complications. Analyses based on fewer than five cases in either group should be viewed with caution. Inferential statistics for such analyses (p-values and confidence intervals) should not be used in conclusions regarding herbicide or dioxin exposure and the risk of cancer.

Table 10-15 lists the sites with fewer than five cases of a malignant systemic neoplasm for either Ranch Hands or Comparisons. If analysis was attempted for neoplasms at that site, the table reference is given. If analysis was not attempted, “Not Analyzed” is given under the heading “Table Reference.” Footnotes in the tables indicate where the analysis was limited or covariates were not included in the adjusted analysis due to small numbers of neoplasms, as adjustment for all covariates was often not possible.

Table 10-15. Body Sites at Which a Sparse Number of Participants Had a Malignant Systemic Neoplasm

Site (ICD-9-CM Codes [with T Codes and M codes])	Table Reference	Number of Participants with a Neoplasm	
		Ranch Hand	Comparison
Eye, Ear, Face, Head, and Neck (160.0 – 160.9, 170.0, 170.1, 171.0, 190.0 – 190.9, 195.0, 234.0, 234.8)	10-16	1	4

10.2.2.1.15 Malignant Systemic Neoplasms (Oral Cavity, Pharynx, and Larynx)

Results from each of the unadjusted and adjusted analyses performed for malignant systemic neoplasms of the oral cavity, pharynx, and larynx for Models 1, 3, and 4 were nonsignificant (Table 10-17(a,b,e-h): $p > 0.09$ for all analyses).

The unadjusted analysis of Model 2 revealed a significant inverse relation between initial dioxin and occurrence of malignant systemic neoplasms of the oral cavity, pharynx, and larynx (Table 10-17(c): Unadjusted RR=0.21, $p=0.017$). The result remained significant after covariate adjustment (Table 10-17(d): Adjusted RR=0.12, $p=0.010$). Of the Ranch Hands in the low dioxin category, 2.9 percent had a malignant systemic neoplasm of the oral cavity, pharynx, or larynx, compared to none in the medium or high dioxin categories.

10.2.2.1.16 Malignant Systemic Neoplasms (Thymus, Heart, and Mediastinum)

The unadjusted and adjusted contrasts analyzed in Model 1 for malignant systemic neoplasms of the thymus, heart, and mediastinum were nonsignificant (Table 10-18(a,b): $p > 0.24$ for both analyses).

Model 2 analysis was not performed because no Ranch Hands with an initial dioxin estimate had a malignant neoplasm of the thymus, heart, or mediastinum. The Model 3 unadjusted and adjusted analyses performed were nonsignificant (Table 10-18(e,f): $p > 0.12$ for all analyses).

The Model 4 unadjusted and adjusted analyses showed a significant inverse association between 1987 dioxin levels and occurrence of malignant systemic neoplasms of the thymus, heart, and mediastinum (Table 10-18(g,h): Unadjusted RR=0.40; $p=0.038$; Adjusted RR=0.04, $p=0.009$, respectively). For Ranch Hands in the low 1987 dioxin category, 0.8 percent had a malignant systemic neoplasm of the thymus, heart and mediastinum, compared to no Ranch Hands in the medium or high dioxin categories.

Low	259	0 (0.0)	0.93 (0.27,3.22)
Medium	253	1 (0.4)	
High	256	0 (0.0)	
			p-Value
			0.912

^aRelative risk for a twofold increase in 1987 dioxin.

Note: Low = ≤7.8 ppt; Medium = >7.8–19.2 ppt; High = >19.2 ppt.

(h) MODEL 4: RANCH HANDS – 1987 DIOXIN – ADJUSTED			
Analysis Results for Log₂ (1987 Dioxin)			
n	Adjusted Relative Risk (95% C.I.)^a		p-Value
763	0.85 (0.21,3.39)		0.817

^aRelative risk for a twofold increase in 1987 dioxin.

Note: Results were not adjusted for race, military occupation, cumulative ionizing radiation exposure, cumulative herbicide exposure, and lifetime cigarette smoking history because of the sparse number of Ranch Hands with a malignant systemic neoplasm of the thyroid gland.

10.2.2.1.18 Malignant Systemic Neoplasms (Bronchus and Lung)

The unadjusted Model 1 analyses of malignant systemic neoplasms of the bronchus and lung revealed a significant difference between Ranch Hands and Comparisons when examined across all occupations (Table 10-20(a): Unadjusted RR=2.86, p=0.021). The result was no longer significant after adjusting for covariates (Table 10-20(b): p=0.120). All other Model 1 contrasts were nonsignificant (Table 10-20(a,b): p≥0.10 for all analyses).

A significantly greater percentage of Ranch Hands in the low dioxin category (3.9%) had a malignant systemic neoplasm of the bronchus or lung than Comparisons (0.6%) in both the unadjusted and adjusted Model 3 analyses (Table 10-20(e,f): Unadjusted RR=6.43, p<0.001; Adjusted RR=3.91, p=0.024, respectively). Also in the unadjusted Model 3 analyses, a greater percentage of Ranch Hands in the low and high dioxin categories combined had a malignant systemic neoplasm of the bronchus or lung than Comparisons (Table 10-20(e): Unadjusted RR=3.01, p=0.047). The result was not significant after covariate adjustment (Table 10-20(f): p=0.162). All other Model 3 unadjusted and adjusted analyses were nonsignificant (Table 10-20(e,f): p≥0.50).

There were no significant findings in the Model 2 and Model 4 unadjusted and adjusted analyses of malignant systemic neoplasms of the bronchus and lung (Table 10-20(c,d,g,h): p>0.17 for all analyses).

Table 10-20. Analysis of Malignant Systemic Neoplasms (Bronchus and Lung)

Note: Results were not adjusted for cumulative herbicide exposure because of the sparse number of Ranch Hands who did not report herbicide exposure.

10.2.2.1.20 Malignant Systemic Neoplasms (Colon and Rectum)

In the unadjusted analyses of Model 1, Ranch Hand officers had a significantly higher occurrence of a malignant systemic neoplasm of the colon or rectum versus Comparison officers (Table 10-22(a): Unadjusted RR=4.15, p=0.037). The prevalences were 2.6 percent and 0.7 percent for Ranch Hands and Comparisons, respectively. After covariate adjustment, the results remained significant (Table 10-22(b): Adjusted RR=4.66, p=0.044). All other Model 1 results were nonsignificant (Table 10-22(a,b): p>0.15 for all analyses).

The Model 3 unadjusted analyses of malignant systemic neoplasms of the colon and rectum displayed a significant difference between Ranch Hands in the low dioxin category and Comparisons. The occurrence of a malignant systemic neoplasm of the colon or rectum was higher for Ranch Hands in the low dioxin category (3.4%) than for Comparisons (0.9%) (Table 10-22(e): Unadjusted RR=3.74, p=0.009). The result was also significant after adjusting for covariates (Table 10-22(f): Adjusted RR=3.74, p=0.035). All other Model 3 contrasts were nonsignificant (Table 10-22(e,f): p≥0.24).

All results from the unadjusted and adjusted analyses of malignant systemic neoplasms of the colon and rectum for Models 2 and 4 were nonsignificant (Table 10-22(c,d,g,h): p>0.08 for all analyses).

Note: Results were not adjusted for cumulative herbicide exposure because of the sparse number of Ranch Hands who did not report herbicide exposure.

10.2.2.1.21 Malignant Systemic Neoplasms (Urinary System)

In the unadjusted analyses of Model 1 of occurrence of malignant systemic neoplasms of the urinary system, the difference between Ranch Hands and Comparisons across all occupations was significant (Table 10-23(a): Unadjusted RR=2.32, p=0.023). More malignant systemic neoplasms of the urinary system occurred in Ranch Hands than in Comparisons (2.3% versus 1.0%, respectively). After adjusting for covariates, the result remained significant (Table 10-23(b): Adjusted RR=3.02, p=0.018). Also, the adjusted analysis of Model 1 revealed a significant difference between Ranch Hand and Comparison officers (Table 10-23(b): Adjusted RR=3.59, p=0.049). Again, more malignant systemic neoplasms of the urinary system occurred among Ranch Hands than among Comparisons (2.6% versus 1.1%, respectively). All other Model 1 contrasts were nonsignificant (Table 10-23(a,b): p≥0.09 for all analyses).

The unadjusted analysis of Model 2 did not reveal significant findings (Table 10-23(c): p=0.983). After covariate adjustment, the results were significant, where the prevalence of malignant systemic neoplasms of the urinary system among Ranch Hands increased as initial dioxin increased (Table 10-23(d): Adjusted RR=2.08, p=0.049). The percentages of Ranch Hands with a malignant systemic neoplasm of the urinary system were 1.5, 2.8, and 2.1 among those in the low, medium, and high initial dioxin categories, respectively.

A significantly greater percentage of Ranch Hands in the background and low dioxin categories had a malignant systemic neoplasm of the urinary system, relative to Comparisons, in the unadjusted Model 3 analyses (Table 10-23(e): Unadjusted RR=2.77, p=0.023 for the background dioxin category; Unadjusted RR=2.80, p=0.042 for the low dioxin category). The percentages of participants with a malignant

systemic neoplasm of the urinary system were 1.0 for Comparisons and 2.6 and 2.9 for Ranch Hands in the background and low dioxin categories, respectively. In the adjusted analyses, the only significant result occurred among the Ranch Hands in the background dioxin category (Table 10-23(f): Adjusted RR=3.62, p=0.018). All other Model 3 contrasts were nonsignificant (Table 10-23(e,f): p>0.10 for all analyses).

There were no significant results in the unadjusted and adjusted Model 4 analyses (Table 10-23(g,h): p>0.43 for both analyses).

Table 10-23. Analysis of Malignant Systemic Neoplasms (Urinary System)

763	0.87 (0.60,1.26)		0.459

^aRelative risk for a twofold increase in 1987 dioxin.

Note: Results were not adjusted for race because of the sparse number of Ranch Hands with a malignant systemic neoplasm of the urinary system. Results were not adjusted for cumulative herbicide exposure because of the sparse number of Ranch Hands who did not report herbicide exposure.

10.2.2.1.22 Malignant Systemic Neoplasms (Kidney and Ureter)

In both the unadjusted and adjusted analyses of malignant systemic neoplasms of the kidney or ureter for Models 1 through 3, there were no significant findings (Table 10-24(a-f): $p > 0.06$ for all analyses). There were also no significant findings in the unadjusted analysis of Model 4 (Table 10-24(g): $p = 0.138$). After covariate adjustment, the results for Model 4 became significant, where the prevalence of malignant systemic neoplasms of the kidney or ureter decreased as 1987 dioxin increased (Table 10-24(h): Adjusted $RR = 0.55$, $p = 0.048$). The percentages of Ranch Hands with a malignant systemic neoplasm of the kidney or ureter for the low, medium, and high 1987 dioxin levels were 1.2, 0.4, and 1.2, respectively.

Table 10-24. Analysis of Malignant Systemic Neoplasms (Kidney and Ureter)

Note: Results were not adjusted for race because of the sparse number of Ranch Hands with a malignant systemic neoplasm of the kidney or ureter. Results were not adjusted for cumulative herbicide exposure because of the sparse number of Ranch Hands who did not report herbicide exposure.

10.2.2.1.23 Malignant Systemic Neoplasms (Prostate)

All results from the Model 1 and Model 4 analyses, both unadjusted and adjusted, of malignant systemic neoplasms of the prostate were nonsignificant (Table 10-25(a,b,g,h): $p > 0.08$ for all analyses).

A significant inverse association between initial dioxin and the occurrence of malignant systemic neoplasms of the prostate was found in the unadjusted Model 2 analysis (Table 10-25(c): Unadjusted $RR = 0.54$, $p < 0.001$). After adjusting for covariates, the association was nonsignificant (Table 10-25(d): $p = 0.069$).

The Model 3 unadjusted analysis revealed a significant difference in the occurrence of a malignant systemic neoplasm of the prostate between Ranch Hands in the low dioxin category and Comparisons (Table 10-25(e): Unadjusted $RR = 2.00$, $p = 0.007$). More Ranch Hands than Comparisons had a malignant systemic neoplasm of the prostate (10.7% versus 5.7%, respectively). After covariate adjustment, this result remained significant (Table 10-25(f): Adjusted $RR = 1.85$, $p = 0.048$). All other Model 3 contrasts, both unadjusted and adjusted, were nonsignificant (Table 10-25(e,f): $p > 0.20$ for all analyses).

10.2.2.1.24 Malignant Systemic Neoplasms (Penis and Other Male Genital Organs)

There were no significant findings among the Model 1 unadjusted analyses and Model 2 unadjusted and adjusted analyses of malignant systemic neoplasms of the penis and other male genital organs (Table 10-26(a,c,d): p>0.05 for all analyses). Adjusted analyses of Models 1 and 3 could not be performed because of the limited number of neoplasms. In the unadjusted analysis of Model 3, a significant difference in the occurrence of a malignant systemic neoplasm of the penis or other male genital organs was found between Ranch Hands in the high dioxin category and Comparisons (Table 10-26(e):

p=0.019). No Comparisons had malignant systemic neoplasms of the penis and other male genital organs compared to 0.9 percent of Ranch Hands in the high dioxin category.

The Model 4 unadjusted analysis did not reveal significant results (Table 10-26(g): p=0.053). After covariate adjustment, a significant positive relation was found between 1987 dioxin and the occurrence of malignant systemic neoplasms of the penis and other male genital organs (Table 10-26(h): Adjusted RR=3.52, p=0.017). Two Ranch Hands in the high 1987 dioxin category had a malignant systemic neoplasm of the penis or other male genital organs, whereas no Ranch Hands in the low 1987 dioxin category or medium 1987 dioxin category had a neoplasm of this type.

			p-Value
			0.053

^aRelative risk for a twofold increase in 1987 dioxin.

Note: Low = \leq 7.8 ppt; Medium = >7.8–19.2 ppt; High = >19.2 ppt.

(h) MODEL 4: RANCH HANDS – 1987 DIOXIN – ADJUSTED			
Analysis Results for Log₂ (1987 Dioxin)			
n	Adjusted Relative Risk (95% C.I.)^a		p-Value
763	3.52 (1.04,11.91)		0.017*

^aRelative risk for a twofold increase in 1987 dioxin.

*: Statistically significant (0.010 < p-value \leq 0.050).

Note: Results were not adjusted for race, military occupation, cumulative ionizing radiation exposure, and cumulative herbicide exposure because of the sparse number of Ranch Hands with a malignant systemic neoplasm of the penis or other male genital organs.

10.2.2.1.25 Malignant Systemic Neoplasms (Testicles)

All unadjusted and adjusted analyses performed for malignant systemic neoplasms of the testicles using Models 1, 2, and 4 were nonsignificant (Table 10-27(a-d,g,h): $p > 0.12$ for all analyses). Due to a sparse number of neoplasms, the adjusted analyses of Model 1 could not be performed.

Significant differences were found in the unadjusted Model 3 analysis between Ranch Hands in the low dioxin category and Comparisons, and between Ranch Hands in the low and high dioxin categories combined and Comparisons (Table 10-27(e): $p = 0.017$ and $p = 0.025$, respectively). The prevalences were 1.0 percent for Ranch Hands in the low dioxin category and 0.7 percent for Ranch Hands in the low and high dioxin categories combined. There were no occurrences of malignant systemic neoplasms of the testicles among Comparisons. The adjusted Model 3 analyses were not possible because of the sparse number of neoplasms of the testicles.

Table 10-27. Analysis of Malignant Systemic Neoplasms (Testicles)

(a) MODEL 1: RANCH HANDS VS. COMPARISONS – UNADJUSTED					
Occupational Category	Group	n	Number (%) Yes	Unadjusted Relative Risk (95% C.I.)	p-Value

10.2.2.1.28 *Carcinoma in Situ (Breast, Digestive Organs, Respiratory, Prostate, Penis and Other Male Genitals, and Bladder and Other and Nonspecified Urinary)*

All results from the unadjusted and adjusted analyses performed of Models 1, 2, and 4 of carcinoma in situ (breast, digestive organs, respiratory, prostate, penis and other male genitals, and bladder and other and nonspecified urinary) were nonsignificant (Table 10-30(a-d,g,h): $p > 0.06$ for all analyses). The unadjusted Model 3 analyses were nonsignificant, but after adjustment for covariates, a significant result was found for the Model 3 analysis of carcinoma in situ between Ranch Hands in the low dioxin category and Comparisons (Table 10-30(f): Adjusted RR=20.75, $p=0.027$). Three Ranch Hands in the low dioxin category (1.5%) and six Comparisons (0.5%) had a carcinoma in situ.

n	Adjusted Relative Risk (95% C.I.)^a		p-Value
763	0.50 (0.01,16.93)		0.653

^aRelative risk for a twofold increase in 1987 dioxin.

Note: Results were not adjusted for race, military occupation, cumulative ionizing radiation exposure, cumulative herbicide exposure, and lifetime cigarette smoking history because of the sparse number of Ranch Hands with Hodgkin's disease.

10.2.2.1.30 Leukemia

There were no significant findings for the analyses of leukemia performed for Models 1 and 3, both unadjusted and adjusted (Table 10-32(a,b,e,f): $p > 0.27$ for all analyses). Model 2 analyses were not performed because of the sparse number of Ranch Hands with leukemia.

For the unadjusted analysis of Model 4, a significant inverse relation was found between 1987 dioxin and occurrence of leukemia (Table 10-32(g): Unadjusted RR=0.43, $p=0.008$). The percentages of Ranch Hands with leukemia were 1.2 for those in the low 1987 dioxin category and 0.4 for those in the medium 1987 dioxin category. There were no occurrences of leukemia among those Ranch Hands in the high 1987 dioxin category. After covariate adjustment, the result remained significant (Table 10-32(h): Adjusted RR=0.40, $p=0.004$).

Table 10-32. Analysis of Leukemia

Note: Results were not adjusted for race, military occupation, cumulative ionizing radiation exposure, and cumulative herbicide exposure because of the sparse number of Ranch Hands with a lymphoreticular sarcoma.

10.2.2.1.33 Skin and Systemic Neoplasms

The Model 1 unadjusted analyses of skin and systemic neoplasms revealed a significant difference between Ranch Hands and Comparisons when examined across all occupations (Table 10-35(a): Unadjusted RR=1.22, p=0.042). After covariate adjustment, the result was no longer significant (Table 10-35(b): p=0.491). All other Model 1 analyses, both unadjusted and adjusted, were nonsignificant (Table 10-35(a,b): p>0.14 for all analyses).

A significant inverse association between initial dioxin and the occurrence of skin or systemic neoplasms was found in the Model 2 unadjusted analysis (Table 10-35(c): Unadjusted RR=0.82, p=0.011). After adjusting for covariates, the result was nonsignificant (Table 10-35(d): p=0.372).

In the Model 3 unadjusted analyses, a significantly higher percentage of Ranch Hands in the low dioxin category had an occurrence of a skin or a systemic neoplasm, relative to Comparisons (Table 10-35(e): Unadjusted RR=1.74; p=0.001). After adjusting for covariates, the result remained significant (Table 10-35(f): Adjusted RR=1.46, p=0.048). The percentages of Ranch Hands in the low dioxin category and Comparisons exhibiting a skin or a systemic neoplasm were 73.8 and 61.7, respectively. All other Model 3 contrasts, as well as the results from the Model 4 analyses, were nonsignificant (Table 10-35(e-h): p≥0.08 for all analyses).

10.2.2.1.34 Malignant Skin and Systemic Neoplasms

A significant difference between Ranch Hands and Comparisons was found in the unadjusted Model 1 analyses of malignant skin and systemic neoplasms for all occupations combined and for officers (Table 10-36(a): Unadjusted RR=1.22, p=0.049 overall; Unadjusted RR=1.41, p=0.027 for officers). All other Model 1 unadjusted analyses were nonsignificant (Table 10-36(a): p>0.05). After adjusting for covariates, all results were nonsignificant (Table 10-36(b): p>0.15 for all analyses).

The unadjusted analysis of Model 2 revealed a significant inverse relation between initial dioxin and occurrence of malignant skin or systemic neoplasms (Table 10-36(c): Unadjusted RR=0.76, p<0.001). After adjusting for covariates, the association was nonsignificant (Table 10-36(d): p=0.540).

Both the unadjusted and adjusted Model 3 analyses revealed a significant difference in the occurrence of malignant skin or systemic neoplasms between Ranch Hands in the low dioxin category and Comparisons (Table 10-36(e,f): Unadjusted RR=1.86, p<0.001; Adjusted RR=1.64, p=0.008, respectively). More Ranch Hands in the low dioxin category than Comparisons had malignant skin or systemic neoplasms (41.4% versus 27.4%, respectively). All other Model 3 contrasts and all unadjusted and adjusted results from the Model 4 analyses were nonsignificant (Table 10-36(e-h): p>0.08 for all analyses).

10.2.2.2 Laboratory Variable

10.2.2.2.1 PSA (Continuous)

All results from the unadjusted and adjusted analyses of Models 1, 3, and 4 for the continuous form of PSA were nonsignificant (Table 10-37(a,b,e-h): $p > 0.06$ for all analyses).

The unadjusted Model 2 analysis revealed a significant inverse association between initial dioxin and PSA as a continuous variable (Table 10-37(c): Slope=−0.064, $p=0.027$). After adjusting for covariates, the association was nonsignificant (Table 10-37(d): $p=0.139$).

10.2.2.2.2 PSA (Discrete)

There were no significant findings in the unadjusted and adjusted analyses of the discrete form of PSA for Models 1, 3, and 4 (Table 10-38(a,b,e-h): $p > 0.10$ for all analyses).

The Model 2 unadjusted analysis of the discrete form of PSA revealed a significant inverse relation between initial dioxin and discrete PSA levels (Table 10-38(c): Unadjusted RR=0.58, $p=0.013$). After covariate adjustment, the result was no longer significant (Table 10-38(d): $p=0.058$).

10.3 DISCUSSION

The 2002 follow-up examination of the AFHS combined physical examination, interval history, and laboratory evaluation to assess the risk of benign and malignant neoplasia to study participants exposed to herbicides (Ranch Hands) compared to matched controls who were not exposed (Comparisons). Data collected at the 2002 follow-up examination were added to data from earlier assessments and a cancer history for each participant who attended the 2002 follow-up examination was created.

Although exposure to herbicides has been determined to be carcinogenic in animal studies, the exposure required for malignant transformation of normal cells and the types of tumors produced are species-dependent. Therefore, while animal studies provide conclusive evidence on the carcinogenic potential of dioxin, the determination of causality in humans remains to be established. Many studies have assessed the carcinogenic potential of dioxin in humans (43-183), as described previously in this chapter (see Section 10.1.1.3). While the cumulative data from these studies have not been entirely consistent, there does appear to be an association between dioxin exposure in humans and an increased risk of developing cancers of the skin, lung, bladder, kidney, connective tissue, and lymphatic system. Part of the apparent inconsistencies may be due to significant differences in cumulative dose, dose-rate (one-time acute exposure versus chronic, low-dose exposure), frequency of assessments, and confounding risk factors or unaccounted exposure to co-promoters or co-carcinogens (e.g., tobacco smoke, either direct or second-hand).

As anticipated, there were several significant dependent variable-covariate associations that emerged from the 2002 data, including a strong association between age and the likelihood of developing most cancers. This association mirrors that seen in the general U.S. population.

Officers, the oldest participants on average, had a higher prevalence of skin cancer, primarily basal cell carcinoma, as well as the highest prevalence of cancer of any type. The prevalence of prostate cancer and abnormally high PSA results and the highest average levels of PSA were greater for officers and enlisted flyers. Enlisted flyers had the highest average PSA levels, while officers had the highest prevalence of abnormal PSA results.

Cancer prevalence was established by medical records review. For chest x-ray findings that were reported as needing follow-up at the 2002 physical examination, the AFHS made every effort to contact and to encourage participants to see their physicians. The participants were recontacted to determine a final diagnosis. Medical records review was accomplished to confirm reported neoplasms and to identify any unreported neoplasms. During physical examinations, newly discovered and suspicious skin lesions were biopsied if the study participant consented. A skin biopsy was indicated for 307 of the 1,951 (15.7%) participants at the 2002 follow-up examination; 289 of these 307 participants (94.1%) consented to the biopsy.

Several associations emerged. For example, there was an increased prevalence of skin cancers in the Ranch Hand cohort when compared against the Comparison cohort (54.2% versus 47.8%, respectively). This difference was further isolated to malignant skin cancer and, in particular, basal cell carcinoma. No significant associations between squamous cell carcinoma or melanoma and herbicide exposure were found. Although Ranch Hands exhibited an increased prevalence of basal cell carcinoma, the association was seen primarily in officers, who, on average, had the lowest dioxin levels. Higher prevalences were also observed in the Ranch Hand subgroups with the lowest levels of initial or 1987 dioxin. A higher percentage of the Ranch Hand cohort also exhibited skin cancers of uncertain behavior or unspecified nature. Again, there appeared to be an inverse correlation between dioxin and development of skin cancers, with the prevalence decreasing as dioxin increased. In summary, the data from this study did not support a dose-response relation between dioxin levels and development of nonmelanoma skin cancers.

Ranch Hands in the low dioxin category had an increased risk of bronchus and lung cancer relative to Comparisons. No trend of an increasing risk with increasing levels of dioxin was evident in the other analyses, however, and the available data from this study did not support a dose-response relation between dioxin levels and the development of lung cancer.

Ranch Hand officers had higher prevalence of colorectal and urinary system cancers. Colorectal cancer in the Ranch Hand low dioxin category and urinary system cancers in the Ranch Hand background dioxin category were increased. No increases in Ranch Hand high dioxin category were observed. These increases were based on fewer than 10 cases per exposure category.

Ranch Hands in the low dioxin category appeared to have an increased risk of developing prostate cancer relative to Comparisons. No association was found between PSA levels and levels of dioxin.

Ranch Hands in the low initial dioxin cohort had an increased risk of skin and systemic neoplasms combined, which reflects the skin neoplasm analyses discussed previously.

In summary, most associations between dioxin levels and cancer were found in the low Ranch Hand dioxin category. Further inferences are limited because of a small number of cancers in this low exposure group. Some of these associations may also be due to chance or lack of adjustment for a factor not

considered in these analyses. The group of Ranch Hands in the low dioxin category may merit additional study to ascertain the cause(s) of their malignancies, but the small size of the cohort and low actual numbers of events may make any additional conclusions difficult.

10.4 SUMMARY

A neoplasia history for each participant who attended the 2002 follow-up examination was developed by combining data from the 2002 follow-up examination with information collected at previous AFHS examinations and verifying the results through a review of medical records. In addition, PSA levels, as determined by the Scripps Clinic laboratory, were analyzed. Associations with herbicide exposure (i.e., group – Model 1), initial dioxin (Model 2), categorized dioxin (Model 3), and 1987 dioxin levels (Model 4) were examined for each variable in the neoplasia assessment. The significant adjusted results are discussed in the sections below.

10.4.1 Model 1: Group Analysis

More Ranch Hands had skin neoplasms, basal cell carcinoma, nonmelanoma, and malignant systemic neoplasms of the urinary system than Comparisons in the overall analyses. When stratified by military occupation, Ranch Hand officers had an increased risk of basal cell carcinoma and, consequently, nonmelanoma skin cancers. Ranch Hand officers also had an increased risk of malignant systemic neoplasms and malignant systemic neoplasms of the colon and rectum and of the urinary system. No results were significant in the adjusted analyses of skin or systemic neoplasms for enlisted flyers or enlisted groundcrew. The results of the group analysis are provided in Table 10-39.

10.4.2 Model 2: Initial Dioxin Analysis

As initial dioxin in Ranch Hands increased, the occurrence of skin neoplasms of uncertain behavior or unspecified nature decreased, as did the prevalence of a malignant neoplasm of the oral cavity, pharynx, or larynx. The prevalence of a malignant systemic neoplasm of the urinary system, however, increased as initial dioxin increased. The results of all unadjusted and adjusted Model 2 analyses are summarized in Table 10-40.

--: The analysis was not performed because of the sparse number of Ranch Hands with a neoplasm.

Note: NS or ns: Not significant ($p>0.05$).

C: Continuous form of dependent variable.

D: Discrete form of dependent variable.

The p-value was given if $p\leq 0.05$. The relative risk was given in parentheses for a significant result from the analysis of a discrete dependent variable. The slope was given in parentheses for a significant result from the analysis of a continuous dependent variable.

A capital “NS” denotes a nonsignificant positive association. A lowercase “ns” denotes a nonsignificant inverse association.

10.4.3 Model 3: Categorized Dioxin Analysis

The significant results of the Model 3 analyses were primarily found when comparing Ranch Hands in the low dioxin category with Comparisons. Ranch Hands in the low dioxin category had an increased risk of a basal cell carcinoma. This pattern was also seen in nonmelanoma skin cancers, malignant skin cancers, and all skin neoplasms (benign, malignant, and uncertain behavior). The risk of a skin neoplasm of uncertain behavior or unspecified nature was also increased for Ranch Hands in the low dioxin category.

The prevalence of a malignant systemic neoplasm, combined across sites, also was significantly increased for Ranch Hands in the low dioxin category relative to Comparisons. Significant results for the site-specific analyses included increased risks to Ranch Hands in the low dioxin category for malignant systemic neoplasms of the bronchus or lung, colon or rectum, prostate, and carcinoma in situ. These findings led to an increased risk for low Ranch Hands for all neoplasms and all malignant neoplasms (combining skin and systemic).

Ranch Hands in the background category had an increased risk of a malignant systemic neoplasm of the urinary system. Ranch Hands in the low and high dioxin categories combined had an increased prevalence of a skin neoplasm of any type. No significant results were found for Ranch Hands in the high dioxin category. The complete results of all unadjusted and adjusted Model 3 analyses are summarized in Table 10-41.

10.4.4 Model 4: 1987 Dioxin Level Analysis

As 1987 dioxin in Ranch Hands increased, the prevalence of a malignant systemic neoplasm of the penis or other male genital organs increased. As 1987 dioxin increased, however, the occurrence of a malignant systemic neoplasm of the thymus, heart, or mediastinum, the kidney or ureter, or leukemia decreased. All results for Model 4 unadjusted and adjusted analyses are summarized in Table 10-42.

10.4.5 Summary of Significant Results

Table 10-43 summarizes the significant results ($p \leq 0.05$) for the adjusted analyses that were performed for the neoplasia assessment. The dependent variable and its table reference are listed along with the model and the contrast or description of the model. The p-value is provided along with analysis statistics that correspond to the type of analysis that was performed (either continuous or discrete). A description of the analysis and the statistics that are presented is referenced under the "Note" column and is explained in footnotes.

Table 10-43. Summary of Results from Significant Adjusted Analyses in the Neoplasia Assessment

Dependent Variable (Table Reference)	Model	Contrast or Description	p-Value	Analysis Statistics	Percent Abnormal	Note
All Skin Neoplasms (10-3)	1	RH vs. C, All	0.012	1.28 (1.06,1.56)	RH: 54.2% C: 47.8%	(a)

Table 10-43. Summary of Results from Significant Adjusted Analyses in the Neoplasia Assessment (Continued)

Dependent Variable (Table Reference)	Model	Contrast or Description	p-Value	Analysis Statistics	Percent Abnormal	Note
Malignant Skin and Systemic Neoplasms (10-36)	3	Low RH vs. C	0.008	1.64 (1.14,2.37)	RH: 41.4% C: 27.4%	(b)

- (a): Discrete variable: adjusted relative risk and 95% confidence interval were presented; percent abnormal is presented for each exposure group in contrast.
- (b): Discrete variable: adjusted relative risk and 95% confidence interval were presented; percent abnormal is presented for each dioxin category in contrast.
- (c): Discrete variable: adjusted relative risk and 95% confidence interval were presented for a twofold increase in initial dioxin; percent abnormal is presented for each of three initial dioxin categories.
- (d): Discrete variable: adjusted relative risk and 95% confidence interval were presented for a twofold increase in 1987 dioxin; percent abnormal is presented for each of three 1987 dioxin categories.

Note: RH = Ranch Hand.
C = Comparison.

Model 2: Low = 32–79 ppt; Medium = >79–199 ppt; High = >199 ppt (Ranch Hands who had a 1987 dioxin measurement greater than 10 ppt).

Model 3: Background (Ranch Hand): 1987 dioxin ≤ 10 ppt.
Low (Ranch Hand): 1987 dioxin > 10 ppt, 10 ppt < initial dioxin ≤ 118 ppt.
High (Ranch Hand): 1987 dioxin > 10 ppt, initial dioxin > 118 ppt.

Model 4: Low = ≤7.8 ppt; Medium = >7.8–19.2 ppt; High = >19.2 ppt (Ranch Hands only).

10.5 CONCLUSION

During the 2002 health interview, each study participant was asked a series of questions on the occurrence of cancer since the date of his last health interview. The self-reported conditions were verified by a medical records review and combined with cancer information collected at previous AFHS examinations. For chest x-ray findings that were reported as needing follow-up at the 2002 physical examination, the AFHS made every effort to contact and encourage participants to see their physicians. The participants were recontacted to determine a final diagnosis. Some possible neoplastic conditions were discovered by the physicians at the physical examination. Contingent upon participant authorization, suspicious skin lesions were biopsied and the pathology determined; no other invasive procedures were used to detect systemic neoplasms.

Skin neoplasms were analyzed by behavior type and cell type. Systemic neoplasms were analyzed by behavior and anatomical site. All skin and systemic neoplasms and all malignant skin and systemic neoplasms also were analyzed. Analyses were conducted on prostate-specific antigen, which was used to detect prostate enlargement and prostate cancer.

Contrasts of Ranch Hands with Comparisons by military occupation showed significant results only for officers. Ranch Hand officers had an increased risk of basal cell carcinoma and, consequently, nonmelanoma skin cancers. Ranch Hand officers also had an increased risk of malignant systemic

neoplasms. The analysis of malignant systemic neoplasms of the colon and rectum and of the urinary system showed a greater risk for Ranch Hand officers.

The prevalence of a malignant systemic neoplasm of the urinary system increased as initial dioxin in Ranch Hands increased.

When comparing categorized levels of dioxin, significant results were primarily found when comparing Ranch Hands in the low dioxin category with Comparisons. Ranch Hands in the low dioxin category had an increased risk of a basal cell carcinoma and, consequently, this pattern was also seen in nonmelanoma skin cancers, malignant skin cancers, and skin neoplasms (benign, malignant, and uncertain behavior). The risk of a skin neoplasm of uncertain behavior or unspecified nature was also increased for Ranch Hands in the low dioxin category.

The prevalence of a malignant systemic neoplasm, combined across sites, also was significantly increased for Ranch Hands in the low dioxin category relative to Comparisons. Significant results for the site-specific analyses included increased risks to Ranch Hands in the low dioxin category for malignant systemic neoplasms of the bronchus or lung, colon or rectum, and prostate. These findings led to an increased risk for Ranch Hands in the low dioxin category for all neoplasms and all malignant neoplasms (combining skin and systemic). Ranch Hands in the background category had an increased risk of a malignant systemic neoplasm of the urinary system. Ranch Hands in the low and high dioxin categories combined had an increased prevalence of a skin neoplasm of any type.

In conclusion, the significant associations between herbicide exposure or dioxin levels and the likelihood of developing cancer were seen primarily for Ranch Hand officers and Ranch Hands in the low dioxin category, which were the lower-exposed subgroups, on average. Some of these associations also may have been due to chance or to a lack of adjustment for a factor not considered in these analyses.

11 NEUROLOGY ASSESSMENT

11.1 INTRODUCTION

11.1.1 Background

11.1.1.1 Organs/Diseases

The Air Force Health Study (AFHS) neurology assessment included the evaluation of cranial nerve function, peripheral nerve status, and central nervous system (CNS) coordination processes based on a physical examination. The cranial nerve function incorporated smell, visual fields, light reaction, ocular movement, facial sensation, corneal reflex, jaw clench, smile, palpebral fissure, balance, gag reflex, speech, tongue position relative to midline, palate and uvula movement, and shoulder shrug. Peripheral nerve status was assessed by light pinprick, light touch (with cotton sticks), visual inspection of muscle mass (and palpation, if indicated), three deep tendon reflexes (patellar, Achilles, and biceps), and the Babinski reflex. In addition, indices of bilateral symmetric distal sensory or sensorimotor polyneuropathy were analyzed based on testing of ankle and toe flexor strength, equilibrium (Romberg sign), Achilles reflex, light touch, pinprick, vibration at the ankle, and joint position of the left and right great toes. The evaluation of CNS coordination processes was based on tremor, coordination, Romberg sign, and gait. Neurobehavioral endpoints, which have been the subject of intensive investigation in this and other studies of Vietnam veterans, are considered separately in Chapter 12, Psychology Assessment.

11.1.1.2 Toxicology

The mechanism by which dioxin could result in neurotoxic effects is not well-known (1), although it has been suggested that the aryl hydrocarbon (Ah) receptor plays a role in neurotoxicity (2). Several studies have investigated the neurotoxic effects of dioxin in laboratory animals with inconsistent results. Rats given a high dose of dioxin (1,000 µg/kg) intraperitoneally demonstrated no apparent neurological deficits (3). The intracerebroventricular administration of dioxin proved far more toxic than the subcutaneous route in producing a wasting syndrome in rats, although specific neurological indices were not examined (4). In another study, the neuromuscular effects associated with acute lethal doses of dioxin in rats were primarily in muscle tissue rather than peripheral nerves (5). A study of Wistar rats receiving a single intraperitoneal low dose of dioxin in one of four strengths documented dose-dependent and statistically significant reductions in motor and sensory nerve conduction velocities relative to the controls (6). Ten months after exposure, microscopic studies confirmed the histologic appearance of a severe peripheral neuropathy of the axonal and demyelinating type (7). No other studies in animals, however, found a similar effect (1).

11.1.1.3 Epidemiology

In humans, only circumstantial evidence linking 2,4-D herbicide exposure to neurotoxicity exists; the arguments against a causal relation were summarized by Mattsson and Eisenbrandt (8). Nevertheless, a host of neurological symptoms have been reported following dioxin exposure. These symptoms were grouped under the generic term “neurasthenia.” Numerous studies were published describing neurological sequelae in populations exposed to dioxin by occupation (9-16), environmental contamination (17-21) and industrial accidents (22-28), and in association with service in Southeast Asia

(SEA) during the Vietnam War (29-36). Epidemiologic studies of neurological sequelae of dioxin exposure were reviewed recently (37) and are discussed in some detail below.

The potential health effects of environmental exposure to dioxin due to industrial accidents were examined in several epidemiologic studies. The 1976 chemical explosion in Seveso, Italy, provided a basis for numerous reports on the exposed population (22-25, 27, 28). Several of these reports included clinical and laboratory indices in the examination protocols, most of which focused on signs and symptoms of peripheral neuropathy as primary clinical endpoints. In one study, 152 subjects with chloracne, a marker for high-level dioxin exposure, were compared with 123 age- and sex-matched controls from nearby towns. Only 1 of 13 neurophysiologic indices (i.e., sensory nerve action potential) was found to be statistically significantly different ($p < 0.02$) between exposed and unexposed subjects, and none of the exposed subjects was found to have a peripheral neuropathy according to World Health Organization criteria (25). Investigators of the Seveso population who included electromyographic studies in the examination protocols reached similar conclusions (22, 24, 27), as did those studying the populations exposed following uncontrolled chemical reactions that occurred in Germany in 1953 (26) and in Nitro, West Virginia, in 1949 (12).

Point-source environmental exposure to dioxin also has been the focus of numerous epidemiologic studies, some of which included neurological indices in their protocols (17-21). In 1971, waste byproducts contaminated with dioxin were mixed with oils and widely sprayed for dust control in residential areas in eastern Missouri. Soil concentrations in some areas reached 2,200 parts per billion, far exceeding the highest degree of ground contamination that occurred at Seveso (21). Comprehensive medical evaluations of exposed and unexposed cohorts included detailed neurological examinations (17-20) and, in one report (19), quantitative studies of tactile, vibratory, and thermal sensory perception. None of the Missouri dioxin studies (21) revealed any clinical evidence for central or peripheral neurological disease associated with exposure to dioxin. In one Missouri study that related neurological endpoints to tissue levels of dioxin (18), no associations were found among 41 subjects between the body burden of dioxin and abnormalities in deep tendon reflexes or pain and vibratory sensation.

Some occupational studies investigated the potential neurological effects of dioxin exposure, such as motor or coordination dysfunction (9, 15, 26). An epidemiologic study conducted by the National Institute of Occupational Safety and Health is one of a few that relates serum dioxin levels to neurological indices (15). The prevalence of peripheral neuropathy was determined in 265 workers with a mean serum dioxin level of 220 parts per trillion (ppt) 15 years after exposure and in 244 referents with a level of 7 ppt. The diagnosis of peripheral neuropathy was established by symptoms and by data collected during physical examination, electrophysiologic studies, and quantitative sensory testing. There was no evidence of a long-term effect of dioxin exposure on peripheral neuropathy.

Other occupational studies evaluating neurological symptoms revealed inconsistent results. In a study of 109 workers employed in a Chinese chemical manufacturing plant, nerve conduction velocities were observed to be slower among workers in an area where exposure to dioxin was highest (16). On the other hand, findings from a morbidity follow-up study of 158 men exposed to dioxin after a chemical accident at the trichlorophenol unit of a BASF chemical facility were inconclusive (26). Exposure to dioxin was determined based on chloracne status and extrapolated blood lipid concentrations. The rate of episodes of illness among exposed workers was compared to the rate in an unexposed population employed at the same facility. Although more frequent episodes of a variety of nervous system disorders may have been related to high dioxin exposure, no evidence for specific peripheral nervous system disorders, such as peripheral neuropathy, was observed.

One occupational study of 47 railroad workers examined 6 years after exposure to polychlorinated phenols (including dioxin) during the cleanup of a chemical spill revealed evidence, through electrophysiologic measurements, of a peripheral neuropathy in 43 of these workers. High prevalence of dystonia (53%) and tremor (78%) were documented (9). In another study, neuralgia was found in 30 percent of 159 workers exposed to chemicals in a herbicide production plant (38). In a recent study of 13 workers involved in herbicide production in the Czech Republic, clinical polyneuropathic signs were found in 38 percent of the employees (39). In addition, electroencephalography abnormalities were found more frequently in workers exposed to higher levels of the herbicide, based on blood dioxin levels (39). The findings in these studies, however, were not contrasted with those in the unexposed control population.

The relation between pesticide exposure and Parkinson's disease was evaluated in 1996, 1998, 2000, and 2002 Institute of Medicine (IOM) reports (1, 40-42). Some indication of an association was seen based on a review of 30 epidemiologic studies, most of which were case-control studies focusing on occupational exposure. An association of Parkinson's disease with exposure to dioxin, however, was not reported in any of these studies. Therefore, the 2002 IOM committee considered the evidence for an association of Parkinson's disease with exposure to dioxin to be inadequate or insufficient (1). A similar conclusion was reached for amyotrophic lateral sclerosis based on a review of five epidemiologic studies, none of which evaluated dioxin exposure specifically (1).

Few studies of Vietnam veterans have incorporated neurological data into their protocols and, with the exception of the AFHS (31-34, 43), none has correlated neurological indices with tissue levels of dioxin. One large-scale study of American Legion veterans who served in Vietnam found an increased incidence of reported neurobehavioral disorders among veterans who reported exposure to herbicides (29).

The Vietnam Experience Study, conducted by the Centers for Disease Control and Prevention (CDC), compared the health status of 2,490 Vietnam veterans with 1,972 non-Vietnam veterans (30). The study protocol included comprehensive neurological examinations, nerve conduction velocity studies, and neurophysiologic indices of vibratory, thermal, and auditory sensations. Aside from an increased prevalence of combat-related high frequency hearing loss in a pattern consistent with prior noise exposure, no neurological abnormalities were noted in association with service in Vietnam. A recent study found no increased prevalence of neurological symptoms across levels of exposure to Agent Orange among 1,224 Korean Vietnam veterans, although the risk of peripheral neuropathy was higher among veterans than nonveterans (36).

The evidence for an association between serum dioxin levels and peripheral neuropathy among Ranch Hand personnel in the AFHS was recently reviewed for the examination years 1982, 1985, 1987, 1992, and 1997 (43). Each Ranch Hand veteran was assigned to one of three dioxin categories (background, low, or high) based on his serum dioxin level. In addition, an unexposed comparison group was selected comprising Air Force veterans who served in SEA during the same time period as the Ranch Hand veterans, but who were not involved with spraying herbicides. Neurological parameters evaluated at the physical examinations included nerve conduction velocity (1982), vibrotactile threshold (1992 and 1997), and symmetrical peripheral abnormalities (all examination years). Peripheral neuropathy was classified as possible, probable, or definite based on the number of signs of peripheral abnormality. No evidence pointed to an association between serum dioxin levels and nerve conduction velocity. Relative risk estimates for any symmetrical peripheral abnormality or possible symmetrical peripheral neuropathy varied little across categories of serum dioxin, with most odds ratios around unity. Only in the 1997 examination was there some indication of an increased risk for these outcomes reported in the highest exposure level (odds ratio=1.8; 95% confidence interval: 1.2-2.7). Some indication for an association with probable peripheral neuropathy was found in the years 1985, 1992, and 1997. Although dose-

response patterns were somewhat inconsistent, in these years the highest risk was observed in the highest exposure group. Finally, in 1992 and 1997, the risk of diagnosed peripheral neuropathy, but not vibrotactile abnormality, was associated with dioxin levels.

In a 1996 report published by the IOM (42), the committee concluded that there is “limited/suggestive” evidence of an association between exposure to certain herbicides used in Vietnam and the development of an acute or subacute transient peripheral neuropathy. This conclusion remained unaltered in the 2002 IOM report (1). The evidence regarding the association between exposure to dioxin and disorders involving persistent peripheral neuropathy, or motor or coordination deficits, was considered inadequate or insufficient (1).

11.1.2 Summary of Previous Analyses of the Air Force Health Study

11.1.2.1 1982 Baseline Examination Summary Results

The 1982 AFHS neurology assessment consisted of questionnaire, physical examination, and electromyographic data obtained by examiners and technicians who were blind to the group identity of each participant. The physical examination required an average of 30 minutes to complete. Analyses were adjusted for reported alcohol usage, exposure to insecticides and industrial chemicals, and glucose intolerance (diabetes).

Results of the questionnaire disclosed no significant group differences in reported neurological diseases. The physical examination did not reveal any statistically significant group differences in the function of the 12 cranial nerves. Peripheral nerve function was assessed by the quality of four reflexes (patellar, Achilles, biceps, and Babinski); muscle strength or bulk; and reaction to the stimuli of pinprick, light touch, and vibration. Other than a statistically significant increase ($p=0.03$) in abnormal Babinski reflexes among Ranch Hands, significant group differences were not detected.

Nerve conduction velocities were obtained on the ulnar nerve above and below the elbow and the peroneal nerve. The results for each segmental measurement were nearly identical in the Ranch Hand and Comparison groups. Conduction velocity showed highly significant inverse relations to both alcohol use and diabetes in almost all of the anatomic measurements. No group associations or interactions were detected with the reported exposure to industrial and degreasing chemicals and insecticides.

No significant group differences were detected in four measures of central neurological function (tremor, finger-nose coordination, modified positive Romberg sign, or abnormal gait). Alcohol usage was significantly associated with the presence of tremor, and glucose intolerance was highly correlated to abnormal balance and the presence of tremor.

11.1.2.2 1985 Follow-up Examination Summary Results

The 1985 AFHS neurological examination did not include the measurements of nerve conduction velocities, but otherwise repeated the baseline examination protocol. The questionnaire maintained a historical focus on neurasthenia through five questions for the 1982–1985 interval. With this similarity in examination and questionnaire, the dependent variables of the analyses were the same as those of the baseline study.

Interval questionnaire data (1982–1985) on neurological illness, verified by medical records, revealed no significant group differences. These data were added to verified baseline examination historical

information to assess possible differences in the lifetime experience of neurological disease. Again, there was no significant difference between the Ranch Hand and Comparison groups.

The neurological examination evaluated neurological integrity in three broad areas: cranial nerve function, peripheral nerve status, and CNS coordination. Assessment of the 12 cranial nerves was based on the measurement of 15 variables. Two summary indices were constructed, and no statistically significant differences between groups were found. In contrast to the baseline examination, there was no significant group difference in Babinski reflex. The analyses of peripheral nerve function, as measured by eight variables (four reflexes, three sensory determinations, and muscle mass), did not reveal significant group differences. Coordination was evaluated by four measurements and a constructed summary variable. The CNS summary index showed significant adverse effects for Ranch Hands.

In conclusion, none of the 27 neurological variables demonstrated a significant group difference, although several showed an aggregation of abnormalities in the Ranch Hand group, which emphasized the need for continued surveillance. Historical reporting of neurological disease was similar in both groups. The longitudinal analyses disclosed a reversal of significant increase among Ranch Hands in Babinski reflex abnormalities at the baseline examination to a nonsignificant difference between groups (RR=1.02) at the 1985 follow-up examination.

11.1.2.3 1987 Follow-up Examination Summary Results

The neurological health of the Ranch Hand group was not substantially different from the Comparison group. For the questionnaire variables related to neurological disease, Ranch Hands had significantly more hereditary and degenerative diseases, such as benign essential tremor. The statistical results of the group contrasts for 30 physical examination variables relating to cranial nerve function, peripheral nerve status, and CNS coordination processes generally were not significant, except for the analysis of coordination. Significantly more coordination abnormalities were found in Ranch Hands than Comparisons. The longitudinal analyses for the cranial nerve index and the CNS index revealed no significant differences.

11.1.2.4 Serum Dioxin Analysis of 1987 Follow-up Examination Summary Results

Overall, the neurology assessment did not indicate that dioxin was associated with neurological disease, although some analyses revealed a significant association between dioxin levels and CNS index and coordination. The adjusted analyses for the historical questionnaire variables were not significant and few statistically significant results were noted for the physical examination variables. The group contrast from the 1987 follow-up examination found that Ranch Hands had significantly more hereditary and degenerative diseases (mostly benign essential tremor) than Comparisons, but the serum dioxin analyses provided no support for the hypothesis that dioxin levels were associated with an increased risk of these diseases. The adjusted categorized dioxin analyses found that Ranch Hands in the high dioxin category had more coordination abnormalities than Comparisons. This was consistent with the previous analysis of the 1987 follow-up examination data, where the Ranch Hand group had significantly more coordination abnormalities than the Comparison group (1.5 percent versus 0.6 percent). The serum dioxin analyses showed significant adverse associations with the CNS index in the initial dioxin, 1987 dioxin, and categorized dioxin analyses.

11.1.2.5 1992 Follow-up Examination Summary Results

Overall, the neurology assessment found the prevalence of neurological disease to be comparable between the Ranch Hand and Comparison groups, and showed no consistent evidence of a dose-response effect

with either estimated initial dioxin levels or 1987 dioxin levels. In the group contrasts stratified by occupation, Ranch Hand enlisted groundcrew had significantly more cranial nerve index abnormalities than Comparison enlisted groundcrew. The enlisted groundcrew was the military occupation category with the highest median level of dioxin; however, analyses of serum dioxin levels did not exhibit a dose-response trend.

11.1.2.6 1997 Follow-up Examination Summary Results

Four neurological disorders and extensive physical examination data on cranial nerve function, peripheral nerve status, and CNS coordination processes were analyzed in the neurology assessment. Inflammatory diseases verified by a medical records review found a significant excess among Ranch Hands (n=7) relative to Comparisons (n=1); however, three of the seven Ranch Hand diseases were caused by bacterial infections, suggesting that this finding was unrelated to herbicide or dioxin exposure. Peripheral disorders, as verified by a medical records review, increased in Ranch Hands as levels of 1987 dioxin increased. Neck range of motion abnormalities were increased in Ranch Hands relative to Comparisons in terms of both a group designation and categorized dioxin levels. The increase in abnormalities for Ranch Hands relative to Comparisons was noted in enlisted flyers. An increase in the risk of an abnormal muscle status was observed in Ranch Hand enlisted groundcrew. A significant association between initial dioxin and both visual field and patellar reflex abnormalities was observed. Indices of polyneuropathy showed an increase in the prevalence of abnormality in Ranch Hands relative to Comparisons and a significant positive association with initial and 1987 dioxin levels. The clinical importance of the increased risk of polyneuropathy was uncertain due to the small number of affected veterans.

In summary, although a common etiology in these findings was not apparent, a statistically significant increase in neurological disease appeared in Ranch Hands historically, on physical examination, and as reflected in several of the composite polyneuropathy indices. Further, the significant associations of neck range of motion abnormalities with categorized dioxin and a history of peripheral disorders with 1987 dioxin levels provided evidence of an association of neurological disease with elevated dioxin levels. The results of the analysis of the polyneuropathy indices also provided support of an association between elevated dioxin levels and neurological disease; however, the clinical importance of this finding was uncertain.

11.1.3 Parameters for the 2002 Neurology Assessment

11.1.3.1 Dependent Variables

The neurology assessment was based on extensive physical examination data on cranial nerve function, peripheral nerve status, and CNS coordination processes. This information was supplemented by verified histories of neurological diseases. Participants who tested positive for syphilis and participants who tested positive for the human immunodeficiency virus (HIV) were excluded from the analysis of all dependent variables. Hamilton AT[®] equipment was used for automated dilution of specimens for HIV testing, and the amount of virus antibody present in the serum was produced and measured using a spectrophotometer. Presence or absence of syphilis was determined through a venereal disease research laboratory (VDRL) test using Difco[®] agglutination assays. The positive VDRL tests were confirmed using the fluorescent treponemal antibody absorption (FTA-ABS) test.

11.1.3.1.1 Medical Records Variables

The 2002 questionnaire captured data on the occurrence of neurological disorders. Medical records review was accomplished to confirm reported neurological disorders and to identify any unreported

neurological conditions for each participant that attended the 2002 physical examination. These data from the 2002 physical examination were combined with data from the 1982 baseline examination and the 1985, 1987, 1992, and 1997 follow-up examinations to form a complete history of neurological disorders for each participant. Neurological diseases and disorders were classified into four categories of the International Classification of Diseases, 9th Revision, Clinical Modification (ICD-9-CM) manual: inflammatory diseases (ICD-9-CM codes 320.0–326), hereditary and degenerative diseases (ICD-9-CM codes 330.0–337.9), peripheral disorders (ICD-9-CM codes 350.1–359.9), and other neurological disorders (ICD-9-CM codes 340–349.9). The majority of other neurological disorders were unspecified encephalopathies, but conditions such as multiple sclerosis, other demyelinating diseases of the CNS, hemiplegia, other paralytic syndromes, epilepsy, migraine, cataplexy or narcolepsy, other conditions of the brain, and other unspecified disorders of the CNS were included. Each of the four categories of disorders was coded as “yes” or “no.” The analyses performed in this chapter were based on the 1,951 participants who attended the 2002 follow-up examination.

Participants with a verified pre-SEA history of the disorder under study were excluded from all analyses pertaining to that disorder.

11.1.3.1.2 Physical Examination Variables

The physical examination included various indicators of cranial nerve function, peripheral nerve status, and CNS coordination processes.

11.1.3.1.2.1 Cranial Nerve Function

The evaluation of cranial nerve function was based on the following 15 variables: smell, visual fields, light reaction, ocular movement, facial sensation, corneal reflex, jaw clench, smile, palpebral fissure, balance, gag reflex, speech, tongue position relative to midline, palate and uvula movement, and shoulder shrug. All of these variables were scored as “normal” or “abnormal,” except for jaw clench and palate and uvula movement, which were scored as “symmetric” or “deviated.” For variables with left and right determinations, the two results were combined to produce a single normal or abnormal result, where normal indicated that both responses were normal, and abnormal indicated that at least one of the responses was abnormal. Abnormal speech conditions included aphasia, dysarthria, agnosia, and other speech abnormalities.

A cranial nerve index was created by combining responses for the 15 cranial nerve parameters. This index was classified as abnormal if at least one of the determinations was abnormal, and was classified as normal if all of the cranial nerve parameters were normal.

11.1.3.1.2.2 Peripheral Nerve Status

Peripheral nerve status was assessed by light pinprick, light touch (cotton sticks), visual inspection of muscle mass (and palpation, if indicated), three deep tendon reflexes (patellar, Achilles, and biceps), and the Babinski reflex. In addition, three indices to assess bilateral symmetric distal sensory or sensorimotor polyneuropathy were analyzed. These indices were constructed based on testing of ankle and toe flexor strength, equilibrium (Romberg sign), Achilles reflexes, light touch, pinprick, vibration at the ankle, and joint position of the left and right great toes.

Pinprick and light touch were considered normal if the reaction was normal on both legs. A variable to judge muscle status was constructed using data on bulk; tone of upper and lower extremities; and the strength of distal wrist extensors, ankle and toe flexors, proximal deltoids, and hip flexors. Bulk was

classified as either “normal” or “abnormal.” Tone was classified as “abnormal” if there was either a decreased or increased response on either the left side, right side, or both sides. The strength of distal wrist extensors, ankle and toe flexors, proximal deltoids, and hip flexors was considered “abnormal” if either the left or right side or both sides were decreased. Composite muscle status was classified as “normal” if all of the components were normal on both the left and right sides and “abnormal” if at least one of the components was abnormal on either or both sides.

The patellar, Achilles, and biceps reflexes were divided into three categories: “absent,” “sluggish,” and “active or very active.” The categories of “active” and “very active” were combined because of the sparse number of participants with very active reflexes. Two contrasts that preserved the ordinal structure of the data were examined: “sluggish or absent” versus “active or very active” (i.e., less than active versus active), and “absent” versus “sluggish, active, or very active” (i.e., reflexes absent versus not absent). When the assessments of the reflex were different between the left and right body side, the more severe condition was assigned. For example, if the left Achilles reflex was sluggish and the right Achilles reflex was absent, the composite Achilles reflex variable was designated as absent.

Three indices were used to assess bilateral peripheral neuropathy. The endpoints discussed previously in this section assessed unilateral abnormalities, whereas these indices assessed bilateral abnormalities and were considered abnormal only if both the left and right determinations were abnormal. These indices were based on the following seven conditions or sets of conditions:

1. Both left and right ankle and toe flexors were abnormal (no, yes)
2. The Romberg sign (equilibratory) was abnormal (no, yes)
3. Both left and right Achilles reflexes were absent (no, yes)
4. Reaction to a light touch was abnormal on both the left and right legs (no, yes)
5. Reaction to a pinprick was abnormal on both the left and right legs (no, yes)
6. Both left and right ankle vibrations (128 Hz) were abnormal (no, yes)
7. The position of both the left and right great toe was abnormal (no, yes).

A symmetric peripheral abnormality index was coded as “present” if the response to any of the above seven bilateral conditions listed above was “yes.” A second index, termed a possible peripheral neuropathy indicator, was coded as “abnormal” if at least one of the following three conditions was found bilaterally: (1) absent Achilles reflex, (2) abnormal vibration at the ankle, or (3) abnormal pinprick (feet). If two of the three above conditions were present bilaterally, a third index, termed probable peripheral neuropathy index, was coded as “present”; otherwise, the probable peripheral neuropathy index was coded as “absent.”

Participants with peripheral edema in the lower extremities were excluded from the analyses of pinprick and light touch. The analysis of the Achilles reflex and the patellar reflex excluded participants with a transient or sustained clonus in these reflexes, respectively. Participants with quadriplegia (ICD-9-CM codes 344.00-344.09), paraplegia (ICD-9-CM code 344.1), injuries (ICD-9-CM codes 806.0-806.9, 907.2-907.9, and 952.0-957.9), amputations (ICD-9-CM codes 887.0-887.7, 897.0-897.7, and procedure codes X84.00-X84.19), or alcohol-related disorders (ICD-9-CM 291.0-291.9, 303.00-303.93, 305.00-305.03, 357.5, 425.5, and 571.0-571.3) were excluded from the symmetric, possible, and probable peripheral neuropathy indicators. As with the other dependent variables in this section, participants who tested positive for syphilis and participants who tested positive for HIV were excluded for all peripheral nerve status dependent variables.

11.1.3.1.2.3 CNS Coordination Processes

The evaluation of CNS coordination processes was based on the analyses of the following variables: tremor, coordination, Romberg sign, gait, and a CNS index. For these variables, multiple determinations, which included left and right as well as upper and lower responses, were combined to form a single result. A result was classified as “normal” if all determinations were normal and “abnormal” if at least one determination was abnormal. Tremor was examined for the left and right upper and lower extremities. Abnormal tremors included resting, essential, intention, and “other tremors.” Coordination was a composite index defined as “normal” if the Romberg sign, finger-nose-finger and heel-knee-shin coordination processes, rapidly alternating movements of pronation and supination of hands, and rapid patting were normal. The Romberg sign variable was equivalent to the “balance” variable analyzed as part of the cranial nerve function assessment. The gait variable was based on the examining physician’s assessment of the participant’s gait. An abnormal gait included conditions such as broad-based, small-stepped, ataxic, or other irregular gait patterns. A CNS index was constructed and based on a composite variable of tremor, coordination, and gait. This index was coded as “normal” if all three of the components were normal and “abnormal” if otherwise.

11.1.3.2 Covariates

Age, race, military occupation, body mass index, lifetime alcohol history, cumulative exposure to insecticides or pesticides, cumulative exposure to industrial chemicals, cumulative exposure to degreasing chemicals, diabetic class, and duration of diabetes were covariates for all adjusted statistical analyses. The peripheral abnormality and neuropathy indicators (symmetrical, possible, and probable) were adjusted for reported exposure to heavy metals and vibrating power equipment in addition to the covariates listed above.

Age, race, and military occupation were determined from military records. Body mass index was calculated as $\text{weight}/(\text{height})^2$, where the weight was measured in kilograms and the height was measured in meters at the physical examination (44). For purposes of covariate associations for discrete dependent variables, body mass index was dichotomized as “not obese” ($\leq 30 \text{ kg/m}^2$) and “obese” ($> 30 \text{ kg/m}^2$).

Lifetime alcohol history was based on information from the 2002 questionnaire and combined with similar information gathered at the 1987, 1992, and 1997 follow-up examinations. Each participant was asked about his drinking patterns throughout his lifetime. When a participant’s drinking pattern changed, he was asked to describe how his alcohol consumption differed and the duration of time that the drinking pattern lasted. The participant’s average daily alcohol consumption was determined for each of the reported drinking pattern periods throughout his lifetime, and an estimate of the corresponding total number of drink-years was derived. One drink-year was the equivalent of drinking 1.5 ounces of an 80-proof alcoholic beverage, one 12-ounce beer, or one 5-ounce glass of wine per day for 1 year. Current alcohol use was defined as the average number of drinks per day during the 2 weeks prior to completing the physical examination.

The participants’ cumulative exposures through 1997 to insecticides or pesticides, industrial chemicals, and degreasing chemicals were updated with information, as reported by the participant, in the 2002 questionnaire.

In the 2002 questionnaire, a general screening question on diabetes was posed. During the in-person health interview each participant was asked: “Since the date of the last interview, has a doctor told you for the first time that you had diabetes?” Medical records review was accomplished to confirm reported diabetes and to identify any unreported diabetes for each participant that attended the 2002 physical examination. These data from the 2002 physical examination were combined with data from the 1982

baseline examination and the 1985, 1987, 1992, and 1997 follow-up examinations to form a complete history of diabetes for each participant. The analyses performed in this chapter were based on the 1,951 participants who attended the 2002 follow-up examination. Participants with a verified history of diabetes, as diagnosed previously by a physician, were combined with those participants with either

- a 2-hour postprandial glucose level of 200 mg/dL or greater on two separate occasions
- a fasting glucose level of 126 mg/dL or greater on two separate occasions, or
- one 2-hour postprandial glucose measurement ≥ 200 mg/dL and one fasting glucose ≥ 126 mg/dL on two separate occasions,

and classified as “diabetic” for the diabetic class covariate. Those participants not classified as “diabetic,” as defined above, but with a 2-hour postprandial glucose level of at least 140 mg/dL or a fasting glucose level of at least 110 mg/dL at the 2002 physical examination, were classified as “impaired.” Those participants not classified as “diabetic” or “impaired” as defined above were classified as “normal.”

For each participant diagnosed as diabetic, a date of diagnosis was recorded. The difference between the date of diagnosis and the date of the 2002 physical examination was calculated to determine the duration of diabetes covariate. Participants who were newly diagnosed as diabetic at or after the 2002 physical examination were assigned a value of 0 years, as were nondiabetic participants.

Two additional covariates, exposure to heavy metals and exposure to vibrating power equipment or tools, were used for the peripheral abnormality or neuropathy indicator dependent variables. The 2002 questionnaire asked each study participant whether he had worked for 30 days or more with lead, mercury, chromium, nickel, copper, cadmium, manganese, arsenic, selenium, or molybdenum. Responses were combined to form a composite exposure to heavy metals covariate. Each participant also was asked in the 2002 questionnaire whether he had ever worked for 30 days or more with vibrating power equipment or tools. The response (yes or no) to this question also was used as a covariate in the assessment of the peripheral neuropathy indicator dependent variables.

11.1.4 Statistical Methods

Table 11-1 summarizes the statistical analysis performed for the 2002 neurology assessment. The first part of this table lists the dependent variables analyzed, source of the data, form of the data, cutpoints, covariates, exclusions, and statistical methods. The second part of the table further describes the covariates. A covariate was used in its continuous form whenever possible for all adjusted analyses. If the covariate was inherently discrete (e.g., military occupation), or if a categorized form was needed to develop measures of association with the dependent variables, the covariate was categorized as shown in Table 11-1.

Abbreviations

Data Source:	LAB: 2002 laboratory results MIL: Air Force military records MR-V: Medical records (verified) PE: 2002 physical examination Q-SR: AFHS health questionnaires (self-reported)
Data Form:	D: Discrete form of dependent variable or covariate C/D: Appropriate form for analysis (either continuous or discrete) of covariate
Statistical Analysis:	U: Unadjusted analysis A: Adjusted analysis
Statistical Methods:	CS: Chi-square contingency table analysis (continuity-adjusted for 2x2 tables) LR: Logistic regression analysis PR: Polytomous logistic regression analysis

Four models were examined for each dependent variable given in Table 11-1. The analyses of these models are presented below. Further details on dioxin and the modeling strategy are found in Chapters 2 and 7, respectively. These analyses were performed both unadjusted and adjusted for covariates. These covariates are given in Table 11-1. Model 1 examined the relation between the dependent variable and group (i.e., Ranch Hand or Comparison). In this model, exposure was defined as “yes” for Ranch Hands and “no” for Comparisons without regard to the magnitude of the exposure. In an attempt to quantify exposure, three contrasts of Ranch Hands and Comparisons were performed along with the overall Ranch Hand versus Comparison contrast. These three contrasts compared Ranch Hands and Comparisons within each military occupational category (i.e., officers, enlisted flyers, and enlisted groundcrew). As described in previous reports and Table 2-4, the median level of exposure to dioxin was highest for enlisted groundcrew, followed by enlisted flyers, then officers.

During the 1987, 1992, 1997, and 2002 examinations, serum dioxin levels were measured by the CDC using high-resolution gas chromatography and high-resolution mass spectrometry and were reported in ppt on a lipid weight basis (45). These dioxin measurements are referred to as “lipid-adjusted.” All measures of dioxin used in this report were based on lipid-adjusted dioxin measurements.

Model 2 examined the relation between the dependent variable and an extrapolated initial dioxin measure for Ranch Hands who had a 1987 dioxin measurement greater than 10 ppt. The initial dioxin was calculated by extrapolating the 1987 dioxin level back in time to the end of the tour of duty that qualified a Ranch Hand veteran for inclusion in this study. If a Ranch Hand did not have a 1987 dioxin level, then the first dioxin measured, either at 1992, 1997, or 2002, was used to estimate the initial dioxin level. Regardless of when the dioxin was measured, Ranch Hand veterans with a level less than or equal to 10 ppt were excluded from statistical analyses based on Model 2. A statistical adjustment for body mass index at the time of the participant’s blood measurement of dioxin was included in this model to account for body mass index-related differences in elimination rate (46).

Model 3 divided the Ranch Hands examined in Model 2 into two categories based on their initial dioxin measures. These two categories were referred to as “low Ranch Hand” and “high Ranch Hand.” Two additional categories—Ranch Hands with serum dioxin levels at or below 10 ppt and Comparisons—were

formed and included in the model. Ranch Hands with serum dioxin levels at or below 10 ppt were assigned to the “background Ranch Hand” category. If a Ranch Hand did not have a 1987 dioxin measurement, the first measured dioxin level was used. Another category was examined by combining the low and high Ranch Hand categories. This combination is referred to in the tables as the “low plus high Ranch Hand” category. These five categories—Comparisons, background Ranch Hands, low Ranch Hands, high Ranch Hands, and low plus high Ranch Hands—were used in Model 3 analyses. The relation between the dependent variable in each of the four Ranch Hand categories and the dependent variable in the Comparison category was examined. As in Model 2, a statistical adjustment for body mass index at the time of the participant's blood measurement of dioxin was included in this model for the unadjusted and adjusted analyses of all dependent variables. One Ranch Hand without a dioxin measure was excluded from statistical analyses based on Model 3.

Model 4 examined the relation between the dependent variable and 1987 dioxin levels in all Ranch Hands with a dioxin measurement. If a Ranch Hand did not have a 1987 dioxin measurement, the first dioxin level obtained, either in 1992, 1997, or 2002, was extrapolated to the date of the 1987 physical examination. If the first dioxin level was not obtained in 1987 and was less than or equal to 10 ppt, it was not extrapolated to 1987 level, but was used at the measured value. One Ranch Hand without a dioxin measurement was excluded from statistical analyses based on Model 4.

The term “unadjusted” was used in the text and tables as follows: Models 1 and 4 did not adjust for any covariates. Models 2 and 3 adjusted only for body mass index at the time of the blood measurement for dioxin. The term “adjusted” was used in the text and tables as follows: Models 1 and 4 adjusted for the covariates shown in Table 11-1 unless otherwise specified by a footnote to the table. Models 2 and 3 additionally adjusted only for body mass index at the time of the blood measurement for dioxin.

Table 11-2 provides a summary of the number of participants with missing dependent variable and covariate data. In addition, the number of participants that were excluded from analyses is given.

EXC = Exclusion.

11.2 RESULTS

11.2.1 Dependent Variable-covariate Associations

The neurology dependent variables were tested for associations with each of the covariates used in the adjusted analyses. The complete results are presented in Appendix F, Table F-3. These associations were pairwise between the dependent variable and the covariate and were not adjusted for any other covariates. A brief summary of the pattern of significant ($p \leq 0.05$) dependent variable-covariate associations is described in the following paragraphs.

Older participants were more likely to be afflicted with the following neurological disorders or abnormalities than younger participants: hereditary and degenerative diseases, peripheral disorders, other neurological disorders, balance, cranial nerve index, pinprick, light touch, patellar reflex, Achilles reflex, and biceps reflex, any symmetrical peripheral abnormality, possible peripheral neuropathy, probable peripheral neuropathy, coordination, Romberg sign, gait, and CNS index.

Blacks were more likely to have had other neurological disorders and an abnormal Babinski reflex than non-Blacks.

More enlisted flyers had other neurological disorders, followed by enlisted groundcrew, then officers. Enlisted flyers had a higher prevalence of sluggish and absent Achilles reflex, followed by officers, then enlisted groundcrew.

For the patellar reflex, nondrinkers had the smallest percentage of active or very active reflexes and the highest percentage of absent patellar reflexes. Heavy drinkers (greater than 40 drink-years), however, had the lowest percentage of active or very active Achilles and biceps reflexes. Moderate drinkers (no more than 40 drink-years) had a lower prevalence of any symmetrical peripheral abnormality and possible peripheral neuropathy. Nondrinkers had a higher prevalence of coordination and CNS index abnormalities.

Obese participants were more likely to have peripheral disorders and peripheral neuropathies than participants who were not obese. Reflexes were more likely to be absent, sluggish, or abnormal (for the Babinski reflex) in obese participants than in participants who were not obese.

Participants exposed to insecticides were more likely to have had other neurological disorders and an abnormal muscle status than participants not exposed to insecticides. Participants with exposure to degreasing chemicals had a higher prevalence of other neurological disorders than participants not exposed to degreasing chemicals. The same pattern was seen for exposure to industrial chemicals. More participants with industrial chemical exposure had an active or very active Achilles reflex than those not exposed.

Diabetic class was associated with hereditary and degenerative diseases, peripheral disorders, and other neurological disorders. Of the 15 cranial nerve function variables, diabetic class was associated with smile and balance. All peripheral nerve status variables except the Babinski reflex, and all CNS coordination processes except tremor, were associated with diabetic class. Increasing abnormalities were seen with increasing diabetic impairment for each of those variables, except smile. Diabetics had an abnormal smile most frequently, followed by participants with normal glucose levels and then by glucose-impaired participants. For the patellar, Achilles, and biceps reflexes, the percentage of absent reflexes increased as diabetic impairment increased, and the percentage of sluggish reflexes increased with diabetic impairment for the patellar and biceps reflexes.

Duration of diabetes was associated with the hereditary and degenerative diseases, peripheral disorders, and other neurological disorders. Of the 15 cranial nerve function variables, duration of diabetes was associated with visual fields, smile, balance, shoulder shrug, and the cranial nerve index. All peripheral nerve status variables, except the Babinski reflex, and all CNS coordination processes, except tremor, were associated with duration of diabetes. More abnormalities were seen in each of these variables for participants with a history of diabetes than nondiabetic or newly diagnosed participants. For the patellar, Achilles and biceps reflexes, the percentage of absent reflexes was greater for previously diagnosed diabetics than nondiabetics or newly diagnosed diabetics, and the percentage of sluggish reflexes was greater in participants with a history of diabetes for patellar and biceps reflexes.

No significant associations were seen between the peripheral abnormality or neuropathy variables and composite exposure to heavy metals or working with power equipment or tools.

11.2.2 Exposure Analysis

The following section presents results of the statistical analyses of the dependent variables shown in Table 11-1. Dependent variables are grouped into two sections: (1) the questionnaire variables, derived from the questionnaire that was administered during the 2002 follow-up and previous AFHS examinations, and (2) variables obtained during the 2002 physical examination.

11.2.2.1 Medical Records Variables

11.2.2.1.1 Inflammatory Diseases

No significant associations were seen between inflammatory diseases and either group or dioxin in Model 1 through Model 4 unadjusted and adjusted analyses (Table 11-3 (a-h): $p > 0.06$ for all analyses).

Table 11-3. Analysis of Inflammatory Diseases

n	Adjusted Relative Risk (95% C.I.) ^a	p-Value
768	0.93 (0.58,1.48)	0.750

^aRelative risk for a twofold increase in 1987 dioxin.

Note: Results were not adjusted for race or duration of diabetes because of the sparse number of Ranch Hands with a history of inflammatory diseases.

11.2.2.1.2 Hereditary and Degenerative Diseases

No significant associations were seen between hereditary and degenerative diseases and group for all participants in the Model 1 unadjusted or adjusted analyses (Table 11-4(a, b): $p > 0.11$ for all analyses). After stratifying for military occupation, however, a significant difference between Ranch Hands and Comparisons was seen in the officer stratum for both the unadjusted and adjusted analyses (Table 11-4(a,b): Unadjusted Relative Risk [RR]=1.62, $p=0.019$; Adjusted RR=1.57, $p=0.030$). More Ranch Hand officers had hereditary and degenerative diseases (18.6%) than Comparison officers (12.4%). No significant differences were detected in the unadjusted or adjusted analyses of the enlisted flyer or enlisted groundcrew strata (Table 11-4(a,b): $p > 0.24$ for all analyses).

The Model 2 through Model 4 unadjusted and adjusted analyses showed no significant association between hereditary and degenerative diseases and dioxin (Table 11-4(c-h): $p > 0.15$ for all analyses).

Table 11-4. Analysis of Hereditary and Degenerative Diseases

11.2.2.1.4 Other Neurological Disorders

The Model 1 and Model 2 unadjusted and adjusted analyses showed no significant association between other neurological diseases and either group or dioxin (Table 11-6(a-d): $p > 0.06$ for all analyses).

The unadjusted analysis of Model 3 showed significant associations between other neurological diseases and categorized dioxin for Ranch Hands in the high dioxin category (Table 11-6(e): Unadjusted $RR = 1.65$, $p = 0.005$) and Ranch Hands in the low and high dioxin categories combined (Table 11-6(e): Unadjusted $RR = 1.53$, $p = 0.002$). After adjusting for covariates, however, neither association was significant (Table 11-6(f): $p > 0.18$ for all contrasts).

The Model 4 unadjusted analysis showed a significant relation between other neurological diseases and 1987 dioxin levels (Table 11-6(g): Unadjusted RR=1.16, p=0.007). After adjusting for covariates, the relation was not significant (Table 11-6(h): p=0.532).

n	Adjusted Relative Risk (95% C.I.)^a		p-Value
766	1.04 (0.91,1.20)		0.532

^aRelative risk for a twofold increase in 1987 dioxin.

11.2.2.2 Physical Examination Variables – Cranial Nerve Function

Many of the cranial nerve function variables had a sparse number of abnormalities. Therefore, analysis may have been limited, and analyses may not be adjusted for certain covariates (in particular, race, because of the sparse number of Black participants in the AFHS). Footnotes are provided with the subsequent tables to indicate where analysis was limited or covariates were not included in the adjusted analysis.

11.2.2.2.1 Smell

No significant associations between group and smell were seen in the Model 1 unadjusted and adjusted analyses (Table 11-7(a,b): p>0.16 for all analyses).

An inverse association between smell and initial dioxin was seen in the Model 2 analyses, both with and without adjustment for covariates (Table 11-7(c,d): Unadjusted RR=0.38, p=0.012; Adjusted RR=0.30, p=0.007). Ranch Hands in the low initial dioxin category were more likely to have an abnormal sense of smell (3.6%) than Ranch Hands in the medium initial dioxin category (2.1%) or Ranch Hands in the high initial dioxin category (0.0%).

The unadjusted and adjusted Model 3 analyses showed no significant association between dioxin category and smell (Table 11-7(e,f): p>0.05 for all analyses).

A significant inverse association was seen between smell and 1987 dioxin levels in the unadjusted and adjusted Model 4 analyses (Table 11-7(g,h): Unadjusted RR=0.71, p=0.018; Adjusted RR=0.64, p=0.010). Abnormal sense of smell was more prevalent in Ranch Hands in the low 1987 dioxin category (4.6%), followed by the medium 1987 dioxin category (2.7%), then the high 1987 dioxin category (0.8%).

**: Statistically significant (p-value≤0.010).

11.2.2.2.2 Visual Fields

In the Model 1 unadjusted and adjusted analyses of all participants, Ranch Hands were significantly more likely to have abnormal visual fields than Comparisons (Table 11-8(a,b): Unadjusted RR=2.60, p=0.040; Adjusted RR=3.08, p=0.022). Abnormal visual fields were seen in 1.6 percent of Ranch Hands compared to 0.6 percent of Comparisons. When stratified by military occupation, no significant associations were seen in the unadjusted or adjusted analyses (Table 11-8(a,b): p>0.05 for all contrasts).

No significant associations were seen between visual fields and initial dioxin in Model 2 unadjusted and adjusted analyses (Table 11-8(c,d): p>0.67 for both analyses).

In the Model 3 unadjusted and adjusted analyses, a significant association was seen between categorized dioxin and visual fields for the background dioxin category (Table 11-8(e,f): Unadjusted RR=4.37, p=0.005; Adjusted RR=5.25, p=0.004). Abnormal visual fields were seen in 2.3 percent of Ranch Hands in the background dioxin category compared to 0.6 percent of Comparisons. No other unadjusted or adjusted Model 3 contrast showed a significant association (Table 11-8(e,f): p>0.44 for all contrasts).

No significant association was seen between visual fields and 1987 dioxin levels in the Model 4 unadjusted and adjusted analyses (Table 11-8(g,h): p>0.10 for all analyses).

764	0.67 (0.42,1.09)		0.109

^aRelative risk for a twofold increase in 1987 dioxin.

Note: Results were not adjusted for race because of the sparse number of Ranch Hands with abnormal visual fields.

11.2.2.2.3 Light Reaction

Light reaction was not significantly associated with group in the Model 1 analyses or dioxin in the Model 3 or Model 4 unadjusted and adjusted analyses (Table 11-9(a,b,e-h): $p > 0.47$ for all analyses).

In the unadjusted Model 2 analyses, a significant association was seen between initial dioxin and light reaction (Table 11-9(c): Unadjusted RR=3.98, $p=0.039$). After adjusting for covariates, however, the association was no longer significant (Table 11-9(d): $p=0.057$).

Table 11-9. Analysis of Light Reaction

(a) MODEL 1: RANCH HANDS VS. COMPARISONS – UNADJUSTED					
Occupational Category	Group	n	Number (%) Abnormal	Unadjusted Relative Risk (95% C.I.)	p-Value

11.2.2.2.5 Facial Sensation

Facial sensation was not significantly associated with group in the Model 1 unadjusted and adjusted analyses or dioxin in the Model 2 and 4 unadjusted and adjusted analyses (Table 11-11(a-d,g,h): $p > 0.24$ for all analyses).

In the Model 3 unadjusted and adjusted analyses, a significant difference in abnormal facial sensation was seen between Ranch Hands in the low dioxin category and Comparisons (Table 11-11(e,f): Unadjusted RR=5.74, $p=0.033$; Adjusted RR=7.94, $p=0.033$). Ranch Hands in the low category were more likely to have abnormal facial sensation (1.4%) than Comparisons (0.3%). No other unadjusted or adjusted Model 3 contrasts were significant (Table 11-11(e,f): $p > 0.39$ for each analysis).

768	1.00 (0.73,1.39)		0.981

^aRelative risk for a twofold increase in 1987 dioxin.

11.2.2.2.10 Balance

No significant associations were seen between balance and group in the Model 1 unadjusted and adjusted analyses (Table 11-15(a,b): $p > 0.25$ for all analyses).

The unadjusted analysis of Model 2 showed no association between initial dioxin levels and balance (Table 11-15(c): $p = 0.961$). After adjusting for covariates, however, the association was significant (Table 11-15(d): Adjusted RR=2.11, $p = 0.033$). The difference between the unadjusted and adjusted results was partially due to more balance abnormalities in officers than enlisted personnel, for Ranch Hands with an initial dioxin estimate. More Ranch Hands in the low and high initial dioxin categories had abnormal balance (2.9% for each category) than those in the medium category (2.1%).

The associations between balance and dioxin in the Model 3 and 4 unadjusted and adjusted analyses were nonsignificant (Table 11-15(e-h): $p > 0.12$ for all analyses).

Table 11-15. Analysis of Balance

Analysis Results for Log₂ (1987 Dioxin)			
n	Adjusted Relative Risk (95% C.I.)^a		p-Value
768	0.81 (0.35,1.86)		0.622

^aRelative risk for a twofold increase in 1987 dioxin.

Note: Results were not adjusted for military occupation, cumulative insecticide exposure, and diabetic class because of the sparse number of Ranch Hands with an abnormal shoulder shrug.

11.2.2.2.16 Cranial Nerve Index

The cranial nerve index was significantly associated with group in Model 1 unadjusted and adjusted analyses of all participants (Table 11-20(a,b): Unadjusted RR=1.43, p=0.025; Adjusted RR=1.47, p=0.020). Of the Ranch Hands, 10.7 percent had an abnormal cranial nerve index, compared to 7.7 percent of Comparisons. After stratifying for military occupation, no significant associations between group and cranial nerve index were seen in unadjusted or adjusted analyses (Table 11-20(a,b): p>0.08 for all analyses).

No significant association between initial dioxin levels and the cranial nerve index was seen in the Model 2 unadjusted and adjusted analyses (Table 11-20(c,d): p>0.21 for both analyses).

In the Model 3 unadjusted analyses, significant relations were seen in the background dioxin category (Table 11-20(e): Unadjusted RR=1.61, p=0.019) and the low dioxin category (Table 11-20(e): Unadjusted RR=1.69, p=0.027). These results remained significant after adjusting for covariates (Table 11-20(f): Adjusted RR=1.65, p=0.018 for background category; Adjusted RR=1.62, p=0.049 for low dioxin category). An abnormal cranial nerve index was observed for 11.5 percent of Ranch Hands in the background dioxin category and 12.4 percent of Ranch Hands in the low dioxin category, compared to 7.7 percent of Comparisons.

No significant associations were seen between cranial nerve index and 1987 dioxin levels in the Model 4 unadjusted and adjusted analyses (Table 11-20(g,h): p>0.32 for both analyses).

11.2.2.3 Physical Examination Variables – Peripheral Nerve Status

11.2.2.3.1 Pinprick

No significant associations were seen between pinprick and group or initial dioxin in the Model 1 and Model 2 unadjusted and adjusted analyses (Table 11-21(a-d): $p>0.09$ for all analyses).

A significant association was seen in the unadjusted and adjusted Model 3 analyses between categorized dioxin and pinprick in the high dioxin category (Table 11-21(e,f): Unadjusted RR=1.76, $p=0.020$; Adjusted RR=1.71, $p=0.050$). Ranch Hands in the high dioxin category were more likely to have had an abnormal pinprick (15.3%) than Comparisons (8.9%).

The Model 4 unadjusted and adjusted analyses showed no relation between 1987 dioxin levels and pinprick (Table 11-21(g,h): $p>0.13$ for both analyses).

Table 11-21. Analysis of Pinprick

11.2.2.3.4 Patellar Reflex

When contrasting active and very active patellar reflexes to sluggish and absent patellar reflexes, no significant association was seen in the Model 1 through Model 4 unadjusted and adjusted analyses (Table 11-24(a-h): $p > 0.06$ for all analyses).

When sluggish, active, and very active patellar reflexes were compared to the absence of a patellar reflex, no significant associations were seen in Model 1 or Model 2 unadjusted or adjusted analyses (Table 11-24(a-d): $p > 0.09$ for all analyses). In Model 3 unadjusted analyses, however, a significant association was seen for Ranch Hands in the low and high dioxin categories combined (Table 11-24(e): Unadjusted $RR = 1.84$, $p = 0.025$). After adjusting for covariates, the results remained significant for the combined low and high dioxin category (Table 11-24(f): Adjusted $RR = 1.89$, $p = 0.027$) and were significant for the high dioxin category as well (Table 11-24(f): Adjusted $RR = 2.11$, $p = 0.048$). More Ranch Hands in the high dioxin category or in the low and high dioxin categories combined had an absent patellar reflex (5.7% for each category) than Comparisons (3.0%). The Model 4 unadjusted and adjusted analyses showed a significant association between 1987 dioxin levels and the patellar reflex (Table 11-24(g,h): Unadjusted $RR = 1.29$, $p = 0.017$; Adjusted $RR = 1.44$, $p = 0.013$). Of the Ranch Hands in the low 1987 dioxin category, 2.3 percent had an absent patellar reflex, compared to 5.5 percent of Ranch Hands in the medium 1987 dioxin category and 5.1 percent of Ranch Hands in the high 1987 dioxin category.

11.2.2.3.5 Achilles Reflex

When active and very active Achilles reflexes were contrasted with sluggish and absent reflexes, a significant association with exposure group was seen for officers in the Model 1 unadjusted and adjusted analyses (Table 11-25(a,b): Unadjusted $RR = 1.46$, $p = 0.013$; Adjusted $RR = 1.42$, $p = 0.031$). Ranch Hand officers were more likely to have sluggish or absent Achilles reflexes (66.0%) than Comparison officers (57.1%). No difference between Ranch Hands and Comparisons was seen in the unadjusted or adjusted Model 1 analyses for all participants or for enlisted flyers and groundcrew (Table 11-25(a,b): $p > 0.16$ for all analyses). No significant associations for this contrast were seen in Model 2, Model 3, or Model 4 unadjusted and adjusted analyses (Table 11-25(c-h): $p \geq 0.07$ for all analyses).

When sluggish, active, and very active Achilles reflexes were compared to absent reflexes, no significant relations were with group or initial dioxin in the Model 1 and Model 2 unadjusted or adjusted analyses (Table 11-25(a-d): $p > 0.25$ for all analyses). In the Model 3 unadjusted analyses, a significant association was seen in the low dioxin category (Table 11-25(e): Unadjusted $RR = 1.45$, $p = 0.029$). After adjusting for covariates, however, this association was no longer significant (Table 11-25(f): $p = 0.167$). No other Model 3 or Model 4 unadjusted or adjusted contrast was significant (Table 11-25(e-h): $p > 0.13$ for all analyses).

(h) MODEL 4: RANCH HANDS – 1987 DIOXIN – ADJUSTED				
Analysis Results for Log ₂ (1987 Dioxin)				
n	Sluggish or Absent vs. Very Active or Active		Absent vs. Very Active, Active, or Sluggish	
	Adjusted Relative Risk (95% C.I.) ^a	p-Value	Adjusted Relative Risk (95% C.I.) ^a	p-Value
767	0.98 (0.87,1.10)	0.738	1.03 (0.90,1.18)	0.671

^aRelative risk for a twofold increase in 1987 dioxin.

11.2.2.3.6 *Biceps Reflex*

No significant association was seen between group or dioxin and the biceps reflex in the Model 1 through Model 4 unadjusted and adjusted analyses, either when absent and sluggish reflexes were compared to active and very active reflexes (Table 11-26(a-h): $p>0.05$ for all contrasts), or when absent reflexes were compared to sluggish, active, and very active reflexes (Table 11-26(a-h): $p>0.08$ for all contrasts).

11.2.2.3.7 *Babinski Reflex*

The Babinski reflex was not significantly associated with group or dioxin in the Model 1 through Model 4 unadjusted and adjusted analyses (Table 11-27(a-h): $p>0.24$ for all analyses).

11.2.2.3.8 *Any Symmetric Peripheral Abnormality*

No significant associations were seen between any symmetrical peripheral abnormality and group or initial dioxin level in the Model 1 and Model 2 unadjusted and adjusted analyses (Table 11-28(a-d): $p>0.18$ for all analyses).

In the Model 3 unadjusted analyses, a significant association was seen in the low dioxin category (Table 11-28(e): Unadjusted RR=1.46, $p=0.027$). After adjusting for covariates, however, the relation was no longer significant (Table 11-28(f): $p=0.244$). No other unadjusted or adjusted Model 3 contrast was significant (Table 11-28(e,f): $p>0.05$ for all contrasts).

Model 4 unadjusted and adjusted analyses showed no significant relation between 1987 dioxin levels and any symmetrical peripheral abnormality (Table 11-28(g,h): $p>0.24$ for all analyses).

11.2.2.3.9 *Possible Peripheral Neuropathy*

No significant associations were seen in the Model 1 and Model 2 unadjusted and adjusted analyses of possible peripheral neuropathy (Table 11-29(a-d): $p>0.32$ for all analyses).

A significant association in the Model 3 unadjusted analyses was seen in the low dioxin category (Table 11-29(e): Unadjusted RR=1.45, $p=0.034$), but no significant associations were seen in the other dioxin categories (Table 11-29(e): $p\geq 0.12$ for all analyses). No significant associations were seen in the Model 3 analyses after adjusting for covariates (Table 11-29(f): $p>0.26$ for all contrasts).

The Model 4 unadjusted and adjusted analyses showed no significant relation between possible peripheral neuropathy and 1987 dioxin levels (Table 11-29(g,h): $p>0.25$ for all analyses).

11.2.2.3.10 *Probable Peripheral Neuropathy*

Probable peripheral neuropathy was not significantly associated with group or dioxin in the Model 1 through Model 4 unadjusted and adjusted analyses (Table 11-30(a-h): $p>0.15$ for all analyses).

Table 11-26. Analysis of Biceps Reflex**(a) MODEL 1: RANCH HANDS VS. COMPARISONS – UNADJUSTED**

^aRelative risk for a twofold increase in 1987 dioxin.

11.2.2.4.2 Coordination

As a reminder, coordination was a composite index defined as “normal” if the Romberg sign, finger-nose-finger and heel-knee-shin coordination processes, rapidly alternating movements of pronation and supination of hands, and rapid patting were normal, and abnormal otherwise.

No difference in coordination was seen between Ranch Hands and Comparisons in the Model 1 unadjusted and adjusted analyses (Table 11-32(a,b): $p>0.20$ for all analyses).

No relation between coordination and initial dioxin was seen in the unadjusted Model 2 analysis (Table 11-32(c): $p=0.148$). This relation, however, was significant after adjusting for covariates (Table 11-32(d): Adjusted RR=2.25, $p=0.002$). Ranch Hands in the high dioxin category were more likely to have abnormal coordination (5.8%), followed by Ranch Hands in the low category (2.9%), then Ranch Hands in the medium category (2.1%). The difference between the unadjusted and adjusted results was partially due to more Romberg sign abnormalities in officers than enlisted personnel, for Ranch Hands with an initial dioxin estimate.

No significant associations were seen between coordination and categorized dioxin or 1987 dioxin levels in the Model 3 and Model 4 unadjusted and adjusted analyses (Table 11-32(e-h): $p>0.08$ for all analyses).

Table 11-32. Analysis of Coordination

^aRelative risk for a twofold increase in 1987 dioxin.

11.2.2.4.3 Romberg Sign

No significant associations were seen between the Romberg sign and group in the Model 1 unadjusted and adjusted analyses (Table 11-33(a,b): $p > 0.25$ for all analyses).

The unadjusted analysis of Model 2 showed no association between initial dioxin and the Romberg sign (Table 11-33(c): $p = 0.961$). After adjusting for covariates, however, the association was significant (Table 11-33(d): Adjusted RR=2.11, $p = 0.033$). The difference between the unadjusted and adjusted results was partially due to more Romberg sign abnormalities in officers than enlisted personnel, for Ranch Hands with an initial dioxin estimate. One more Ranch Hand in the low initial dioxin category and the high initial dioxin categories had an abnormal Romberg sign (2.9% for each category) than in the medium category (2.1%).

The associations between Romberg sign and dioxin in Models 3 and 4 unadjusted and adjusted analyses were nonsignificant (Table 11-33(e-h): $p > 0.12$ for all analyses).

Table 11-33. Analysis of Romberg Sign

11.2.2.4.5 CNS Index

A CNS index was constructed and based on a composite variable of tremor, coordination, and gait. This index was coded as “normal” if all three of the components were normal and “abnormal” if otherwise. The Model 1 through Model 4 unadjusted and adjusted analyses showed no significant relation between group or dioxin and the CNS index (Table 11-35(a-h): p>0.18 for all analyses).

Table 11-35. Analysis of CNS Index

11.3 DISCUSSION

The AFHS neurology assessment included the evaluation of cranial nerve function, peripheral nerve status, and CNS coordination processes based on a physical examination. In addition, a cranial nerve index was created by combining responses for the 15 cranial nerve parameters. This index was classified as abnormal if at least one of the determinations was abnormal, and was classified as normal if all of the cranial nerve parameters were normal. The motor and sensory peripheral nerve findings and the cranial nerve examination provide highly specific clues to the anatomic site of possible neurological problems. The various data from the neurology assessment can be relied upon to detect the presence, if not the cause, of neurological disease, particularly disorders of the peripheral nerve system. Pertinent to the current study, the neurological examination was highly sensitive in detecting the presence of peripheral neuropathy, a condition thought to be related to herbicide exposure. The evaluation of CNS coordination processes was based on the presence of tremor, coordination, Romberg sign, and gait, which also are thought to be highly sensitive indicators of herbicide exposure. The neurological evaluations performed in the AFHS were considered sensitive and can be relied upon to detect the presence of peripheral neuropathy.

Dependent variable-covariate analysis confirmed associations with age and diabetes that are well established. Diabetes was by far the strongest covariate and was significantly associated with a history of neurological disease, assessments from the physical examination, and for all the composite indices, particularly those for peripheral neuropathy. Association of neurological endpoints with alcohol use was more sporadic and less prominent.

More Ranch Hand officers than Comparison officers had hereditary and degenerative disease. This result does not appear to be dose-response related, however, as officers had the lowest median value of dioxin and other models did not indicate a dose-response effect.

Based on results from the assessment of the cranial nerves in the neurological examination, more Ranch Hands than Comparisons had abnormal visual fields. The majority of Ranch Hands with abnormal visual fields were in the background dioxin category, and Ranch Hands in the low and high dioxin categories were not significantly different from Comparisons. More Ranch Hands in the low dioxin category had abnormal facial sensation than Comparisons, but the total number of participants with an abnormal facial sensation was small. After adjustment for military occupation, as the initial dioxin level in Ranch Hands increased, the prevalence of abnormal balance increased. More Ranch Hands than Comparisons also had an abnormal cranial nerve index, and this increase was seen in the background and low dioxin categories. There was no dose-response effect, however, within the Ranch Hands. Based on these results, there was no significant clinical evidence of a herbicide or dioxin effect on cranial nerve function.

In assessing the peripheral nerve status of AFHS participants, more Ranch Hands in the high dioxin category had an abnormal pinprick examination. In addition, more Ranch Hands in the high dioxin category and the combined low and high dioxin categories had absent patellar reflexes than Comparisons. As the 1987 dioxin level increased, the prevalence of absent patellar reflex increased as well. More Ranch Hand officers had absent or sluggish Achilles reflexes than Comparison officers, but without evidence of a strong dose-response relation in other occupational cohorts. In addition, no evidence of a strong dose response was found in Models 2 and 4. Although pinprick, balance, and the Achilles reflex are components of the peripheral abnormality index and the peripheral neuropathy indices, these composite indices showed no significant associations.

As in previous studies, there has been some indication for increased risk of peripheral neuropathy in those personnel exposed to the highest level of dioxin. Some indication for an association with probable peripheral neuropathy was found in the 1985, 1992, and 1997 follow-up examinations. Although a dose-response pattern was somewhat inconsistent in those years, the highest risk was observed in the group with the highest dioxin levels, most notably in the 1997 follow-up examination. In the 2002 follow-up examination, Ranch Hands in the high dioxin category had an increased risk for an abnormal pinprick examination and an absent patellar reflex. The risk of an absent patellar reflex increased as the 1987 dioxin level increased.

For the CNS coordination processes, abnormalities in the Romberg sign and the composite index of coordination increased as initial dioxin levels in Ranch Hands increased. Coordination was based on the results of the Romberg sign, finger-nose-finger and heel-knee-shin coordination processes, rapidly alternating movements of pronation and supination of hands, and rapid patting. This result was seen after adjustment for military occupation.

In conclusion, there was no clinical evidence to support a relation between dioxin and cranial nerve function or other CNS processes.

11.4 SUMMARY

The neurology assessment was based on questionnaire data, which was subsequently verified by a review of medical records, and physical examination data. Associations with herbicide exposure (i.e., group – Model 1), initial dioxin (Model 2), categorized dioxin (Model 3), and 1987 dioxin levels (Model 4) were examined for each variable in the neurology assessment. The significant adjusted results are discussed in the sections below.

11.4.1 Model 1: Group Analysis

The results of the group analysis are provided in Table 11-36. Model 1 analyses showed significant differences between all Ranch Hands and Comparisons for visual fields and cranial nerve index. Ranch Hands were more likely to have abnormal visual fields and an abnormal cranial nerve index than Comparisons. When stratified by military occupation, a significant association was seen in officers for hereditary and degenerative diseases and Achilles reflex. More Ranch Hand officers had hereditary or degenerative diseases and sluggish or absent Achilles reflexes than Comparison officers.

A capital "NS" denotes a nonsignificant positive association. A lowercase "ns" denotes a nonsignificant inverse association.

11.4.2 Model 2: Initial Dioxin Analysis

The results of the initial dioxin analysis are shown in Table 11-37. Model 2 analyses showed a significant inverse association between initial dioxin and smell. Significant positive relations were seen between balance, coordination, and Romberg sign and initial dioxin. Balance and Romberg sign are equivalent, and one of the components of the coordination variable is the Romberg sign.

Note: NS or ns: Not significant ($p>0.05$).

D: Discrete dependent variable.

The p-value was given if $p\leq 0.05$. The relative risk was given in parentheses for a significant result.

A capital “NS” denotes a nonsignificant positive association. A lowercase “ns” denotes a nonsignificant inverse association.

11.4.3 Model 3: Categorized Dioxin Analysis

The results of the categorized dioxin analysis are presented in Table 11-38. More Ranch Hands in the background dioxin category than Comparisons showed abnormal visual fields and an abnormal cranial nerve index. More Ranch Hands in the low dioxin category than Comparisons showed an abnormal facial sensation and an abnormal cranial nerve index. More Ranch Hands in the high dioxin category had an abnormal reaction to pinprick and absent patellar reflexes than Comparisons. This difference in patellar reflexes was also seen in the low and high dioxin categories combined.

A capital “NS” denotes a nonsignificant positive association. A lowercase “ns” denotes a nonsignificant inverse association.

11.4.5 Summary of Significant Results

Table 11-40 summarizes the significant results ($p \leq 0.05$) for the adjusted analyses that were performed for the neurology assessment. The dependent variable and its table reference are listed, along with the model and the contrast or description of the model. The p-value is provided along with analysis statistics that correspond to the type of analysis that was performed (either continuous or discrete). A description of the analysis and the statistics that are presented is referenced under the “Note” column and explained in footnotes.

Table 11-40. Summary of Results from Significant Adjusted Analyses in the Neurology Assessment

Dependent Variable (Table Reference)	Model	Contrast or Description	p-Value	Analysis Statistics	Percent Abnormal	Note
Hereditary and Degenerative Diseases (11-4)	1	RH vs. C, Officer	0.030	1.57 (1.04,2.36)	RH: 18.6% C: 12.4%	(a)
Smell (11-7)	2	RH (1987 dioxin >10 ppt): Initial Dioxin	0.007	0.30 (0.10,0.89)	Low: 3.6% Medium: 2.1% High: 0.0%	(b)
	4	All RH: 1987 Dioxin	0.010	0.64 (0.45,0.90)	Low: 4.6% Medium: 2.7% High: 0.8%	(c)

	3	Low RH vs. C	0.049	1.62 (1.00,2.61)	RH: 12.4% C: 7.7%	(d)

Table 11-40. Summary of Results from Significant Adjusted Analyses in the Neurology Assessment (Continued)

Dependent Variable (Table Reference)	Model	Contrast or Description	p-Value	Analysis Statistics	Percent Abnormal	Note
Pinprick (11-21)	3	High RH vs. C	0.050	1.71 (1.00,2.93)	RH: 15.3% C: 8.9%	(d)
Patellar Reflex (11-24)	3	High RH vs. C – Absent vs. Very Active, Active, or Sluggish	0.048	2.11 (1.01,4.43)	RH: 5.7% C: 3.0%	(d)
	3	Low and High RH vs. C – Absent vs. Very Active, Active, or Sluggish	0.027	1.89 (1.07,3.33)	RH: 5.7% C: 3.0%	(d)
	4	All RH: 1987 Dioxin – Absent vs. Very Active, Active, or Sluggish	0.013	1.44 (1.07,1.95)	Low: 2.3% Medium: 5.5% High: 5.1%	(c)
Achilles Reflex (11-25)	1	RH vs. C, Officer – Sluggish or Absent vs. Very Active or Active	0.031	1.42 (1.03,1.95)	RH: 66.0% C: 57.1%	(a)
Coordination (11-32)	2	RH (1987 dioxin >10 ppt): Initial Dioxin	0.002	2.25 (1.30,3.90)	Low: 2.9% Medium: 2.1% High: 5.8%	(b)
Romberg Sign (11-33)	2	RH (1987 dioxin >10 ppt): Initial Dioxin	0.033	2.11 (1.03,4.34)	Low: 2.9% Medium: 2.1% High: 2.9%	(b)

- (a): Discrete variable: adjusted relative risk and 95% confidence interval were presented; percent abnormal was presented for each exposure group in contrast.
- (b): Discrete variable: adjusted relative risk and 95% confidence interval were presented for a twofold increase in initial dioxin; percent abnormal was presented for each of three initial dioxin categories.
- (c): Discrete variable: adjusted relative risk and 95% confidence interval were presented for a twofold increase in 1987 dioxin; percent abnormal was presented for each of three 1987 dioxin categories.
- (d): Discrete variable: adjusted relative risk and 95% confidence interval were presented; percent abnormal was presented for each dioxin category in contrast.

Note: RH = Ranch Hand.
C = Comparison.

Model 2: Low = 32–79 ppt; Medium = >79–199 ppt; High = >199 ppt (Ranch Hands who had a 1987 dioxin measurement greater than 10 ppt).

Model 3: Background (Ranch Hand): 1987 dioxin ≤ 10 ppt.
Low (Ranch Hand): 1987 dioxin > 10 ppt, 10 ppt < initial dioxin ≤ 118 ppt.
High (Ranch Hand): 1987 dioxin > 10 ppt, initial dioxin > 118 ppt.

Model 4: Low = ≤7.8 ppt; Medium = >7.8–19.2 ppt; High = >19.2 ppt (Ranch Hands only).

11.5 CONCLUSION

The AFHS neurology assessment included the evaluation of cranial nerve function, peripheral nerve status, and CNS coordination processes based on a physical examination. The motor and sensory peripheral nerve findings and the cranial nerve examination provided specific clues to the anatomic site of possible neurological problems. The neurological evaluations performed in the AFHS were sensitive, and can be relied upon to detect the presence of peripheral neuropathy. These results are summarized below by statistical model.

With regard to group contrasts, Ranch Hands were more likely to have abnormal visual fields and an abnormal cranial nerve index than Comparisons. More Ranch Hand officers had hereditary or degenerative diseases and sluggish or absent Achilles reflexes than Comparison officers.

Significant positive relations were seen between balance and coordination and extrapolated initial dioxin levels.

Analyses based on dioxin category showed an increased risk of abnormal visual fields in the background dioxin category and an increased risk of abnormal facial sensation for Ranch Hands in the low dioxin category. Ranch Hands in both the background and low dioxin categories showed an increased risk of abnormalities for the cranial nerve index, a composite index of the individual 15 cranial nerve endpoints studied in this assessment. More Ranch Hands in the high dioxin category had an abnormal reaction to pinprick and absent patellar reflexes than Comparisons.

Analyses of 1987 dioxin levels showed a significant positive association with the absence of the patellar reflex.

Based on the results of the analysis of pinprick, balance, and the patellar reflex in this follow-up examination, there was some limited support of an association between dioxin levels and neurological disease related to the peripheral nerves. In conclusion, there was no clinical evidence to support a relation between dioxin and cranial nerve function or other CNS processes.

12 PSYCHOLOGY ASSESSMENT

12.1 INTRODUCTION

12.1.1 Background

12.1.1.1 Organs/Diseases

The Symptom Checklist-90-Revised (SCL-90-R) (1) and the Wechsler Memory Scale-Revised (WMS-R) (2) were used in the psychology assessment of participants in the Air Force Health Study (AFHS). The SCL-90-R was used to measure symptomatic psychological distress in terms of anxiety, depression, hostility, interpersonal sensitivity, obsessive-compulsive behavior, paranoid ideation, phobic anxiety, psychoticism, and somatization. The SCL-90-R was also used to measure three global distress indices: global severity index (GSI), positive symptom total (PST), and positive symptom distress index (PSDI). The WMS-R is an instrument used for appraising major dimensions of memory functions in adolescents and adults, including memory for verbal and figural stimuli, meaningful and abstract material, and delayed as well as immediate recall. Psychological disorders as verified through medical records review, such as psychoses, alcohol and drug dependence, anxiety, and other neuroses, were studied to supplement the psychological evaluation.

12.1.1.2 Toxicology

Signs of dioxin neurotoxicity in animals (e.g., lethargy, stupor, poor coordination, lack of feeding, and agitation) were observed in multiple studies in many species and have been attributed to the “wasting syndrome” of multi-organ toxicity rather than to primary central nervous system (CNS) involvement (3). Pharmacokinetic studies in rats (4), mice (5), and monkeys (6) demonstrated that the blood-brain barrier is relatively impermeable to dioxin; therefore, experimental animal studies provide little insight into the potential neuropsychological consequences of dioxin in humans.

In rats exposed to high doses of dioxin (1,000 micrograms intraperitoneally), only slight differences were noted in spontaneous motor activity and maze performance relative to controls (7). A study from the same laboratory found no neurobehavioral impairment in rats given a sublethal dose of dioxin sufficient to cause the wasting syndrome (8). These findings were supported in recent studies showing that alterations in cognitive function in rats, if any, after dioxin exposure early in life were very subtle (9, 10). In a recent report, rats exposed to dioxin during gestation and lactation also showed very subtle effects on cognitive function (11). In contrast, experiments in monkeys documented “subtle” behavioral dysfunction and cognitive impairment consequent to dioxin exposure in utero (12-15).

12.1.1.3 Epidemiology

Numerous studies were published describing psychological sequelae in populations exposed to dioxin through environmental contamination, industrial accidents, occupation, and in association with service in Southeast Asia (SEA) during the Vietnam War.

A limited number of epidemiologic studies (16-18) examined neurobehavioral health effects of environmental exposure to dioxin. Neuropsychiatric testing was included in the medical evaluations reported in two studies of 154 mobile home park residents exposed to dioxin by contaminated soil in Quail Run, Missouri (16, 17). Relative to 155 unexposed controls residing at similar mobile home parks

without dioxin contamination, exposed subjects had poorer scores on the tension or anxiety and anger or hostility scales of the Profile of Mood States Inventory, as well as in the vocabulary subtest of the Wechsler Adult Intelligence Scale (WAIS) (19). Furthermore, the exposed group performed worse on the depression/dejection and fatigue/inertia scales relative to unexposed controls (17).

A small study in Germany evaluated the neuropsychological effects of chronic exposure to dioxins among 19 persons exposed to environmental contamination from a metal reclamation plant (18). Subjects were compared according to blood levels of dioxins and furans below and above the median exposure level in the study population. A substantial proportion of subjects reported irritability (42%), depressed feelings (37%), and fatigue (44%). Irritability and depressed feelings were more frequently reported by those with exposure levels above the median relative to those with lower exposures.

Some occupational studies investigated the potential neuropsychological effects of dioxin exposure, but few studies related serum dioxin levels to neuropsychological indices. Early studies of industrial chemical workers provided the first suggestion of associated psychological effects using chloracne as a marker for high-level dioxin exposure. Studies conducted shortly after the Nitro, West Virginia, accident in 1949 documented nervousness, fatigue, irritability, cold intolerance, and decreased libido in many of the workers with chloracne. Most of these symptoms resolved over a 4-year period (20, 21). In addition, two follow-up studies were conducted of expanded Nitro plant cohorts in 1979 (22, 23). Moses and colleagues, in a cross-sectional health survey, found chloracne in 52 percent of 226 workers. Differences in the prevalence of insomnia and decreased libido were observed between the groups with and without chloracne (22). Similar findings were reported in another investigation of 204 exposed and 163 unexposed workers, with a higher prevalence of nervousness and decreased libido in the exposed group (23).

Other industrial-based studies reported a wide range of acute and subacute symptoms associated with exposure to chlorophenols. In addition to those cited above, impotence, reduced emotional responses, sensory deficits, reading difficulties, memory loss, and emotional instability were described (24-29). Employing the Minnesota Multiphasic Personality Inventory (MMPI) (30), an early study of 73 male chemical production workers found an exposure-response association between the development of chloracne and hypomania, and a significantly increased incidence of personality disorders in those employees most heavily exposed (28). Furthermore, a case report described marked personality changes in two of three chemists involved in the synthesis of dioxin (29). Yet another study of 55 Czechoslovakian workers with dioxin intoxication initially found a significant prevalence of encephalopathy (7%) and neurasthenia (75%) among the workers. Over time, the prevalence of psychic disturbances decreased substantially (27). In a recent follow-up study of 13 workers in this cohort, plasma dioxin levels were negatively correlated with the memory quotient from the WMS, the verbal intelligence quotient (IQ) from the WAIS-Revised (31), and the Benton Revised Visual Retention Test (32-34).

The National Institute for Occupational Safety and Health's (NIOSH's) study of chemical plant workers is one of a few epidemiologic studies in humans that incorporates serum dioxin data into psychometric analyses (35). This cross-sectional study of 281 exposed workers in two industrial plants and 260 unexposed community controls investigated the association between exposure to chemicals (including dioxin) and symptoms of depression based on a battery of psychological screening tests (the Beck Depression Inventory and the depression subscale of the SCL-90-R). The mean serum dioxin level in the exposed cohort was 220 parts per trillion (ppt) versus 6 ppt in referents. By both scales, the prevalence of depression was comparable in each group. No association between dioxin exposure and scores in the two psychological tests was found based on either group membership or serum exposure levels.

In a morbidity follow-up study of 158 men exposed to dioxin after a chemical accident at the trichlorophenol unit of a BASF chemical facility, the rate of episodes of illness among exposed workers was compared to the rate in an unexposed population employed at the same facility (36). Exposure to dioxin was determined based on chloracne status and extrapolated blood lipid concentrations. An increase was found in episodes of mental disorders (International Classification of Diseases, 9th Revision, Clinical Modification [ICD-9-CM] 290-317) among those with severe chloracne; however, no association with dioxin levels in the blood was observed.

The association between psychological symptoms and reported herbicide exposure during military service in Vietnam has been the subject of several studies (37-39). Some studies have focused on dioxin exposure specifically (40-45). In one study of 153 veterans who reported at least a 5-year history of continuous daily drug abuse, a subgroup of 58 subjects reporting moderate to high herbicide exposure had MMPI scores that indicated depression, poor morale, organic symptoms, family problems, and hypomania compared to the remaining 95 veterans (37). In another study of 7,924 U.S. Army veterans, those with Vietnam experience were at increased risk of psychological problems and illicit drug use as compared to non-Vietnam veterans (38). Among Vietnam veterans, the level of reported herbicide exposure was related to unfavorable mental health outcomes in an exposure-response fashion (38). Some evidence from the Vietnam Experience Study, conducted by the Centers for Disease Control and Prevention (CDC), indicates that service in Vietnam may be associated with psychological morbidity independent of exposure to herbicides (39). A recent study of 1,224 Korean Vietnam veterans found insufficient evidence for an increased prevalence of psychiatric disorders (46).

The evidence for an association between serum dioxin levels and cognitive functioning among Ranch Hand personnel in the AFHS was recently evaluated (40, 45). Cognitive functioning was assessed in 1982 using the WAIS-Revised, the WMS, the Halstead-Reitan Neuropsychological Test Battery (HRB) (47), and the Wide Range Achievement Test (48). In addition, information was collected on psychiatric diagnoses and psychotropic medication use during the 1982 physical examination. Each veteran was assigned to a background, low, or high dioxin exposure category based on serum dioxin levels determined in 1987 and 1992. There was no consistent effect of dioxin exposure on cognitive functioning, and dose-response gradients were generally absent. Although several measures of memory functioning were decreased among those with the highest dioxin levels, the differences were considered relatively small and of unknown clinical relevance (40).

Other reports of the AFHS also found inconclusive evidence for an association between psychological indices and dioxin exposure among Ranch Hands (41-44). The 1987 examinations suggested an association between serum dioxin levels and some scales on the Millon Clinical Multiaxial Inventory (MCMI) (49), but there was no evidence for a relation with indices on the SCL-90-R (44). In the analysis of the 1997 follow-up examination results, a dose-response pattern between 1987 dioxin concentrations and the prevalence of other neuroses among Ranch Hands was limited to the enlisted groundcrew, the subgroup with the highest dioxin levels (41). Otherwise, few significant associations were found (50). Similarly, Michalek and colleagues found little evidence for an association between serum dioxin levels and psychological functioning determined by the MMPI and the MCMI among Ranch Hand veterans (45).

In the 2002 report published by the Institute of Medicine (50), the committee concluded that there is “inadequate or insufficient” evidence of an association between exposure to certain herbicides used in Vietnam and cognitive or neuropsychiatric disorders.

12.1.2 Summary of Previous Analyses of the Air Force Health Study

12.1.2.1 1982 Baseline Examination Summary Results

An extensive battery of psychological parameters was assessed on all participants during the 1982 baseline questionnaire and as part of the physical examination process. There were no questionnaire differences for past history of emotional or psychological illnesses between the Ranch Hand and Comparison groups. For the psychological indices of fatigue, anger, erosion of skills, anxiety, and severity of depression, no group differences were detected among the college-educated Ranch Hands. For the high school-educated stratum, Ranch Hands demonstrated significantly more fatigue, anger, erosion of skills, and anxiety. An analysis of the isolation index adjusted for education level showed significantly higher (adverse) scores in the Ranch Hand group. The isolation index was based on the answers to three questions that are related to the amount of activity that the participant has with friends, relatives, and community.

At the time of the physical examination, additional data were collected with the Cornell Index (CI) (51) and the MMPI. The CNS functional testing was conducted by a modified HRB and intelligence was measured by the WAIS.

The CI showed a significant increase in psychophysiological symptoms in the high school-educated Ranch Hands. MMPI results in the high school-educated participants showed Ranch Hand mean values significantly increased in the scales of denial, hypochondria, masculinity-femininity, and mania-hypomania. The social introversion scale was significantly decreased in the college-educated Ranch Hands. None of the self-reported data, including those from the in-home questionnaire, was adjusted for possible group differences in post-traumatic stress disorder (PTSD) or combat experience and intensity.

Performance testing by the HRB showed no neuropsychiatric impairment in the Ranch Hands in contrast to the results of the self-administered MMPI and the CI. WAIS intelligence scores revealed group similarities in the full-scale and verbal and performance scales. The IQ of the college-educated participants was significantly higher than the IQ of the high school-educated participants.

12.1.2.2 1985 Follow-up Examination Summary Results

Two of the psychological tests (MMPI, HRB) conducted at the 1982 baseline examination were repeated at the first follow-up examination in 1985. An updated history of mental and emotional disorders and combat experience in Vietnam also was obtained on all participants. An indicator of PTSD was derived from a new MMPI subscale and was used for covariate adjustments of non-MMPI psychological data. The Cornell Medical Index (CMI) (52) was substituted for the CI in the 1985 psychology assessment. Higher scores on these instruments may reflect an adverse condition in the psychological health of the participant. Questionnaire data (verified by a medical records review) for the lifetime events of psychotic illness, alcohol dependence, anxiety, or other neuroses disclosed no significant differences between groups for these conditions.

The group distributions for the 14 MMPI variables, each stratified by the three occupational categories, were examined. Ranch Hand enlisted flyers had a lower psychopathic deviate mean than Comparison enlisted flyers, and Ranch Hand officers had a higher mania/hypomania mean than Comparison officers. The group distributions of the total CMI score were similarly contrasted, with separate analyses performed with stratification by the five covariates of age, race, occupation, education, and current alcohol drinking status. For one stratum of each of these covariates (born in or after 1942, non-Black, enlisted groundcrew, high school education, and current alcohol drinker), a significant difference in the distribution of the Ranch Hand and Comparison scores was found. In all cases for the CMI, the Ranch

Hand mean was greater than the Comparison mean, suggesting more illness for Ranch Hands relative to Comparisons.

The adjusted analyses of the MMPI scales of denial and masculinity-femininity were statistically significant, where Comparisons showed an adverse effect over Ranch Hands. Ranch Hands had significantly higher mean scores than Comparisons on the A-H area subscore of the CMI, suggesting that Ranch Hands had more diffuse medical problems. The M-R subscore of the CMI, a broad indicator of emotional health, was not statistically different between the two groups.

The HRB impairment index, a measure of CNS functional integrity, did not differ significantly between the Ranch Hand and Comparison groups.

Because of interactions in models and slightly different psychological testing parameters, a direct contrast between the psychological results of the baseline and 1985 follow-up examinations was not always possible. Several broad patterns, however, were observed: (1) the discordance between distributional tests and results from traditional statistical models of the MMPI variables was noted with data from both examinations; (2) there was a narrowing of group differences at the 1985 follow-up examination for most variables, either by a decrease in Ranch Hand reporting or by an increase in Comparison reporting; and (3) as at the baseline examination, functional CNS testing, as measured by the HRB impairment index, showed no group differences and did not support an organic basis for differences in self-reported symptomatology. The longitudinal analysis of two MMPI scales—depression and denial—showed a significant reversal of depression seen at the baseline examination in the high school-educated Ranch Hands. The number of depression abnormalities decreased in Ranch Hands and increased in Comparisons.

The determination of PTSD in both Air Force cohorts by a relatively new MMPI scale showed a prevalence rate of less than 1 percent. This low rate was strongly influenced by characteristics of the study population (e.g., age, education, and military occupation).

In conclusion, significant test results were present in both groups or were noted in specific subgroups of a covariate. Tests of the CNS by the HRB demonstrated a similar prevalence of abnormality in both groups. Ranch Hands exhibited an increased mean A-H subscore of the CMI, suggesting they had more illness than Comparisons.

12.1.2.3 1987 Follow-up Examination Summary Results

The psychology assessment was based on verified psychological disorders, reported sleep disorders, and two clinical psychological tests, the SCL-90-R and the MCMI, where higher scores may indicate an adverse condition in the psychological health of the participant. Lifetime psychological disorders showed no group differences for psychoses, drug dependence, and anxiety. The Ranch Hands reported experiencing great or disabling fatigue during the day and talking in their sleep more frequently than the Comparisons. After adjusting for the covariates, a significant increase in the Ranch Hand mean was seen on the MCMI narcissistic score. The Comparisons had a significantly higher mean MCMI dependent score than the Ranch Hands.

12.1.2.4 Serum Dioxin Analysis of 1987 Follow-up Examination Summary Results

In general, the results of the analyses of the verified psychological disorders, reported sleep disorders, and the SCL-90-R variables did not reveal significant associations with initial dioxin or 1987 dioxin and time since tour of duty or find significant differences among the four dioxin categories (Comparisons, Ranch

Hands with no more than 10 ppt of 1987 dioxin in the blood, and Ranch Hands with more than 10 ppt of 1987 dioxin in the blood divided into two categories: “Low Ranch Hands” and “High Ranch Hands”). In contrast, several of the analyses of the MCMI variables displayed significant results. There was a lack of consistency across similar variables included in the SCL-90-R, MCMI, and reported information. In conclusion, the body burden of dioxin did not appear to be related to psychological or psychophysiological disorders.

12.1.2.5 1992 Follow-up Examination Summary Results

The psychology assessment was based on verified psychological disorders and the SCL-90-R. Differences in the SCL-90-R inventory variables were found between Ranch Hand and Comparison groups. Variables revealing significant differences in adjusted analyses were other neuroses and the SCL-90-R scores for anxiety, obsessive-compulsive behavior, paranoid ideation, somatization, and the GSI. These differences were observed when combining participants across all occupations. All significant results showed a greater percentage of Ranch Hands than Comparisons that had a history of other neuroses or high (adverse) SCL-90-R scores.

Most of the significant results in the adjusted analysis of the association between the psychological endpoints and categorized dioxin were from the contrasts of Ranch Hands in the background dioxin category with Comparisons. These differences between Ranch Hands in the background dioxin category and Comparisons were found in the analysis of the SCL-90-R obsessive-compulsive behavior, paranoid ideation, and somatization scores. The analysis also revealed that Ranch Hands in the background category had a greater percentage of high SCL-90-R scores than did Comparisons. The adjusted analysis of categorized dioxin also showed a significant increase in the percentage of Ranch Hands in the high dioxin category with a high SCL-90-R anxiety score over Comparisons. In the analyses of 1987 dioxin, a significant inverse association between whole weight 1987 dioxin, adjusted for total lipids, and a history of alcohol dependence was observed.

12.1.2.6 1997 Follow-up Examination Summary Results

Five psychological disorders, which were verified by a medical records review, and 12 measures from the SCL-90-R inventory were examined in the psychology assessment. The SCL-90-R consisted of nine primary symptom dimensions and three broad indices of psychological distress. In enlisted groundcrew, a significantly greater percentage of Ranch Hands than Comparisons had a history of other neuroses. All other adjusted analyses of Ranch Hands versus Comparisons that were significant showed a greater percentage of Comparisons than Ranch Hands with high SCL-90-R scores. High scores on the SCL-90-R may indicate an adverse effect to psychological health.

Associations between initial dioxin and the psychological endpoints in the analyses were either nonsignificant or revealed a significant decrease in high SCL-90-R scores as initial dioxin increased.

Differences in the history of psychological disorders and the prevalence of high SCL-90-R scores were examined between Comparisons and Ranch Hands categorized by dioxin levels. Ranch Hands in the low dioxin category and the low and high dioxin categories combined displayed a significantly higher prevalence of other neuroses than Comparisons.

The relation between the 1987 dioxin levels and the psychological endpoints was examined; all results were nonsignificant.

In conclusion, Ranch Hand veterans exhibited a significantly increased prevalence of other neuroses among enlisted groundcrew, the occupation with the highest dioxin levels and, presumably, the greatest

herbicide exposure. No consistent relation was found between any SCL-90-R score and any measure of herbicide or dioxin exposure.

12.1.3 Parameters for the 2002 Psychology Assessment

12.1.3.1 Dependent Variables

Data collected through the SCL-90-R and the WMS-R were used in the psychology assessment. In addition, psychological disorders, as verified through medical records review, were used to supplement the psychological evaluation for the 2002 follow-up examination. Three Ranch Hands and two Comparisons who tested positive for the human immunodeficiency virus (HIV) were excluded from the analyses of all dependent variables because of the psychological issues associated with initial diagnosis, side effects of anti-viral drug therapy, and the neurocognitive component associated with the disease process.

12.1.3.1.1 Medical Records Variables

At the face-to-face interview during the 2002 examination, each participant was asked whether he had a mental or emotional disorder since the date of his last interview. Medical records review was accomplished to confirm reported mental or emotional disorders and to identify any unreported mental or emotional conditions for each participant that attended the 2002 physical examination. These data from the 2002 physical examination were combined with data from the 1982 baseline examination and the 1985, 1987, 1992, and 1997 follow-up examinations to form a series of variables regarding a verified history of psychological disorders for each participant. In particular, the verified histories of psychoses (ICD-9-CM codes 290.0–298.9), alcohol dependence (ICD-9-CM codes 303.00–303.93, 303.97–303.98), drug dependence (ICD-9-CM codes 304.00–304.93), anxiety (ICD-9-CM codes 300.00–300.09), and other neuroses (ICD-9-CM codes 300.10–302.9, 305.00–305.03, 305.20–309.9, and 311) were studied. The greatest category of other neuroses resulted from a physiological malfunction arising from mental factors (category name in the ICD-9-CM manual, ICD-9-CM 306). The physiological malfunctions included psychogenic physical symptoms and physiological manifestations. Depressive disorders not elsewhere classified also showed a high prevalence (ICD-9-CM 311). The analyses performed in this chapter were based on the 1,951 participants who attended the 2002 follow-up examination.

In addition to the HIV-positive participants described previously, participants with a verified pre-SEA history of a psychological disorder under study were excluded from the analyses pertaining to that disorder.

12.1.3.1.2 Psychological Examination Variables

The SCL-90-R was used in the psychology assessment for the 2002 follow-up examination, and had been used previously in the AFHS at the 1987, 1992, and 1997 follow-up examinations. The SCL-90-R is a multidimensional self-reported symptom inventory designed to measure symptomatic psychological distress in terms of nine primary symptom dimensions. The nine dimensions are anxiety, depression, hostility, interpersonal sensitivity, obsessive-compulsive behavior, paranoid ideation, phobic anxiety, psychoticism, and somatization. Each participant was asked to respond to 90 questions in terms of the following 5-point scale: 0=not at all, 1=a little bit, 2=moderately, 3=quite a bit, and 4=extremely. High scores on these questions lead to high (adverse) scores for the scales characterizing the nine primary symptom dimensions. Responses were grouped into the nine primary symptom categories, and a raw score for a participant for a category was determined by adding the scores of the answered questions in that category and dividing by the number of answered questions in that category. The raw scores were then converted to T-scores (reference scores for a given population norm) for analysis.

The SCL-90-R also measures distress using three global indices that also were analyzed. The distress indices are the GSI, PST, and PSDI. The GSI is defined as the sum of the scores of all answered questions divided by the number of answered questions on the entire test. This index combines information on the number of symptoms and the intensity of distress. The PST is the number of questions to which the participant responds positively (i.e., on the 5-point scale, responses 1, 2, 3, or 4). The PSDI is determined by adding the scores of all answered questions and dividing by the PST. This index describes the intensity of the positive symptoms. Each of these indices also was converted to a T-score.

The T-scores for the nine primary symptom dimensions and the three global indices were then classified as abnormal or normal, where abnormal was defined as a T-score of 63 or greater. The maximum T-score for AFHS participants attending the 2002 follow-up examination was 81. All participants were included in the analyses of the nine primary symptom dimensions and the three global indices of distress, including those participants who responded “not at all” to all 90 questions.

The WMS-R is an individually administered clinical instrument for appraising major dimensions of memory functions in adolescents and adults. The functions assessed include memory for verbal and figural stimuli, meaningful and abstract material, and delayed as well as immediate recall. The original memory scale was developed by Wechsler in 1945 to permit clinicians in different settings and at different times to assess the same memory functions of their patients. The original WMS was rapid, simple, and practical, but it was limited in its coverage of memory functions believed to be clinically important. The WMS-R modified the content from the original WMS to improve and simplify the scoring system to reduce inter-administrator variability in the grading of the tests. The original WMS was administered for the 1982 AFHS baseline examination and the WMS-R was used for the AFHS 2002 follow-up examination. Three tests of the WMS-R were administered for the AFHS 2002 follow-up examination: the Logical Memory test (immediate and delayed recall), the Verbal Paired Associates test, and the Visual Reproduction test (immediate and delayed recall).

The Logical Memory test includes two brief stories that are read to the participant. After each one, the participant retells the story from memory (immediate recall). Following a delay of 30 minutes, the participant is again asked to relate each story (delayed recall). In the Verbal Paired Associates test, the participant learns eight word pairs, four of which reflect easy associations (e.g., metal – iron) and four of which are more difficult (e.g., crush – dark). For the Visual Reproduction test, the participant is asked to draw from memory four simple geometric designs that are each exposed for 10 seconds (immediate recall). Following a delay of 30 minutes, the participant is again asked to draw each design (delayed recall).

For the Verbal Paired Associates test, four easy associations and four difficult associations are asked three times to each participant. Therefore, a participant could score 12 for the easy items and 12 for the difficult items. In an attempt to mimic the scoring procedure for the WMS, Version 1, which was administered at the baseline examination, a score was constructed by taking the total for the easy items, dividing this score by 2, and adding the total for the difficult items. Therefore, the maximum possible score was 18.

The maximum possible score on each of the two stories read to the participant for the Logical Memory test was 25. An average score across both tests, which were of equal complexity, was used in the analysis in an attempt to mimic the scoring procedure for the WMS, Version 1. Therefore, the maximum possible average was 25. This scoring method was used for both the immediate and delayed recall.

For the Visual Reproduction test, the analysis was based on the sum of the scores from the reproduction of the four geometric figures, as was done for the baseline examination. The maximum possible score was 34. This scoring method was used for both the immediate and delayed recall.

12.1.3.2 *Covariates*

Covariates to be examined in the adjusted statistical analyses of the psychology assessment included age, race, military occupation, education level (high school, which comprised participants who achieved at most a high school education, and college, which comprised participants who earned a degree beyond high school), current alcohol use (average number of drinks per day during the 2 weeks prior to physical examination), lifetime alcohol history (drink-years), current total household income, current employment (yes, no), current marital status (married, not married), and current parental status (currently having a child under the age of 18 living at home [yes, no]).

Age, race, and military occupation were used as covariates in adjusted statistical analyses evaluating all psychological dependent variables. Age, race, and military occupation were determined from military records. Lifetime alcohol history was based on information from the 2002 questionnaire and combined with similar information gathered at the 1987, 1992, and 1997 follow-up examinations. Each participant was asked about his drinking patterns throughout his lifetime. When a participant's drinking pattern changed, he was asked to describe how his alcohol consumption differed and the duration of time that the drinking pattern lasted. The participant's average daily alcohol consumption was determined for each of the reported drinking pattern periods throughout his lifetime, and an estimate of the corresponding total number of drink-years was derived. One drink-year was the equivalent of drinking 1.5 ounces of an 80-proof alcoholic beverage, one 12-ounce beer, or one 5-ounce glass of wine per day for 1 year. Current alcohol use was defined as the average number of drinks per day during the 2 weeks prior to completing the physical examination. These alcohol covariates were not used in adjusted analyses of alcohol dependence.

Current total household income information was collected in the 2002 questionnaire in categories with \$5,000 increments, between \$5,000 and \$100,000. The midpoint of each category was used as the current total household income, with \$102,500 used for the \$100,000 or more category. Participants who were working full- or part-time were considered to be employed. Those participants who were unemployed, retired, in school, or keeping house were designated as not employed.

Educational level, current employment, current marital status, and current parental status were all based on self-reported information from the questionnaire.

The covariates current total household income, current employment, current marital status, and current parental status were used in the analysis of dependent variables based on medical records data (psychoses, alcohol dependence, drug dependence, anxiety, and other neuroses). Although these dependent variables captured a history of the condition, and the covariates described above were based on the current status of a participant's life, the covariates were used as surrogate information to describe the participant's life experience. In addition, lifetime alcohol history was used as a covariate for these dependent variables, but current alcohol use was not used. Current alcohol use reflected a participant's alcohol use only in the 2 weeks prior to the physical examination. The lifetime alcohol history covariate was used to investigate the cumulative lifetime effects of alcohol use.

12.1.4 **Statistical Methods**

Table 12-1 summarizes the statistical analysis performed for the 2002 psychology assessment. The first part of this table lists the dependent variables analyzed, source of the data, form of the data, cutpoints, covariates, exclusions, and statistical methods. The second part of the table further describes the covariates. A covariate was used in its continuous form whenever possible for all adjusted analyses. If the covariate was inherently discrete (e.g., military occupation), or if a categorized form was needed to

develop measures of association with the dependent variables, the covariate was categorized as shown in Table 12-1.

Four models were examined for each dependent variable given in Table 12-1. The analyses of these models are presented below. Further details on dioxin and the modeling strategy are found in Chapters 2 and 7, respectively. These analyses were performed both unadjusted and adjusted for covariates. These covariates are given in Table 12-1. Model 1 examined the relation between the dependent variable and group (i.e., Ranch Hand or Comparison). In this model, exposure was defined as “yes” for Ranch Hands and “no” for Comparisons without regard to the magnitude of the exposure. In an attempt to quantify exposure, three contrasts of Ranch Hands and Comparisons were performed along with the overall Ranch Hand versus Comparison contrast. These three contrasts compared Ranch Hands and Comparisons within each military occupational category (i.e., officers, enlisted flyers, and enlisted groundcrew). As described in previous reports and Table 2-4, the median level of exposure to dioxin was highest for enlisted groundcrew, followed by enlisted flyers, then officers.

During the 1987, 1992, 1997, and 2002 examinations, serum dioxin levels were measured by the CDC using high-resolution gas chromatography and high-resolution mass spectrometry and were reported in ppt on a lipid weight basis (53). These dioxin measurements are referred to as “lipid-adjusted.” All measures of dioxin used in this report were based on lipid-adjusted dioxin measurements.

Model 2 examined the relation between the dependent variable and an extrapolated initial dioxin measure for Ranch Hands who had a 1987 dioxin measurement greater than 10 ppt. The initial dioxin was calculated by extrapolating the 1987 dioxin level back in time to the end of the tour of duty that qualified a Ranch Hand veteran for inclusion in this study. If a Ranch Hand did not have a 1987 dioxin level, then the first dioxin measured, either at 1992, 1997, or 2002, was used to estimate the initial dioxin level. Regardless of when the dioxin was measured, Ranch Hand veterans with a level less than or equal to 10 ppt were excluded from statistical analyses based on Model 2. A statistical adjustment for body mass index at the time of the participant’s blood measurement of dioxin was included in this model to account for body mass index-related differences in elimination rate (54).

Model 3 divided the Ranch Hands examined in Model 2 into two categories based on their initial dioxin measures. These two categories were referred to as “low Ranch Hand” and “high Ranch Hand.” Two additional categories—Ranch Hands with serum dioxin levels at or below 10 ppt and Comparisons—were

formed and included in the model. Ranch Hands with serum dioxin levels at or below 10 ppt were assigned to the “background Ranch Hand” category. If a Ranch Hand did not have a 1987 dioxin measurement, the first measured dioxin level was used. Another category was examined by combining the low and high Ranch Hand categories. This combination is referred to in the tables as the “low plus high Ranch Hand” category. These five categories—Comparisons, background Ranch Hands, low Ranch Hands, high Ranch Hands, and low plus high Ranch Hands—were used in Model 3 analyses. The relation between the dependent variable in each of the four Ranch Hand categories and the dependent variable in the Comparison category was examined. As in Model 2, a statistical adjustment for body mass index at the time of the participant's blood measurement of dioxin was included in this model for the unadjusted and adjusted analyses of all dependent variables. One Ranch Hand without a dioxin measure was excluded from statistical analyses based on Model 3.

Model 4 examined the relation between the dependent variable and 1987 dioxin levels in all Ranch Hands with a dioxin measurement. If a Ranch Hand did not have a 1987 dioxin measurement, the first dioxin level obtained, either in 1992, 1997, or 2002, was extrapolated to the date of the 1987 physical examination. If the first dioxin level was not obtained in 1987 and was less than or equal to 10 ppt, it was not extrapolated to 1987 level, but was used at the measured value. One Ranch Hand without a dioxin measurement was excluded from statistical analyses based on Model 4.

The term “unadjusted” was used in the text and tables as follows: Models 1 and 4 did not adjust for any covariates. Models 2 and 3 adjusted only for body mass index at the time of the blood measurement for dioxin. The term “adjusted” was used in the text and tables as follows: Models 1 and 4 adjusted for the covariates shown in Table 12-1 unless otherwise specified by a footnote to the table. Models 2 and 3 additionally adjusted only for body mass index at the time of the blood measurement for dioxin.

Table 12-2 provides a summary of the number of participants with missing dependent variable and covariate data. In addition, the number of participants that were excluded from analyses is given. As noted in Table 12-2, 55 participants did not provide information for current total household income. Most of these participants refused to answer this question. In an attempt not to exclude a substantial number of participants, a limited version of a stepwise procedure was used. If current total household income was not significant ($p > 0.05$) for the adjusted analysis of a particular model for a dependent variable, this covariate was excluded from the analysis. Excluding current total household income from the model allowed these 55 participants to be included in the analysis of the model and thus increased the sample size. The parameters of the model were then re-estimated; these statistics are shown in the tables in this chapter. Those models for which current total household income was deleted as a covariate are noted in a footnote to the table.

Table 12-2. Number of Participants Excluded or with Missing Data for the Psychology Assessment

12.2 RESULTS

12.2.1 Dependent Variable-covariate Associations

The psychological dependent variables were tested for associations with each of the covariates used in the adjusted analyses. The complete results are presented in Appendix F, Table F-4. These associations were pairwise between the dependent variable and the covariate and were not adjusted for any other covariates. The following paragraphs provide a brief summary of the pattern of significant ($p \leq 0.05$) dependent variable-covariate associations. In the discussion of the results below, low levels are considered adverse for the WMS-R test scores.

Age was significantly associated with a history of anxiety, as verified by a medical records review. Age was also associated with all WMS-R tests conducted. The SCL-90-R subscales of anxiety, hostility, interpersonal sensitivity, paranoid ideation, phobic anxiety, GSI, and PST showed a significant association with age. Scores on the WMS-R were greater for younger participants. A greater percentage of younger participants had a history of anxiety or high SCL-90-R scores than did older participants.

Black participants had a significantly higher history of psychoses, as verified by a medical records review, than did non-Black participants. The same pattern was observed for the SCL-90-R subscales of anxiety, interpersonal sensitivity, paranoid ideation, phobic anxiety, psychoticism, GSI, and PST. Non-Black participants scored higher on both the immediate and delayed recall portions of the Logical Memory and Visual Reproduction WMS-R tests.

All dependent variables were significantly associated with military occupation, except for drug dependence. Officers consistently had the smallest percentage of abnormal results and the highest scores on the WMS-R memory tests. Enlisted groundcrew had the greatest percentage of abnormalities on the variables derived from medical records and on the majority of SCL-90-R subscales. Enlisted flyers had the lowest average score on all WMS-R tests. These significant results may be related to the strong relation between education and occupation, as noted for the 1982 baseline examination and observed in all subsequent follow-up examinations. Many of the participants with at most a high-school education were enlisted personnel, whereas the majority of college-educated participants were officers.

Participants with at most a high school education had significantly higher prevalences of psychoses, anxiety, and other neuroses. Participants with college degrees had lower prevalences of abnormally high scores on all SCL-90-R subscales and higher average scores on all WMS-R tests.

Current alcohol use was significantly associated with the delayed and immediate recall portions of the Logical Memory and Visual Reproduction WMS-R tests. Scores on these memory tests increased as current alcohol use increased. These significant associations were probably due to the associations between military occupation and the memory tests and between military occupation and current alcohol use. Officers were heavier current drinkers than enlisted personnel, and officers also scored higher on the memory tests.

Lifetime alcohol history was significantly associated with a history of psychoses and other neuroses and the WMS-R Visual Reproduction (both delayed and immediate) tests. The SCL-90-R subscales of depression, hostility, obsessive-compulsive behavior, paranoid ideation, psychoticism, GSI, and PST also showed significant associations with lifetime alcohol history. In most cases, the heaviest lifetime drinkers (in terms of drink-years) had the greatest percentage of abnormalities on the variables derived from medical records or high SCL-90-R subscale scores. As lifetime alcohol consumption increased, the scores on the Visual Reproduction tests decreased.

All dependent variables were significantly associated with current total household income, except for drug dependence. Participants who had a higher income displayed a smaller prevalence of abnormalities. In addition, as income increased, the scores on the WMS-R memory tests increased.

Current employment was significantly associated with a history of psychoses, other neuroses, and all SCL-90-R and WMS-R tests. Participants who were currently employed had a smaller percentage of abnormalities and higher scores on the WMS-R memory tests than participants who were not currently employed.

Current marital status was significantly associated with all variables verified by a medical records review. With the exception of hostility, somatization, and the PSDI, current marital status was significantly associated with the SCL-90-R dependent variables. Participants who were not currently married had a greater percentage of abnormal scores. Participants who were currently married had higher average scores on the delayed recall portion of the WMS-R Logical Memory test and the immediate and delayed recall portions of the Visual Reproduction test.

Participants who currently had a child less than 18 years of age living at home had a greater prevalence of a history of other neuroses than participants who did not. In addition, the participants who had a child less than 18 years of age living at home scored higher, on average, on the immediate and delayed recall portions of the WMS-R Visual Reproduction test.

12.2.2 Exposure Analysis

The following section presents results of the statistical analyses of the dependent variables shown in Table 12-1. Dependent variables are grouped into two sections: (1) the questionnaire variables, derived from the questionnaire that was administered in the 2002 follow-up and previous AFHS examinations, and (2) the psychological examination variables, obtained during the 2002 physical examination.

12.2.2.1 Medical Records Variables

12.2.2.1.1 Psychoses

All results from the unadjusted and adjusted analyses of a history of psychoses (Models 1 through 4) were nonsignificant (Table 12-3(a-h): $p > 0.20$ for each analysis).

Table 12-3. Analysis of Psychoses

Analysis Results for Log₂ (1987 Dioxin)			
n	Adjusted Relative Risk (95% C.I.)^a		p-Value
772	0.87 (0.72,1.06)		0.180

^aRelative risk for a twofold increase in 1987 dioxin.

Note: Current total household income was not included in the model (see Section 12.1.4).

12.2.2.1.3 Drug Dependence

Due to a small prevalence of participants with a verified history of drug dependence, only limited analyses of drug dependence were possible. All results from unadjusted and adjusted analyses performed for Models 1, 3, and 4 were nonsignificant (Table 12-5(a,b,e-h): $p > 0.17$ for each analysis). No Ranch Hands in the Model 2 analyses had a history of drug dependence and analysis was not possible.

Table 12-5. Analysis of Drug Dependence

(a) MODEL 1: RANCH HANDS VS. COMPARISONS – UNADJUSTED					
Occupational Category	Group	n	Number (%) Present	Unadjusted Relative Risk (95% C.I.)	p-Value
<i>All</i>	<i>Ranch Hand</i>	<i>774</i>	<i>2 (0.3)</i>	<i>0.60 (0.12,3.12)</i>	<i>0.535</i>
	<i>Comparison</i>	<i>1,172</i>	<i>5 (0.4)</i>

Medium	258	0 (0.0)		
High	255	0 (0.0)		

^aRelative risk for a twofold increase in 1987 dioxin.

Note: Low = ≤7.8 ppt; Medium = >7.8–19.2 ppt; High = >19.2 ppt.

(h) MODEL 4: RANCH HANDS – 1987 DIOXIN – ADJUSTED			
Analysis Results for Log₂ (1987 Dioxin)			
n	Adjusted Relative Risk (95% C.I.)^a		p-Value
768	0.51 (0.16,1.61)		0.224

^aRelative risk for a twofold increase in 1987 dioxin.

Note: Results were not adjusted for race, military occupation, current total household income, current employment, current marital status, and current parental status because of the sparse number of Ranch Hands with drug dependence present.

12.2.2.1.4 Anxiety

All Model 1 through Model 3 results were nonsignificant for the unadjusted and adjusted analyses of anxiety (Table 12-6(a-f): $p > 0.05$ for each analysis). A significant positive association between 1987 dioxin levels and the prevalence of a history of anxiety was found in the unadjusted Model 4 analysis (Table 12-6(g): $p = 0.003$, Unadjusted Relative Risk [RR]=1.16). The Model 4 result was nonsignificant after adjusting for covariates (Table 12-6(h): $p = 0.547$).

Table 12-6. Analysis of Anxiety

765	0.97 (0.87,1.08)	0.547

^aRelative risk for a twofold increase in 1987 dioxin.

Note: Current total household income was not included in the model (see Section 12.1.4).

12.2.2.1.5 Other Neuroses

Model 1 unadjusted and adjusted analyses of other neuroses revealed a significant difference between Ranch Hands and Comparisons within the officer stratum (Table 12-7(a,b): $p=0.029$, Unadjusted $RR=0.72$; and $p=0.043$, Adjusted $RR=0.73$, respectively). The percentages of Comparison and Ranch Hand officers who had a verified history of other neuroses were 51.5 and 43.5, respectively. All other Model 1 contrasts were nonsignificant, as was each result from the Model 2 unadjusted and adjusted analyses (Table 12-7(a-d): $p>0.06$ for each result).

Several significant contrasts were found in the Model 3 unadjusted analysis of other neuroses (Table 12-7(e): $p=0.020$, Unadjusted $RR=0.75$, for Ranch Hands in the background dioxin category versus Comparisons; $p=0.028$, Unadjusted $RR=1.43$, for Ranch Hands in the high dioxin category versus Comparisons; and $p=0.048$, Unadjusted $RR=1.27$, for Ranch Hands in the low and high dioxin categories combined versus Comparisons). The percentage of participants with a verified history of other neuroses was higher for Comparisons (59.6%) than Ranch Hands in the background dioxin category (51.7%), but lower for Comparisons than for Ranch Hands in both the high dioxin category and low and high dioxin categories combined (68.3% and 65.4%, respectively). The remaining Model 3 unadjusted contrast was nonsignificant, as was each contrast in the adjusted Model 3 analysis (Table 12-7(f): $p>0.35$ for each contrast).

A significant positive association between 1987 dioxin levels and other neuroses was found within the Model 4 unadjusted analysis (Table 12-7(g): $p<0.001$, Unadjusted $RR=1.19$). After adjusting for covariates, the association was nonsignificant (Table 12-7(h): $p=0.819$).

12.2.2.2 Psychological Examination Variables

The 12 variables contained in this section are derived from the SCL-90-R. These 12 variables comprise primary symptom categories and three global indices of distress. A short description, which has been taken from the SCL-90-R reference manual (1), of each of the primary symptom categories and global indices of distress is given before the description of the results of the statistical analyses. The function of each of these global measures of the SCL-90-R, the GSI, the PSDI, and the PST, is to communicate in a single score the level or depth of the individual's psychopathology.

Seven items are part of the SCL-90-R, but not part of any of the primary symptom dimensions. These seven items, which influence several of the dimensions but are not unique to any of them, are a poor appetite, overeating, trouble falling asleep, awakening in the early morning, restless or disturbed sleep, thinking of death or dying, and feeling guilty. While in this sense they violate one of the statistical criteria for inclusion in the test, they are a part of the item set because they are clinically important. These items contribute to the global scores on the SCL-90-R and are intended to be used to give additional understanding of the clinical significance of the primary symptom dimensions. Thus, a high depression score with "early morning awakening" and "poor appetite" may mean something quite different from a similar score with these symptoms absent. By the same token, the presence of conscious "feelings of guilt" is an important clinical indicator that communicates important information to the clinician. The additional items are not scored collectively as a dimension but are summed into the global scores.

12.2.2.2.1 SCL-90-R Anxiety

The anxiety dimension is a set of signs and symptoms that are associated clinically with high levels of manifest anxiety. General signs such as nervousness, tension, and trembling are included in the definition, as are panic attacks and feelings of terror. Cognitive components involving feelings of apprehension and dread, and some of the somatic correlates of anxiety, also are included as dimensional components. The symptoms comprising the anxiety dimension are experiencing nervousness or shakiness inside, trembling, being suddenly scared for no reason, feeling fearful, experiencing heart pounding or racing, feeling tense and keyed up, having spells of terror and panic, feeling so restless you couldn't sit still, feeling that something bad is going to happen, and experiencing frightening thoughts and images.

Unadjusted and adjusted analysis results for SCL-90-R anxiety were nonsignificant for Model 1 through Model 3 (Table 12-8(a-f): $p > 0.05$ for each analysis).

The unadjusted analysis of Model 4 revealed a significant positive association between the 1987 dioxin levels and the prevalence of high SCL-90-R anxiety scores (Table 12-8(g): $p = 0.047$, Unadjusted $RR = 1.17$). After covariate adjustment, the association was nonsignificant (Table 12-8(h): $p = 0.443$).

Note: Current total household income was not included in the model (see Section 12.1.4).

12.2.2.2.2 SCL-90-R Depression

The symptoms of the depression dimension reflect a broad range of the manifestations of clinical depression. Symptoms of dysphoric mood and affect are represented, as are signs of withdrawal of life interest, lack of motivation, and loss of vital energy. In addition, feelings of hopelessness, thoughts of suicide, and other cognitive and somatic correlates of depression are included. The symptoms comprising

the depression dimension are losing sexual interest or pleasure, feeling low in energy or slowed down, thinking of ending your life, crying easily, feeling trapped or caught, blaming yourself for things, feeling lonely, feeling blue, worrying too much about things, feeling no interest in things, feeling hopeless about the future, feeling everything is an effort, and feeling worthless.

All results from the analysis of SCL-90-R depression (Model 1 through Model 4) were nonsignificant, both unadjusted and adjusted for covariates (Table 12-9(a-h): $p > 0.07$ for each analysis).

Table 12-9. Analysis of SCL-90-R Depression

12.2.2.2.3 SCL-90-R Hostility

The hostility dimension reflects thoughts, feelings, or actions that are characteristic expressions of anger. The items comprising the hostility dimension were selected to measure the three modes of manifestation (i.e., thoughts, feelings, actions) and reflect qualities such as aggression, irritability, rage, and resentment. The dimension's symptoms are feeling easily annoyed or irritated; having uncontrollable temper outbursts; having urges to beat, injure, or harm someone; having urges to break or smash things; getting into frequent arguments; and shouting or throwing things.

No significant results were found from all unadjusted and adjusted analyses of SCL-90-R hostility for Model 1 through Model 4 (Table 12-10(a-h): $p \geq 0.06$ for each analysis).

Table 12-10. Analysis of SCL-90-R Hostility

12.2.2.2.4 SCL-90-R Interpersonal Sensitivity

The interpersonal sensitivity dimension focuses on feelings of personal inadequacy and inferiority, particularly in comparison with others. Self-deprecation, feelings of uneasiness, and marked discomfort during interpersonal interactions are characteristic manifestations of interpersonal sensitivity. In addition, individuals with high scores on interpersonal sensitivity report acute self-consciousness and negative expectations concerning the communications and interpersonal behaviors with others. The symptoms comprising the interpersonal sensitivity dimension are feeling critical of others, feeling shy or uneasy with the opposite sex, having feelings easily hurt, feeling others do not understand or are unsympathetic to, feeling that people are unfriendly or dislike you, feeling inferior to others, feeling uneasy when people are watching or talking about you, feeling very self-conscious with others, and feeling uncomfortable about eating or drinking in public.

Significant differences between Ranch Hands and Comparisons were revealed in the Model 1 unadjusted analysis of SCL-90-R interpersonal sensitivity when examined across all occupational strata and within the officer stratum (Table 12-11(a): $p=0.014$, Unadjusted RR=0.67; and $p=0.040$, Unadjusted RR=0.47, respectively). Both contrasts revealed more Comparisons than Ranch Hands with high SCL-90-R interpersonal sensitivity scores (Table 12-11(a): overall: 10.7% for Comparisons versus 7.4% for Ranch Hands; and officer: 6.7% for Comparisons versus 3.3% for Ranch Hands). Results remained significant after adjusting for covariates (Table 12-11(b): $p=0.013$, Adjusted RR=0.65; and $p=0.045$, Adjusted RR=0.47). All other Model 1 results, both unadjusted and adjusted, were nonsignificant (Table 12-11(a,b): $p>0.19$ for all remaining Model 1 contrasts).

Model 2 and Model 4 results were nonsignificant in both the unadjusted and adjusted analyses of SCL-90-R interpersonal sensitivity (Table 12-11(c,d,g,h): $p\geq 0.35$ for each analysis).

The unadjusted Model 3 analysis of SCL-90-R interpersonal sensitivity displayed two significant contrasts: the background dioxin category versus Comparisons and the low dioxin category versus Comparisons. In both contrasts, Comparisons had a higher SCL-90-R interpersonal sensitivity score than Ranch Hands (Table 12-11(e): $p=0.034$, Unadjusted RR=0.61; and $p=0.010$, Unadjusted RR=0.42, respectively). In the adjusted analysis, the contrast involving Ranch Hands in the background dioxin category became nonsignificant (Table 12-11(f): $p=0.163$), while the contrast involving Ranch Hands in the low dioxin category remained significant (Table 12-11(f): $p=0.011$, Adjusted RR=0.40). In addition, the adjusted Model 3 analysis of Ranch Hands in the low and high dioxin categories combined versus Comparisons was significant (Table 12-11(f): $p=0.013$, Adjusted RR=0.56). All other Model 3 unadjusted and adjusted results were nonsignificant (Table 12-11(e,f): $p>0.05$ for all remaining contrasts).

12.2.2.2.5 SCL-90-R Obsessive-compulsive Behavior

The obsessive-compulsive dimension reflects symptoms that are highly identified with the standard clinical syndrome of the same name. This measure focuses on thoughts, impulses, and actions that are experienced as unremitting and irresistible by the individual and inconsistent with the individual's own beliefs about what is desirable or reasonable. Behaviors and experiences of a more general cognitive performance attenuation also are included in this measure. The symptoms comprising the obsessive-compulsive dimension are experiencing repeated unpleasant thoughts that won't leave the mind, having trouble remembering things, worrying about sloppiness or carelessness, feeling blocked in getting things done, having to do things very slowly to ensure correctness, having to check and double-check what is done, having difficulty making decisions, having mind go blank, having trouble concentrating, and having to repeat the same actions (e.g., touching, counting, washing).

All unadjusted and adjusted results from the analysis of SCL-90-R obsessive-compulsive behavior were nonsignificant for Models 1, 2, and 3 (Table 12-12(a-f): $p > 0.08$ for each test).

A significant positive association was revealed between the prevalence of high SCL-90-R obsessive-compulsive behavior scores and 1987 dioxin levels in the Model 4 unadjusted analysis (Table 12-12(g): $p = 0.043$, Unadjusted RR=1.13), but after adjusting for covariates, the result became nonsignificant (Table 12-12(h): $p = 0.877$).

Note: Current total household income was not included in the model (see Section 12.1.4).

12.2.2.2.6 SCL-90-R Paranoid Ideation

The present dimension represents paranoid behavior fundamentally as a disordered mode of thinking. The cardinal characteristics of projective thought, hostility, suspiciousness, grandiosity, centrality, fear of loss of autonomy, and delusions are viewed as primary reflections of this disorder; item selection was oriented toward representing this conceptualization. The symptoms comprising the paranoid ideation dimension are feeling others are to blame for most of your troubles, feeling that most people cannot be trusted, feeling that you are watched or talked about by others, having ideas and beliefs that others do not share, not receiving proper credit from others for your achievements, and feeling that people will take advantage of you if you let them.

Significant differences between Ranch Hands and Comparisons were revealed in the Model 1 unadjusted analyses of SCL-90-R paranoid ideation across all occupations and within the enlisted groundcrew stratum (Table 12-13(a): $p=0.010$, Unadjusted RR=0.55; and $p=0.032$, Unadjusted RR=0.53, respectively). More Comparisons than Ranch Hands exhibited a high paranoid ideation score in both contrasts (Table 12-13(a): overall: 5.6% for Comparisons versus 3.1% for Ranch Hands; and enlisted groundcrew: 8.8% for Comparisons versus 4.8% for Ranch Hands). The same contrasts were significant in the adjusted analysis (Table 12-13(b): overall: $p=0.011$, Adjusted RR=0.53; and enlisted groundcrew: $p=0.033$, Adjusted RR=0.51). All other Model 1 contrasts were nonsignificant, as were all results from the Model 2 unadjusted and adjusted analysis (Table 12-13(a-d): $p>0.15$ for each nonsignificant result).

The Model 3 unadjusted analysis of SCL-90-R paranoid ideation revealed a significant contrast between Comparisons and Ranch Hands in the low dioxin category. More Comparisons (5.6%) than Ranch Hands in the low dioxin category (1.9%) had a high SCL-90-R paranoid ideation score (Table 12-13(e): $p=0.032$, Unadjusted RR=0.33). In the adjusted analysis of Model 3, this contrast was nonsignificant (Table 12-13(f): $p=0.052$). Another significant contrast was found in the unadjusted analysis between Ranch Hands in the low and high dioxin categories combined and Comparisons (Table 12-13(e): $p=0.047$, Unadjusted RR=0.52). More Comparisons (5.6%) than Ranch Hands (3.3%) had a high SCL-90-R paranoid ideation score. The contrast remained significant in the adjusted analysis (Table 12-13(f): $p=0.019$, Adjusted RR=0.45). All other Model 3 unadjusted and adjusted results were nonsignificant (Table 12-13(e,f): $p>0.05$ for each remaining contrast).

Results from both the unadjusted and adjusted analyses of SCL-90-R paranoid ideation in Model 4 were nonsignificant (Table 12-13(g,h): $p>0.59$ for each analysis).

^aRelative risk for a twofold increase in 1987 dioxin.

Note: Current total household income was not included in the model (see Section 12.1.4).

12.2.2.2.7 SCL-90-R Phobic Anxiety

Phobic anxiety is defined as a persistent fear response to a specific person, place, object, or situation that is characterized as being irrational and disproportionate to the stimulus and which leads to avoidance or escape behavior. The items of the present dimension focus on the more pathognomonic and disruptive manifestations of phobic behavior. The symptoms comprising the phobic anxiety dimension are feeling afraid in open spaces or on the street; feeling afraid to go out of the house alone; feeling afraid to travel on buses, subways, or trains; having to avoid certain things, places, or activities because they are frightening; feeling uneasy in crowds, such as while shopping or at a movie; feeling nervous when left alone; and feeling afraid of fainting in public.

All unadjusted and adjusted results from the analysis of SCL-90-R phobic anxiety for Models 1, 2, and 3 were nonsignificant (Table 12-14(a-f): $p > 0.07$ for each analysis). The Model 4 unadjusted result from the analysis of SCL-90-R phobic anxiety was nonsignificant (Table 12-14(g): $p = 0.891$). After adjusting for covariates, however, a significant inverse association between 1987 dioxin levels and a high SCL-90-R phobic anxiety score was found (Table 12-14(h): $p = 0.014$, Adjusted RR=0.80).

Table 12-14. Analysis of SCL-90-R Phobic Anxiety

(a) MODEL 1: RANCH HANDS VS. COMPARISONS – UNADJUSTED

Analysis Results for Log₂ (1987 Dioxin)		
n	Adjusted Relative Risk (95% C.I.)^a	p-Value
766	0.80 (0.66,0.96)	0.014*

^aRelative risk for a twofold increase in 1987 dioxin.

*: Statistically significant ($0.01 < p\text{-value} \leq 0.050$).

Note: Current total household income was not included in the model (see Section 12.1.4).

12.2.2.2.8 SCL-90-R Psychoticism

The psychoticism scale was developed in a fashion to represent the construct as a continuous dimension of human experience. Items indicative of a withdrawn, isolated, schizoid lifestyle were included, as were Schneiderian first-rank symptoms of schizophrenia, such as hallucinations and thought broadcasting. The symptoms comprising the psychoticism dimension are having the idea that someone else can control your thoughts, hearing voices that other people do not hear, believing that other people are aware of your private thoughts, having thoughts that are not your own, feeling lonely even when you are with people, having thoughts about sex that bother you a lot, believing that you should be punished for your sins, thinking that something serious is wrong with your body, never feeling close to another person, and thinking that something is wrong with your mind.

The unadjusted and adjusted analysis of SCL-90-R psychoticism displayed no significant results for Models 1 and 2 (Table 12-15(a-d): $p > 0.25$ for each analysis).

A significant difference in the prevalence of high SCL-90-R psychoticism scores was found between Ranch Hands in the low dioxin category (5.7%) and Comparisons (10.5%) for the Model 3 unadjusted analysis (Table 12-15(e): $p = 0.030$, Unadjusted RR=0.51). The difference was nonsignificant after adjusting for covariates (Table 12-15(f): $p = 0.055$). All other Model 3 unadjusted and adjusted results, as well as the Model 4 unadjusted and adjusted analysis results, were nonsignificant (Table 12-15(e-h): $p > 0.13$ for each remaining analysis).

Table 12-15. Analysis of SCL-90-R Psychoticism

Note: Current total household income was not included in the model (see Section 12.1.4).

12.2.2.2.9 SCL-90-R Somatization

The somatization dimension reflects distress arising from perceptions of bodily dysfunction. Complaints focusing on cardiovascular, gastrointestinal, respiratory, and other systems with strong autonomic mediation are included. Headaches, pain, and discomfort of the gross musculature and additional somatic equivalents of anxiety are components of the definition. These symptoms and signs have all been demonstrated to have high prevalence in disorders demonstrated to have a functional etiology, although all may be reflections of true physical disease. The symptoms comprising the somatization dimension are headaches, faintness or dizziness, pains in heart or chest, pains in lower back, nausea or upset stomach, soreness of muscles, trouble getting breath, hot or cold spells, numbness or tingling in parts of body, lump in throat, weakness in parts of body, and heavy feelings in arms or legs.

All unadjusted and adjusted results from the analysis of SCL-90-R somatization were nonsignificant for Models 1, 2, and 3 (Table 12-16(a-f): $p>0.05$ for each analysis).

The Model 4 unadjusted analysis of SCL-90-R somatization displayed a significant positive association between SCL-90-R somatization and 1987 dioxin levels (Table 12-16(g): $p=0.015$, Unadjusted RR=1.17). The adjusted analysis result was nonsignificant (Table 12-16(h): $p=0.862$).

Note: Current total household income was not included in the model (see Section 12.1.4).

12.2.2.2.10 SCL-90-R GSI

The GSI represents the best single indicator of the current level or depth of the disorder and should be used in most instances in which a single summary measure is required. The GSI combines information on numbers of symptoms and intensity of perceived distress.

No significant results were found from the analysis of SCL-90-R GSI from Models 1, 2, or 3 in either the unadjusted or adjusted analyses (Table 12-17(a-f): $p > 0.07$ for each analysis).

The Model 4 unadjusted analysis of SCL-90-R GSI displayed a positive significant association between 1987 dioxin levels and a prevalence of high GSI scores (Table 12-17(g): $p = 0.040$, Unadjusted RR=1.16). The association became nonsignificant after adjusting for covariates (Table 12-17(h): $p = 0.672$).

High RH	210	33 (15.7)	1.28 (0.84,1.93)	0.246
Low plus High RH	420	51 (12.1)	0.92 (0.65,1.31)	0.639

^aAdjusted for body mass index at the time of the blood measurement of dioxin.

^bRelative risk and confidence interval relative to Comparisons.

Note: RH = Ranch Hand.

Background (Ranch Hand): 1987 dioxin ≤ 10 ppt.

Low (Ranch Hand): 1987 dioxin > 10 ppt, 10 ppt < initial dioxin ≤ 118 ppt.

High (Ranch Hand): 1987 dioxin > 10 ppt, initial dioxin > 118 ppt.

(f) MODEL 3: RANCH HANDS VS. COMPARISONS BY DIOXIN CATEGORY – ADJUSTED			
Dioxin Category	n	Adjusted Relative Risk (95% C.I.)^a	p-Value
Comparison	1,135		
Background RH	342	0.81 (0.52,1.27)	0.353
Low RH	201	0.65 (0.37,1.13)	0.123
High RH	205	0.90 (0.58,1.40)	0.639
Low plus High RH	406	0.76 (0.52,1.11)	0.160

^aRelative risk and confidence interval relative to Comparisons.

Note: RH = Ranch Hand.

Background (Ranch Hand): 1987 dioxin ≤ 10 ppt.

Low (Ranch Hand): 1987 dioxin > 10 ppt, 10 ppt < initial dioxin ≤ 118 ppt.

High (Ranch Hand): 1987 dioxin > 10 ppt, initial dioxin > 118 ppt.

(g) MODEL 4: RANCH HANDS – 1987 DIOXIN – UNADJUSTED				
1987 Dioxin Category Summary Statistics			Analysis Results for Log₂ (1987 Dioxin)	
1987 Dioxin	n	Number (%) Abnormal	Unadjusted Relative Risk (95% C.I.)^a	p-Value
Low	259	19 (7.3)	1.16 (1.01,1.34)	0.040*
Medium	258	24 (9.3)		
High	254	37 (14.6)		

^aRelative risk for a twofold increase in 1987 dioxin.

*: Statistically significant (0.01 < p-value ≤ 0.050).

Note: Low = ≤ 7.8 ppt; Medium = > 7.8–19.2 ppt; High = > 19.2 ppt.

Table 12-17. Analysis of SCL-90-R GSI (Continued)

(h) MODEL 4: RANCH HANDS – 1987 DIOXIN – ADJUSTED		
Analysis Results for Log₂ (1987 Dioxin)		
n	Adjusted Relative Risk (95% C.I.)^a	p-Value
766	0.97 (0.83,1.13)	0.672

^aRelative risk for a twofold increase in 1987 dioxin.

Note: Current total household income was not included in the model (see Section 12.1.4).

12.2.2.2.11 SCL-90-R PST

The PST is simply a count of the number of symptoms the participant reports as experiencing to any degree. When used configurally in conjunction with the GSI, information on style of response and numbers of symptoms endorsed can be helpful in appreciating the clinical picture.

Both the unadjusted and adjusted Model 1 analyses of SCL-90-R PST revealed a significant inverse association between Ranch Hands and Comparisons when examined across all occupational strata (Table 12-18(a,b): $p=0.042$, Unadjusted RR=0.74; and $p=0.033$, Adjusted RR=0.72, respectively). More Comparisons (12.6%) than Ranch Hands (9.6%) exhibited a high PST score. All other Model 1 unadjusted and adjusted contrasts, as well as each of the unadjusted and adjusted Model 2 analyses, were nonsignificant (Table 12-18(a-d): $p>0.11$ for analysis).

The Model 3 unadjusted analysis of SCL-90-R PST displayed a significant difference between Ranch Hands in the low dioxin category (8.5%) and Comparisons (12.6%) with a high PST score (Table 12-18(e): $p=0.014$, Unadjusted RR=0.49). The result remained significant in the adjusted analysis (Table 12-18(f): $p=0.019$, Adjusted RR=0.49). The adjusted analysis also found a significant difference between Ranch Hands in the low and high dioxin categories combined and Comparisons (Table 12-18(f): $p=0.025$, Adjusted RR=0.64). Similarly, more Comparisons than Ranch Hands displayed a high PST score in this contrast. All other Model 3 unadjusted and adjusted contrasts and each result from the Model 4 unadjusted and adjusted analysis were nonsignificant (Table 12-18(e-h): $p>0.07$ for each remaining analysis).

Table 12-18. Analysis of SCL-90-R PST

(a) MODEL 1: RANCH HANDS VS. COMPARISONS – UNADJUSTED					
Occupational Category	Group	n	Number (%) Abnormal	Unadjusted Relative Risk (95% C.I.)	p-Value

Note: Current total household income was not included in the model (see Section 12.1.4).

12.2.2.2.12 SCL-90-R PSDI

The PSDI is a pure intensity measure, in a sense, “corrected” for numbers of symptoms. It functions primarily as a measure of response style in the sense of communicating whether the patient is “augmenting” or “attenuating” symptomatic distress in his style of reporting his disorder.

More Comparisons (15.1%) than Ranch Hands (7.5%) had a high SCL-90-R PSDI score within the enlisted flyer stratum in the Model 1 unadjusted and adjusted analysis (Table 12-19 (a,b): $p=0.043$, Unadjusted RR=0.46; and $p=0.036$, Adjusted RR=0.43, respectively). All other Model 1 unadjusted and adjusted contrasts were nonsignificant (Table 12-19(a,b): $p\geq 0.34$ for each contrast). Results from each Model 2 and 3 unadjusted and adjusted analysis were also nonsignificant (Table 12-19(c-f): $p>0.09$ for each analysis).

A significant positive relation between 1987 dioxin levels and prevalence of high PSDI scores was found from the unadjusted Model 4 analysis (Table 12-19(g): $p=0.016$, Adjusted RR=1.23). The relation became nonsignificant after adjusting for covariates (Table 12-19(h): $p=0.497$).

Table 12-19. Analysis of SCL-90-R PSDI

(a) MODEL 1: RANCH HANDS VS. COMPARISONS – UNADJUSTED					
Occupational Category	Group	n	Number (%) Abnormal	Unadjusted Relative Risk (95% C.I.)	p-Value

12.2.2.2.13 WMS-R Verbal Paired Associates

All results from the analysis of WMS-R Verbal Paired Associates test for Model 1 through Model 3 were nonsignificant, both unadjusted and adjusted for covariates (Table 12-20(a-f): p>0.15 for each analysis).

The unadjusted Model 4 analysis of WMS-R Verbal Paired Associates test revealed an inverse significant association between 1987 dioxin levels and WMS-R Verbal Paired Associates scores (Table 12-20(g): p=0.020, Slope=-0.168). As 1987 dioxin increased, the scores on the Verbal Paired Associates test decreased. In the adjusted analysis, the relation became nonsignificant after adjusting for covariates (Table 12-20(h): p=0.458).

Table 12-20. Analysis of WMS-R Verbal Paired Associates

1987 Dioxin Category Summary Statistics			Analysis Results for Log ₂ (1987 Dioxin)		
1987 Dioxin	n	Adjusted Mean	R ²	Adjusted Slope (Standard Error)	p-Value
Low	259	10.71	0.073	-0.060 (0.081)	0.458
Medium	257	10.64			
High	251	10.62			

Note: Low = ≤7.8 ppt; Medium = >7.8–19.2 ppt; High = >19.2 ppt.

Current total household income was not included in the model (see Section 12.1.4).

12.2.2.2.14 WMS-R Logical Memory, Immediate Recall

No significant results were found within the unadjusted or adjusted analyses of the immediate recall for the WMS-R Logical Memory test for Models 1, 2, or 3 (Table 12-21(a-f): $p \geq 0.06$ for each analysis). A significant inverse relation between 1987 dioxin levels and the immediate recall scores for the Logical Memory test was found from the Model 4 unadjusted analysis (Table 12-21(g): $p=0.001$, Slope=-0.237). As 1987 dioxin increased, the scores on this test decreased. After adjusting for covariates, however, the result became nonsignificant (Table 12-21(h): $p=0.541$).

Table 12-21. Analysis of WMS-R Logical Memory, Immediate Recall

(a) MODEL 1: RANCH HANDS VS. COMPARISONS – UNADJUSTED					
Occupational Category	Group	n	Unadjusted Mean	Difference of Unadjusted Means (95% C.I.)	p-Value
<i>All</i>	<i>Ranch Hand</i>	773	11.70	0.12 (-0.18,0.42)	0.431

^aAdjusted for body mass index at the time of the blood measurement of dioxin.

Note: RH = Ranch Hand.

Background (Ranch Hand): 1987 dioxin ≤ 10 ppt.

Low (Ranch Hand): 1987 dioxin > 10 ppt, 10 ppt < initial dioxin ≤ 118 ppt.

High (Ranch Hand): 1987 dioxin > 10 ppt, initial dioxin > 118 ppt.

(f) MODEL 3: RANCH HANDS VS. COMPARISONS BY DIOXIN CATEGORY – ADJUSTED				
Dioxin Category	n	Adjusted Mean	Difference of Adjusted Mean vs. Comparisons (95% C.I.)	p-Value
Comparison	1,164	11.33		
Background RH	350	11.39	0.06 (-0.33,0.44)	0.776
Low RH	210	11.67	0.33 (-0.13,0.79)	0.158
High RH	207	11.38	0.05 (-0.43,0.53)	0.844
Low plus High RH	417	11.52	0.19 (-0.16,0.55)	0.291

Note: RH = Ranch Hand.

Background (Ranch Hand): 1987 dioxin ≤ 10 ppt.

Low (Ranch Hand): 1987 dioxin > 10 ppt, 10 ppt < initial dioxin ≤ 118 ppt.

High (Ranch Hand): 1987 dioxin > 10 ppt, initial dioxin > 118 ppt.

Current total household income was not included in the model (see Section 12.1.4).

Table 12-21. Analysis of WMS-R Logical Memory, Immediate Recall (Continued)

(g) MODEL 4: RANCH HANDS – 1987 DIOXIN – UNADJUSTED					
1987 Dioxin Category Summary Statistics			Analysis Results for Log ₂ (1987 Dioxin)		
1987 Dioxin	n	Unadjusted Mean	R ²	Slope (Standard Error)	p-Value
Low	259	12.15	0.013	-0.237 (0.073)	0.001**
Medium	258	11.88			
High	255	11.08			

Note: Low = ≤7.8 ppt; Medium = >7.8-19.2 ppt; High = >19.2 ppt.

** : Statistically significant (p-value≤0.010).

(h) MODEL 4: RANCH HANDS – 1987 DIOXIN – ADJUSTED					
1987 Dioxin Category Summary Statistics			Analysis Results for Log ₂ (1987 Dioxin)		
1987 Dioxin	n	Adjusted Mean	R ²	Adjusted Slope (Standard Error)	p-Value
Low	259	11.31	0.093	-0.050 (0.082)	0.541
Medium	257	11.39			
High	251	10.96			

Note: Low = ≤7.8 ppt; Medium = >7.8–19.2 ppt; High = >19.2 ppt.

Current total household income was not included in the model (see Section 12.1.4).

12.2.2.2.15 WMS-R Logical Memory, Delayed Recall

The Model 1 unadjusted and adjusted analyses of the delayed recall portion of the WMS-R Logical Memory test revealed a significant difference in means between Ranch Hands and Comparisons within the enlisted groundcrew stratum (Table 12-22(a,b): p=0.021, difference of means=0.57; and p=0.039, difference of means =0.50, respectively). Mean scores were higher for Ranch Hands than for Comparisons. All other Model 1 unadjusted and adjusted contrasts and each Model 2 unadjusted and adjusted analysis were nonsignificant (Table 12-22(a-d): p>0.18 for each contrast).

A significant difference in means was found from the unadjusted analysis of the delayed recall portion of the WMS-R Logical Memory test from Model 3, contrasting Ranch Hands in the background dioxin category with Comparisons (Table 12-22(e): p=0.027, difference of means=0.49). The difference was nonsignificant after adjusting for covariates (Table 12-22(f): p=0.612). All other Model 3 unadjusted and adjusted results were nonsignificant (Table 12-22(e,f): p>0.12 for each result).

The Model 4 unadjusted analysis of the delayed recall portion of the WMS-R Logical Memory test revealed an inverse significant relation between 1987 dioxin levels and logical memory, delayed recall scores (Table 12-22(g): p=0.004, Slope=-0.237). As 1987 dioxin increased, the scores on this test decreased. The relation was nonsignificant after adjusting for covariates (Table 12-22(h): p=0.762).

Table 12-22. Analysis of WMS-R Logical Memory, Delayed Recall

(a) MODEL 1: RANCH HANDS VS. COMPARISONS – UNADJUSTED

12.3 DISCUSSION

The AFHS assessed cognitive and psychopathological functioning using the Verbal Paired Associates, Logical Memory, and the Visual Reproduction tests from the WMS-R and 12 SCL-90-R subscales. Both the WMS-R and the SCL-90-R have been found valid and reliable for these purposes. In prior years of the AFHS, cognitive functioning had been assessed using other tests, such as the HRB, the WAIS-Revised, and the WMS. Psychopathology had been studied in previous follow-up examinations with other measures, such as the MMPI, the CMI, and the MCMI. For the 2002 AFHS, the WMS-R was chosen in large part due to prior findings that used the WMS and found small decreases in memory skills

among the Ranch Hand veterans (40). The SCL-90-R was selected in part because of ease and brevity of administration.

Memory, in basic terms, involves the perception and encoding of information, followed by the retrieval of this stored information. One way of measuring memory functioning is to present material to a participant and then record the accuracy with which he is able to repeat the information. The time between the initial presentation and the recall can vary. A time gap of less than a minute is considered immediate recall, while a 30-minute time gap is considered delayed recall. Both immediate and delayed recall are considered short-term memory. This is in contrast to long-term memory, in which the time gap would be in terms of days, weeks, months or years. When memory impairment occurs, it is typically more evident in short-term memory rather than long-term memory. Memory can be adversely impacted by a variety of influences, such as emotional state, physical injury, or chemical exposure. One of the purposes of the AFHS was to evaluate whether exposure to herbicides led to decreased short-term memory skills.

Psychopathology is a more complex concept than memory because it often involves the interplay of such things as deep-rooted personality traits, coping skills, chronic and situational stressors, and biochemical changes. A person's reported symptoms are clustered into categories that are labeled as psychopathological states (e.g., depression, anxiety, and paranoia). The 2002 AFHS evaluated the possible influence of exposure to herbicides based on the presence of these psychopathological states in the study participants.

The results from investigating the associations of the memory assessment with covariates were generally in line with expectations. Memory skills decrease as a person ages. Scores on memory tests are higher for college-educated, wealthier, employed officers than for high-school educated, less wealthy, not employed, enlisted men. Memory has a moderate correlation to intelligence (55) and intelligence is correlated with success in education and employment.

The SCL-90-R results showed a similar trend to the results from the WMS-R, with lower income, less educated, not employed, enlisted men reporting more overall psychopathology, evidenced by higher scores on the anxiety, depression, hostility, interpersonal sensitivity, obsessive-compulsive, paranoid ideation, phobic anxiety, psychoticism, and somatization scales.

Test results indicate there were no adverse effects for the Ranch Hand group as compared to the Comparisons. In fact, the Ranch Hand group displayed fewer symptoms of psychological distress with a smaller prevalence of abnormally high scores on the interpersonal sensitivity, paranoid ideation, and phobic anxiety scales. None of the memory functioning and psychopathology scales were adversely associated with exposure to herbicides or dioxin.

12.4 SUMMARY

The psychology assessment was based on questionnaire data, which was subsequently verified by a review of medical records, and data from the SCL-90-R and the WMS-R. Associations with herbicide exposure (i.e., group – Model 1), initial dioxin (Model 2), categorized dioxin (Model 3), and 1987 dioxin levels (Model 4) were examined for each variable in the psychology assessment. The significant adjusted results are discussed in the sections below.

12.4.1 Model 1: Group Analysis

Model 1 analyses examined differences between Ranch Hands and Comparisons across all occupations and within each occupational stratum. Each significant result in the adjusted analysis revealed more Comparisons than Ranch Hands with either a history of other neuroses or with a high score on an SCL-90-R scale. More Comparisons than Ranch Hands had high scores on the SCL-90-R interpersonal sensitivity, paranoid ideation, and PST scales. More Comparison officers than Ranch Hand officers had a history of other neuroses and had high scores on the SCL-90-R interpersonal sensitivity scale. More Comparison enlisted flyers than Ranch Hand enlisted flyers had high scores on the SCL-90-R PSDI. More Comparison enlisted groundcrew than Ranch Hand enlisted groundcrew had high scores on the SCL-90-R paranoid ideation scale. Comparison enlisted groundcrew had a lower mean score on the delayed recall of the Logical Memory test of the WMS-R than Ranch Hand enlisted groundcrew. Table 12-25 displays the results of the group analysis.

A capital "NS" denotes a nonsignificant positive association. A lowercase "ns" denotes a nonsignificant inverse association.

12.4.2 Model 2: Initial Dioxin Analysis

No significant relations were found between initial dioxin and any of the psychological or memory endpoints examined in this chapter. Table 12-26 shows the results of the initial dioxin analysis.

Table 12-26. Summary of Initial Dioxin Analysis (Model 2) for Psychology Variables (Ranch Hands Only)

D: Discrete form of dependent variable.

A capital "NS" denotes a nonsignificant positive association. A lowercase "ns" denotes a nonsignificant inverse association.

12.4.3 Model 3: Categorized Dioxin Analysis

All significant results for the contrasts of Ranch Hand dioxin categories and Comparisons revealed that Comparisons had a greater prevalence of abnormally high scores on the SCL-90-R subscales. For the SCL-90-R interpersonal sensitivity and PST scales, Comparisons had a significantly greater prevalence of abnormally high scores than Ranch Hands in the low dioxin category and in the low and high dioxin categories combined. For the SCL-90-R paranoid ideation scale, Comparisons had a significantly greater prevalence of abnormally high scores than Ranch Hands in the low and high dioxin categories combined. Table 12-27 presents the results of the categorized dioxin analysis.

A capital "NS" denotes a nonsignificant positive association. A lowercase "ns" denotes a nonsignificant inverse association.

12.4.4 Model 4: 1987 Dioxin Level Analysis

The only significant relation between 1987 dioxin and any of the psychological or memory endpoints studied occurred with the SCL-90-R phobic anxiety scale. The relation was inverse, however. As 1987 dioxin levels increased, the prevalence of high phobic anxiety scores in Ranch Hands decreased. Table 12-28 displays the results of the 1987 dioxin analysis.

^aA negative slope was considered adverse for this variable.

Note: NS or ns: Not significant (p>0.05).

C: Continuous form of dependent variable.

D: Discrete form of dependent variable.

The p-value was given if p≤0.05. The relative risk was given in parentheses for a significant result from the analysis of a discrete dependent variable. The slope was given in parentheses for a significant result from the analysis of a continuous dependent variable.

A capital “NS” denotes a nonsignificant positive association. A lowercase “ns” denotes a nonsignificant inverse association.

12.4.5 Summary of Significant Results

Table 12-29 summarizes the significant results ($p \leq 0.05$) for the adjusted analyses that were performed for the psychology assessment. The dependent variable and its table reference are listed along with the model and the contrast or description of the model. The p-value is provided along with analysis statistics that correspond to the type of analysis that was performed (either continuous or discrete). A description of the analysis and the statistics that are presented is referenced under the “Note” column and is explained in footnotes.

(a): Discrete variable: adjusted relative risk and 95% confidence interval were presented; percent abnormal was presented for each exposure group in contrast.

(b): Discrete variable: adjusted relative risk and 95% confidence interval were presented; percent abnormal was presented for each dioxin category in contrast.

(c): Discrete variable: adjusted relative risk and 95% confidence interval were presented for a twofold increase in initial dioxin; percent abnormal was presented for each of three 1987 dioxin categories.

(d): Continuous variable: difference of adjusted means and 95% confidence interval was presented; adjusted means were presented for each exposure group in contrast.

Table 12-29. Summary of Results from Significant Adjusted Analyses in the Psychology Assessment (Continued)

^aA positive difference in means (Comparison mean less than Ranch Hand mean) was considered adverse to Comparisons for this variable.

Note: RH = Ranch Hand.
C = Comparison.

Model 3: Background (Ranch Hand): 1987 dioxin \leq 10 ppt.
Low (Ranch Hand): 1987 dioxin $>$ 10 ppt, 10 ppt $<$ initial dioxin \leq 118 ppt.
High (Ranch Hand): 1987 dioxin $>$ 10 ppt, initial dioxin $>$ 118 ppt.

Model 4: Low = \leq 7.8 ppt; Medium = $>$ 7.8–19.2 ppt; High = $>$ 19.2 ppt (Ranch Hands only).

12.5 CONCLUSION

Five psychological disorders, which were verified by a medical records review, 12 measures from the SCL-90-R inventory, and 5 tests from the WMS-R, were examined in the psychology assessment. The SCL-90-R consisted of nine primary symptom dimensions and three broad indices of psychological distress.

More Comparisons than Ranch Hands had high scores on the SCL-90-R interpersonal sensitivity, paranoid ideation, and PST scales. Significant results within the three occupational stratum showed that more Comparisons than Ranch Hands had a history of other neuroses and high scores on the SCL-90-R interpersonal sensitivity, PSDI, and paranoid ideation scale. Comparison enlisted groundcrew had a lower mean score on the delayed recall portion of the WMS-R Logical Memory test than Ranch Hand enlisted groundcrew.

No significant relations were found between initial dioxin and any of the psychological or memory endpoints examined in this chapter. A significant inverse relation between 1987 dioxin and the SCL-90-R phobic anxiety scale was found.

Ranch Hands had a smaller percentage of abnormally high scores on the SCL-90-R interpersonal sensitivity, paranoid ideation, and PST scales. Ranch Hand enlisted groundcrew had an increased mean score on the delayed recall portion of the WMS-R Logical Memory test. The percentage of abnormally high scores on the SCL-90-R phobic anxiety scale score decreased with increased 1987 dioxin levels. None of the memory functioning and psychopathology scales were adversely associated with exposure to herbicides or dioxin.

13 GASTROINTESTINAL ASSESSMENT

13.1 INTRODUCTION

13.1.1 Background

13.1.1.1 Organs/Diseases

The following seven categories, based on self-reporting by participants, were evaluated as part of the gastrointestinal assessment in the Air Force Health Study (AFHS): uncharacterized hepatitis, jaundice, alcohol-related chronic liver disease and cirrhosis, chronic liver disease and cirrhosis not related to alcohol, liver abscess and sequelae of chronic liver disease, enlarged liver (hepatomegaly), and other disorders of the liver. The self-reported data were verified by a medical records review. Current hepatomegaly was determined at the 2002 physical examination. The AFHS gastrointestinal assessment also included an evaluation of laboratory data of 28 measurements, which included the following: aspartate aminotransferase (AST), alanine aminotransferase (ALT), gamma glutamyltransferase (GGT), alkaline phosphatase, total bilirubin, direct bilirubin, lactate dehydrogenase (LDH), cholesterol, high-density lipoprotein (HDL) cholesterol, the ratio of cholesterol to HDL cholesterol, triglycerides, creatine phosphokinase, serum amylase, antibodies for hepatitis A, serological evidence of prior hepatitis B infection, antibodies for hepatitis C, stool hemoccult, prothrombin time, and 10 components in a protein profile.

Several factors have been studied that can affect lipid levels or are associated with liver disease, including diet, genetic makeup, acute or chronic illness, diabetes, and obesity. Important determinants of liver disease include excessive alcohol ingestion and chronic viral infection, while peptic ulcer disease is associated with bacterial infection and genetic predisposition (1). The occurrence of ulcers had been investigated for the analyses of the 1985 and 1987 AFHS follow-up examinations. The results were nonsignificant in these analyses, however, and analysis of ulcers was not performed for the 1992, 1997, or 2002 follow-up examination reports.

13.1.1.2 Toxicology

The digestive system, particularly the liver (2-8) and stomach (3, 9-13), were clearly defined as target organs for dioxin toxicity in laboratory animals. Dioxin ingested by rodents (14-19) and adult monkeys (20) is absorbed by the intestinal lymphatics, transported by chylomicrons in the enterohepatic circulation, and preferentially stored in adipose tissue and the liver. Hepatotoxic manifestations, which appear to be dose- and time-dependent, include cellular hypertrophy, parenchymal necrosis (principally centrilobular), fatty degeneration, and the production of altered hepatic foci, a microscopic precursor in hepatic carcinogenesis (7, 21-23). Gastric endpoints were the subject of several reports focused on histologic changes (3, 11, 12, 24) and endocrine secretory abnormalities (e.g., hypergastrinemia and hypothyroxinemia) (9, 10, 25) associated with dioxin toxicity.

Many hepatic biochemical reactions related to dioxin toxicity were studied in rats, including lipid peroxidation (26-34), hepatic prostaglandin synthase activity (35, 36), liver ethoxyresorufin O-deethylase activity (37), and inhibition of glutathione peroxidase (27, 38, 39). Results from several lines of biochemical investigation created a bridge between animal and human studies, including research into lipid (30, 40, 41) and porphyrin metabolism (42-44). In rats, dioxin has been shown to increase the

activity of glucuronyl transferase (45), an observation that led to the use of urinary d-glucaric acid as a marker for dioxin exposure in several human epidemiologic studies (46-50). Direct effects of dioxin on gastrointestinal organs other than the liver have not been observed, and human data are lacking to evaluate whether and how subjects exposed to dioxin have a modified lipoprotein metabolism (1).

In two case reports of extreme phenoxyherbicide toxicity by ingestion in three workers, effects included coma, rhabdomyolysis, and renal failure rather than effect on the digestive system (51, 52). Recently, a case study of two workers with severe dioxin intoxication found moderately elevated levels of blood lipids (triglycerides and cholesterol) in one worker and normal levels in the other relative to those generally seen in unexposed persons (53).

13.1.1.3 Epidemiology: Blood Chemistry Levels

Studies of exposure to dioxin resulting from industrial accidents or point-source contamination in the environment generally found little evidence for an effect of dioxin exposure on blood chemistry levels. The 1976 chemical explosion in Seveso, Italy, resulted in several reports on the exposed residents (54-57). In one study, 152 subjects with chloracne, a marker for high-level dioxin exposure, were compared with 123 age- and gender-matched controls from nearby towns. None of the serum biochemistry indices, such as GGT, triglycerides, and cholesterol, showed substantial differences between exposed and unexposed subjects (54). Other studies of the Seveso population reached similar conclusions (48, 49, 55, 56, 58, 59).

The relation between point-source environmental exposure to dioxin and levels of lipids and liver enzymes has been the focus of a limited number of epidemiologic studies. In 1971, waste byproducts contaminated with dioxin were mixed with oils and widely sprayed for dust control in residential areas in eastern Missouri. Two studies were conducted: one at Quail Run, Missouri, in 1984-85 (47) and the other at Times Beach, Missouri, in 1983 (60). No effects of dioxin exposure on lipid levels were seen among 154 exposed and 155 unexposed persons at Quail Run (47); however, a positive association of unknown clinical relevance was observed between liver enzyme levels (AST, ALT, GGT, alkaline phosphatase, and alanine aminopeptidase) and years of exposure in this population (47). No indication for hepatic enzyme elevations or increased lipid levels in association with adipose dioxin levels in the Times Beach population was found (60, 61).

Although numerous occupational studies reported on lipid levels and liver enzymes associated with dioxin exposure (46, 51-53, 62-73), these studies did not all use the same clinical measures or report similar outcomes. Elevated levels of GGT and triglycerides were observed among workers with chloracne relative to those without chloracne in a study population of 226 employees exposed to dioxin during the manufacturing of trichlorophenol (64). Another follow-up study of 55 dioxin-exposed workers in the same industry reported that more than half the workers suffered from hyperlipemia and hypercholesterolemia and 20 percent of the subjects were found to have hepatic lesions (66).

The epidemiologic study conducted by the National Institute of Occupational Safety and Health (NIOSH) is one of several occupational studies relating serum dioxin levels to serum lipid and liver enzyme concentrations (46, 63). No association between dioxin exposure and out-of-normal-range liver enzyme concentrations other than GGT was found. This relation with GGT, however, was limited to exposed workers with a history of substantial alcohol consumption and did not appear to be directly related to the body burden of dioxin (46). In contrast, some indication for a positive association between serum dioxin levels and concentrations of triglyceride and HDL was found (63).

Various blood chemistry measures were associated with dioxin exposure in other occupational studies. Elevated levels of the liver enzyme GGT provide some evidence for the hepatic effects of dioxin exposure during the manufacturing of the herbicide 2,4,5-T, as found in a study of 159 cases of chloracne relative to worker controls (65). Hyperlipidemia was associated with serum dioxin levels among 96 Japanese workers exposed to dioxins in emission gases from municipal waste incinerators (74). A small study of 13 workers involved in herbicide production in the Czech Republic revealed positive correlations between serum dioxin levels and concentrations of cholesterol, triglycerides, and plasma lipids and beta-lipoproteins (67, 71).

Recently, a study of 133 municipal waste incinerator workers found cholesterol levels to be elevated in workers with high blood dioxin levels as compared to workers with low exposure (72). Some indication of elevated liver enzyme concentrations (AST, ALT, total bilirubin, and triglycerides) and the risk of fatty liver existed, but results were not statistically significant (72). A recent study of 96 Japanese municipal incinerator workers chronically exposed to dioxins, however, did not find a correlation between blood dioxin levels and blood chemistry parameters (73). Other occupational studies also found little evidence for an association between levels of hepatic enzymes and serum dioxin (68-70, 75).

Several reports of Vietnam veterans focused on the potential association of hepatic dysfunction with dioxin exposure (76-81). In one retrospective cohort study of 100 Vietnam veterans, job classification, self-reported herbicide use, and duration of exposure were used as surrogates for exposure to Agent Orange. Liver abnormalities in the form of elevated ALT, AST, or alkaline phosphatase levels were shown to be related only to the duration of exposure, which was attributed to alcoholism and viral hepatitis rather than Agent Orange exposure (79). In the 1987 follow-up examination of Ranch Hand personnel in the AFHS, the risk of an abnormal level of triglycerides was slightly elevated among 995 Ranch Hands relative to 1,299 Comparison subjects (78). More recently, serum dioxin levels measured in 1987 and 1992 were compared with indicators of gastrointestinal abnormalities among Ranch Hands with follow-up examinations in 1982, 1985, 1987, and 1992. Based on liver function test results obtained in 1992, levels of ALT and GGT were positively associated with serum dioxin levels in a dose-response fashion. Similar results were reported for the 1997 follow-up examination (81); however, the plausibility of these associations has been questioned (77).

In a 1994 report published by the Institute of Medicine (IOM), the committee concluded that there is “inadequate or insufficient” evidence of an association between exposure to dioxin and changes in hepatic enzymes or lipid abnormalities (82). This conclusion remained unaltered in the 2002 IOM report (1).

13.1.1.4 Epidemiology: Gastrointestinal Diseases

The Seveso studies found little indication of an increased risk of digestive diseases. A recent follow-up study of the Seveso population, comprising approximately 6,700 residents with high exposure and more than 200,000 unexposed controls, found little evidence for an increased risk of mortality from nonmalignant digestive diseases (57, 83).

A number of occupational cohort studies were conducted to evaluate the mortality and morbidity experience among workers exposed to dioxin (46, 70, 84-89). In the NIOSH study (46), no increased risk of hepatic and gastrointestinal disease was found among 281 exposed workers as compared to 260 unexposed controls. In addition, no evidence of an increased mortality risk of nonmalignant digestive system diseases was found among 549 Dutch workers (84) and 21,863 other European workers in 12 countries exposed to dioxin in the production of phenoxy herbicides (86, 89). Although a substantially increased risk of mortality from gastric and duodenal ulcer was reported in a cohort of 770 workers with potential pentachlorophenol exposure, the number of observed cases was too small to establish an

association with dioxin exposure (88). In a cohort of 243 workers exposed to dioxin after a chemical accident at the trichlorophenol unit of a BASF chemical facility, little evidence for a positive association between lipid dioxin levels and mortality from digestive system diseases was found (87). In an earlier morbidity study of the same cohort, the rates of illness episodes of gastrointestinal diseases were similar between dioxin-exposed workers and unexposed referents; however, the rate of chronic liver disease was slightly increased among those with high dioxin exposure (70).

The evidence for an association between serum dioxin levels and gastrointestinal disease among Ranch Hand personnel in the AFHS was reported (76-78, 80, 81). In the 1987 follow-up examination, some indication of an increased risk was found for “not alcohol-related chronic liver disease and cirrhosis” and “other liver conditions” among Ranch Hands as compared to the control population (78). Among 1,261 Ranch Hands followed through 1993, an increased risk of digestive disease mortality (n=9) was found compared to the mortality experience of veterans who were not involved in spraying herbicides in Vietnam (76). These analyses were not adjusted for alcohol consumption. Recently, an increased risk of “other liver disorders” was observed among Ranch Hand veterans with the highest dioxin levels, but the interpretation was uncertain (77, 81). Some indication of an increased risk of mortality from digestive system diseases was found in other studies of Vietnam veterans, but indicators of dioxin exposure were not evaluated (90, 91).

In their reports, the IOM committees concluded that there is “inadequate or insufficient” evidence for an association between exposure to dioxin and gastrointestinal and digestive diseases (1, 82, 92-94).

13.1.2 Summary of Previous Analyses of the Air Force Health Study

13.1.2.1 1982 Baseline Examination Summary Results

The 1982 AFHS examination included an extensive evaluation of hepatic status by questionnaire, physical examination, and laboratory testing. The questionnaire elicited data on liver conditions, liver disease, and symptoms compatible with porphyria cutanea tarda (PCT), as well as detailed information on PCT risk factors (e.g., alcohol consumption, chemical exposures). The physical examination measured hepatomegaly, or enlarged liver, when present and determined liver function and porphyrin patterns using a comprehensive battery of 12 laboratory tests.

The questionnaire showed that Ranch Hands reported more miscellaneous liver conditions (verified by a medical records review) and more skin changes compatible with PCT than their Comparisons. Although the reported skin changes were statistically significant, no cases of PCT were diagnosed at examination in either cohort.

Ranch Hands had significantly higher GGT and LDH means and lower cholesterol means; no differences were found for bilirubin or alkaline phosphatase means. There were no significant group differences in uroporphyrin, coproporphyrin, or d-aminolevulinic acid levels, nor did any test set support a diagnosis of PCT.

A comprehensive hepatic evaluation did not reveal any consistent pattern of significant liver damage in the Ranch Hand group.

13.1.2.2 1985 Follow-up Examination Summary Results

The 1985 AFHS examination continued the emphasis on gastrointestinal function and expanded the porphyrin test battery to six assays. The interval questionnaire revealed sparse reporting of liver disorders

from 1982 to 1985. Reported liver diseases were verified by medical records, and these data were added to the verified baseline history to assess possible lifetime differences. No significant differences were found.

Emphasis was placed on nine laboratory test variables measuring liver functions: AST, ALT, GGT, alkaline phosphatase, total bilirubin, direct bilirubin, LDH, cholesterol, and triglycerides. In addition, uroporphyrin and coproporphyrin measurements were obtained to assess the likelihood of PCT.

The results showed a significantly lower mean ALT level, a greater mean alkaline phosphatase level, and a lower mean uroporphyrin level.

Overall, the 1985 follow-up examination laboratory data showed no adverse clinical or exposure patterns. The continuous statistical tests detected significant mean shifts that were not mirrored by the discrete tests. These findings were generally consistent with the 1982 baseline examination data.

Interval reporting of PCT-like symptoms of skin patches, bruises, and sensitivity was significantly increased in Ranch Hands. When these historic data were contrasted to both uroporphyrin and coproporphyrin abnormalities, no correlation was apparent, nor were there any significant group differences. The likelihood of actual PCT among Ranch Hands appeared to be remote.

13.1.2.3 1987 Follow-up Examination Summary Results

Overall, the gastrointestinal assessment did not find the health of the Ranch Hand group to be significantly different from that of the Comparison group. Group differences based on verified historical data from the questionnaire were not significant for eight categories of liver disease. No significant group difference was found for past or present occurrence of peptic ulcers. The prevalence of hepatomegaly diagnosed at the physical examination also was not significantly different between the two groups. The only significant finding from the laboratory examination variables was that Ranch Hands had a higher mean alkaline phosphatase than Comparisons, also noted at the 1985 follow-up examination. Group differences for the other laboratory variables (AST, ALT, GGT, total bilirubin, direct bilirubin, LDH, cholesterol, HDL, cholesterol-HDL ratio, triglycerides, and creatine phosphokinase) were not significant.

13.1.2.4 Serum Dioxin Analysis of 1987 Follow-up Examination Results

The serum dioxin analysis of the 1987 follow-up examination results did not show a significant association with any of the verified historical liver disorder variables. The analyses of the laboratory variables detected significant associations between dioxin (1987 and estimated initial) and lipid-related health indices such as cholesterol, HDL cholesterol, the cholesterol-HDL ratio, and triglycerides. These findings were consistent with significant associations seen for fat-related variables in other clinical assessments, such as the body fat results in the general health assessment and the diabetes and glucose results noted in the endocrinology assessment, and may represent a dioxin-mediated alteration of biochemical processes.

13.1.2.5 1992 Follow-up Examination Summary Results

The gastrointestinal assessment found isolated significant differences between Ranch Hands and Comparisons, but overall, the health of the two groups did not differ substantially. The serum dioxin analyses indicated that estimated initial dioxin generally was not associated with historical liver disorders or current laboratory measurements. The analyses did reveal that 1987 dioxin levels were often highly associated with lipid-related health indices, such as cholesterol, HDL cholesterol, the cholesterol-HDL

ratio, and triglycerides, as well as with some of the hepatic enzymes (ALT and GGT) and proteins. These seemingly discordant results may have been explained in part because the initial dioxin analyses adjusted for differential half-life elimination related to body fat, while no adjustment was made in the analyses of 1987 dioxin. These significant findings may have been the result of a subclinical dioxin effect on lipid metabolism.

13.1.2.6 1997 Follow-up Examination Summary Results

The gastrointestinal assessment was based on eight disorders as determined from a review and verification of each participant's medical records, a physical examination determination of hepatomegaly, and 29 laboratory measurements or indices. The laboratory parameters included measurements of hepatic enzyme activity, hepatobiliary function, lipid and carbohydrate indices, and a protein profile. In addition, the presence of hepatitis and fecal occult blood was investigated.

Analyses of Ranch Hands versus Comparisons showed higher mean levels of alkaline phosphatase, α -1-antitrypsin, and haptoglobin in Ranch Hands than in Comparisons. In addition, significantly more Ranch Hands than Comparisons had high haptoglobin levels. A review of medical records showed a positive association between other liver disorders and initial dioxin. Twelve percent of the participants with the other liver disorders condition had nonspecific laboratory test elevations. A significant association between initial dioxin and high levels of AST also was revealed.

Analyses of categorized dioxin revealed a significantly higher percentage of other liver disorders among Ranch Hands in the high dioxin category than among Comparisons. Higher mean levels of GGT, triglycerides, and α -1-antitrypsin were observed in Ranch Hands in the high dioxin category than in Comparisons. Ranch Hands in the high dioxin category had a greater prevalence of abnormal AST, triglyceride, and prealbumin levels than did Comparisons.

Many significant associations between the laboratory examination variables and 1987 dioxin levels were observed. In both the continuous and discrete forms, the hepatic enzymes ALT, AST, and GGT revealed significant positive associations with 1987 dioxin. In addition, significant positive associations between 1987 dioxin and the cholesterol-HDL ratio, triglycerides, and creatine phosphokinase were present.

In summary, the analysis of the 1997 follow-up examination data reflected patterns that have been observed and documented in prior examinations. The composite category of disease named "other liver disorders" exhibited a dose-response relation with dioxin. Isolated group differences exist, but 1987 dioxin levels were strongly related to hepatic enzymes such as AST, ALT, and GGT, and to lipid-related health indices such as cholesterol, HDL, and triglycerides. These results were consistent with a dose-response effect and may be related to unknown subclinical effects of dioxin. Although hepatic enzymes showed an association with dioxin, there was no evidence of an increase in overt liver disease.

13.1.3 Parameters for the 2002 Gastrointestinal Assessment

13.1.3.1 Dependent Variables

Questionnaire, physical examination, and laboratory data were used in the gastrointestinal assessment. The questionnaire data were organized by ICD-9-CM medical coding categories.

13.1.3.1.1 Medical Records Variables

During the 2002 health interview, each study participant was asked about the occurrence of hepatitis, jaundice, cirrhosis, enlarged liver, and other liver conditions. Medical records review was accomplished to confirm reported problems for these conditions and to identify any unreported liver conditions for each participant that attended the 2002 physical examination. These data from the 2002 physical examination were combined with data from the 1982 baseline examination and the 1985, 1987, 1992, and 1997 follow-up examinations to form a complete history of liver conditions for each participant. The analyses performed in this chapter were based on the 1,951 participants who attended the 2002 follow-up examination.

The verified results were grouped into the following seven categories of disorders for analysis:

(1) uncharacterized hepatitis (non-A, non-B, and non-C), (2) jaundice (unspecified, not of the newborn), (3) chronic liver disease and cirrhosis (alcohol-related), (4) chronic liver disease and cirrhosis (nonalcohol-related), (5) liver abscess and sequelae of chronic liver disease, (6) enlarged liver (hepatomegaly), and (7) other disorders of the liver. The purpose of the uncharacterized hepatitis (non-A, non-B, and non-C) category was to define a category that was neither clearly A nor B nor C, so that liver disease misdiagnosed as “viral hepatitis” could be detected. This approach to historical hepatitis created a group of cases that could have been chemically induced. The following ICD-9-CM codes were used for these disorders: uncharacterized hepatitis (ICD-9-CM codes 70.49, 70.59, 70.6, 70.9, 571.40, 571.41, 571.49, and 573.3), jaundice (ICD-9-CM code 782.4), alcohol-related chronic liver disease and cirrhosis (ICD-9-CM codes 571.0–571.3), nonalcohol-related chronic liver disease and cirrhosis (ICD-9-CM codes 571.40–571.9), liver abscess and sequelae of chronic liver disease (ICD-9-CM codes 572.0–572.8), enlarged liver (ICD-9-CM code 789.1), and other disorders of the liver (ICD-9-CM codes 573.0–573.9, 790.4, 790.5, and 794.8). An analysis of the history of acute and subacute necrosis of the liver (ICD-9-CM code 570) also was planned, but no occurrences were found in this population.

For each condition under study, participants with a pre-Southeast Asia (SEA) diagnosis were excluded from the analysis. In addition, the analysis of alcohol-related chronic liver disease and cirrhosis excluded participants with zero lifetime alcohol history because nondrinkers would not be at risk for alcohol-related liver disease.

13.1.3.1.2 Physical Examination Variable

One variable from the 2002 physical examination, current hepatomegaly, was analyzed in the gastrointestinal assessment. This variable was coded as “yes” or “no.” Participants whose blood contained hepatitis B surface antigen (HBsAg) or hepatitis C antibodies were excluded from the analysis of current hepatomegaly to account for the effects of these viruses on chronic hepatic disease.

13.1.3.1.3 Laboratory Variables

The 2002 examination emphasized the evaluation of laboratory data through the analysis of 28 measurements. These laboratory variables were AST (U/L), ALT (U/L), GGT (U/L), alkaline phosphatase (U/L), total bilirubin (mg/dL), direct bilirubin (mg/dL), LDH (U/L), cholesterol (mg/dL), HDL cholesterol (mg/dL), cholesterol-HDL ratio, triglycerides (mg/dL), creatine phosphokinase (U/L), serum amylase (U/L), antibodies for hepatitis A, serological evidence of prior hepatitis B infection (positive anti-HBsAg or positive hepatitis B core antibody), antibodies for hepatitis C, stool hemocult, prothrombin time (seconds), and 10 components (in mg/dL) in a protein profile (prealbumin, albumin, α -1-acid glycoprotein, α -1-antitrypsin, α -2-macroglobulin, apolipoprotein B, C3 complement, C4 complement, haptoglobin, and transferrin). IgA, IgG, and IgM were also part of this profile, but they were analyzed in the immunology assessment (see Chapter 19). Participants who were immunized for

hepatitis B were determined from medical records review and were not considered as positive for serological evidence of prior hepatitis B infection.

All assays for the 2002 gastrointestinal assessment, except for serological evidence of prior hepatitis B infection and antibodies for hepatitis C, were performed by Scripps Clinic. The hepatitis B and C measurements were determined by laboratories at Brooks City-Base. Dade Behring Dimension[®] RxL equipment was used to quantify AST, ALT, GGT, alkaline phosphatase, total bilirubin, direct bilirubin, LDH, cholesterol, HDL, triglycerides, creatine phosphokinase, serum amylase, and albumin. The Beckman Coulter Image[®] System quantified all components of the protein profile except albumin. Prothrombin time was measured on Dade Behring Dimension Blood Coagulation System equipment. Abbott Commander[®] equipment was used to determine the presence or absence of antibodies for hepatitis A. Serological evidence of prior hepatitis B infection and antibodies for hepatitis C was determined using enzyme Abbott[®] immunoassays by laboratories at Brooks City-Base. Stool hemocult was determined using a Beckman Coulter[®] hemocult kit.

All laboratory variables were analyzed in both continuous and discrete forms, except for direct bilirubin, antibodies for hepatitis A, serological evidence of prior hepatitis B infection, current hepatitis B, antibodies for hepatitis C, and stool hemocult, which were analyzed only in discrete form. Direct bilirubin was analyzed only in its discrete form because there were few distinct measurements, precluding a meaningful continuous analysis.

Participants whose blood contained hepatitis B surface antigen or hepatitis C antibodies and participants with body temperatures greater than or equal to 100 degrees Fahrenheit were excluded from the analysis of all laboratory variables, except antibodies for hepatitis A, serological evidence of prior hepatitis B infection, antibodies for hepatitis C, and prothrombin time. For serological evidence of prior hepatitis B infection, participants who had received the hepatitis B vaccine were included in the analysis as negative for serological evidence of prior hepatitis B infection. For the other hepatitis variables, no participants were excluded. Attempts were made to determine, from a medical records review, which occurrences of the types of hepatitis described above were prior to service in SEA, but the date of hepatitis onset was not available for the majority of participants. Consequently, all occurrences of hepatitis were included for these variables. Participants who tested positive for the human immunodeficiency virus (HIV) and participants taking anticoagulants (e.g., Coumadin[®]) or aspirin were excluded from the prothrombin time analysis.

13.1.3.2 Covariates

Statistical analyses of all medical records variables were adjusted for age, race, military occupation, body mass index, lifetime smoking history, lifetime alcohol history, cumulative industrial chemical exposure, and cumulative degreasing chemical exposure.

Current hepatomegaly was adjusted only for age, race, military occupation, and body mass index. Statistical analyses of all laboratory variables except alkaline phosphatase and α -1-antitrypsin were adjusted for age, race, military occupation, body mass index, current smoking, current alcohol use, lifetime alcohol history, cumulative degreasing chemical exposure, and cumulative industrial chemical exposure.

Age, race, and occupation were determined from military records. Current cigarette smoking and lifetime cigarette smoking history were based on questionnaire data. For lifetime cigarette smoking history, the respondent's average smoking was estimated over his lifetime based on his responses to the 2002 questionnaire, with 1 pack-year defined as 365 packs of cigarettes smoked during a single year.

Body mass index was calculated as $\text{weight}/(\text{height})^2$, where the weight was measured in kilograms and the height was measured in meters at the physical examination (95). For purposes of covariate associations for discrete dependent variables, body fat was dichotomized as “not obese” ($\leq 30 \text{ kg/m}^2$) and “obese” ($>30 \text{ kg/m}^2$).

Lifetime alcohol history was based on information from the 2002 questionnaire and combined with similar information gathered at the 1987, 1992, and 1997 follow-up examinations. Each participant was asked about his drinking patterns throughout his lifetime. When a participant’s drinking pattern changed, he was asked to describe how his alcohol consumption differed and the duration of time that the drinking pattern lasted. The participant’s average daily alcohol consumption was determined for each of the reported drinking pattern periods throughout his lifetime, and an estimate of the corresponding total number of drink-years was derived. One drink-year was the equivalent of drinking 1.5 ounces of an 80-proof alcoholic beverage, one 12-ounce beer, or one 5-ounce glass of wine per day for 1 year. Current alcohol use was defined as the average number of drinks per day during the 2 weeks prior to completing the physical examination.

Wine consumption showed a strong inverse association with alkaline phosphatase in the 1985, 1987, 1992, and 1997 follow-up examinations. The inverse association persisted in the 2002 follow-up examination data; therefore, current wine consumption and lifetime wine history replaced current alcohol use and lifetime alcohol history as covariates in the adjusted analyses of alkaline phosphatase. Current wine consumption also replaced current alcohol use in the adjusted analysis of α -1-antitrypsin based on covariate associations in the 1997 follow-up examination data, which showed that α -1-antitrypsin was highly associated with current wine consumption but not associated with current alcohol use.

13.1.4 Statistical Methods

Table 13-1 summarizes the statistical analysis performed for the 2002 gastrointestinal assessment. The first part of this table lists the dependent variables analyzed, source of the data, form of the data, cutpoints, covariates, exclusions, and statistical methods. The second part of this table further describes the covariates. A covariate was used in its continuous form whenever possible for adjusted analyses. If the covariate was inherently discrete (e.g., military occupation), or if a categorized form was needed to develop measures of association with the dependent variables, the covariate was categorized as shown in Table 13-1.

Table 13-1. Statistical Analysis for the Gastrointestinal Assessment

^aCovariates:

- (1) age, race, military occupation, body mass index, lifetime alcohol history, cumulative industrial chemical exposure, cumulative degreasing chemical exposure, lifetime smoking history.
- (2) age, race, military occupation, body mass index.
- (3) age, race, military occupation, body mass index, current alcohol consumption, lifetime alcohol history, cumulative industrial chemical exposure, cumulative degreasing chemical exposure, current smoking.
- (4) age, race, military occupation, body mass index, current wine consumption, lifetime wine history, cumulative industrial chemical exposure, cumulative degreasing chemical exposure, current smoking.
- (5) age, race, military occupation, body mass index, current alcohol consumption, lifetime alcohol history, cumulative industrial chemical exposure, cumulative degreasing chemical exposure, current smoking, compliance to dietary restrictions.
- (6) age, race, military occupation, body mass index, current wine consumption, lifetime alcohol history, cumulative industrial chemical exposure, cumulative degreasing chemical exposure, current cigarette smoking.

^bExclusions:

- (a) participants with a pre-SEA history of the disorder.
- (b) participants with a pre-SEA history of the disorder, participants with no lifetime alcohol history.
- (c) participants whose blood contained hepatitis B surface antigen or hepatitis C antibodies.

Table 13-1. Statistical Analysis for the Gastrointestinal Assessment (Continued)

- (d) participants whose blood contained hepatitis B surface antigen or hepatitis C antibodies, participants with body temperatures greater than or equal to 100 degrees Fahrenheit.
- (e) participants testing positive for HIV, participants taking an anticoagulant (e.g., Coumadin[®]) or aspirin at the time of the examination.

Four models were examined for each dependent variable given in Table 13-1. The analyses of these models are presented below. Further details on dioxin and the modeling strategy are found in Chapters 2 and 7, respectively. These analyses were performed both unadjusted and adjusted for covariates. These covariates are given in Table 13-1. Model 1 examined the relation between the dependent variable and group (i.e., Ranch Hand or Comparison). In this model, exposure was defined as “yes” for Ranch Hands and “no” for Comparisons without regard to the magnitude of the exposure. In an attempt to quantify exposure, three contrasts of Ranch Hands and Comparisons were performed along with the overall Ranch Hand versus Comparison contrast. These three contrasts compared Ranch Hands and Comparisons within each military occupational category (i.e., officers, enlisted flyers, and enlisted groundcrew). As described in previous reports and Table 2-4, the median level of exposure to dioxin was highest for enlisted groundcrew, followed by enlisted flyers, then officers.

During the 1987, 1992, 1997, and 2002 examinations, serum dioxin levels were measured by the Centers for Disease Control and Prevention (CDC) using high-resolution gas chromatography and high-resolution mass spectrometry and were reported in parts per trillion (ppt) on a lipid weight basis (96). These dioxin measurements are referred to as “lipid-adjusted.” All measures of dioxin used in this report were based on lipid-adjusted dioxin measurements.

Model 2 examined the relation between the dependent variable and an extrapolated initial dioxin measure for Ranch Hands who had a 1987 dioxin measurement greater than 10 ppt. The initial dioxin was calculated by extrapolating the 1987 dioxin level back in time to the end of the tour of duty that qualified a Ranch Hand veteran for inclusion in this study. If a Ranch Hand did not have a 1987 dioxin level, then the first dioxin measured, either at 1992, 1997, or 2002, was used to estimate the initial dioxin level. Regardless of when the dioxin was measured, Ranch Hand veterans with a level less than or equal to 10 ppt were excluded from statistical analyses based on Model 2. A statistical adjustment for body mass index at the time of the participant’s blood measurement of dioxin was included in this model to account for body mass index-related differences in elimination rate (97).

Model 3 divided the Ranch Hands examined in Model 2 into two categories based on their initial dioxin measures. These two categories were referred to as “low Ranch Hand” and “high Ranch Hand.” Two additional categories—Ranch Hands with serum dioxin levels at or below 10 ppt and Comparisons—were formed and included in the model. Ranch Hands with serum dioxin levels at or below 10 ppt were assigned to the “background Ranch Hand” category. If a Ranch Hand did not have a 1987 dioxin measurement, the first measured dioxin level was used. Another category was examined by combining the low and high Ranch Hand categories. This combination is referred to in the tables as the “low plus

high Ranch Hand” category. These five categories—Comparisons, background Ranch Hands, low Ranch Hands, high Ranch Hands, and low plus high Ranch Hands—were used in Model 3 analyses. The relation between the dependent variable in each of the four Ranch Hand categories and the dependent variable in the Comparison category was examined. As in Model 2, a statistical adjustment for body mass index at the time of the participant's blood measurement of dioxin was included in this model for the unadjusted and adjusted analyses of all dependent variables. One Ranch Hand without a dioxin measure was excluded from statistical analyses based on Model 3.

Model 4 examined the relation between the dependent variable and 1987 dioxin levels in all Ranch Hands with a dioxin measurement. If a Ranch Hand did not have a 1987 dioxin measurement, the first dioxin level obtained, either in 1992, 1997, or 2002, was extrapolated to the date of the 1987 physical examination. If the first dioxin level was not obtained in 1987 and was less than or equal to 10 ppt, it was not extrapolated to 1987 level, but was used at the measured value. One Ranch Hand without a dioxin measurement was excluded from statistical analyses based on Model 4.

The term “unadjusted” was used in the text and tables as follows: Models 1 and 4 did not adjust for any covariates. Models 2 and 3 adjusted only for body mass index at the time of the blood measurement for dioxin. The term “adjusted” was used in the text and tables as follows: Models 1 and 4 adjusted for the covariates shown in Table 13-1 unless otherwise specified by a footnote to the table. Models 2 and 3 additionally adjusted only for body mass index at the time of the blood measurement for dioxin.

Table 13-2 provides a summary of the number of participants with missing dependent variable and covariate data. In addition, the number of participants that were excluded from analyses is given.

13.2 RESULTS

13.2.1 Dependent Variable-covariate Associations

The gastrointestinal dependent variables were tested for associations with each of the covariates used in the adjusted analyses. The complete results are presented in Appendix F, Table F-5. These associations were pairwise between the dependent variable and the covariate and were not adjusted for any other covariates. A brief summary of the pattern of significant ($p \leq 0.05$) dependent variable-covariate associations is described in the following paragraphs. In the discussion of the results below, low levels are considered adverse for HDL cholesterol, prealbumin, albumin, C3 complement, C4 complement, and transferrin.

13.2.1.1 Age

Total bilirubin, LDH, HDL cholesterol, serum amylase, α -1-antitrypsin, α -2-macroglobulin, haptoglobin, and prothrombin time increased with age. ALT, GGT, alkaline phosphatase, cholesterol, cholesterol-HDL ratio, triglycerides, creatine phosphokinase, prealbumin, albumin, apolipoprotein B, C3 complement, C4 complement, and transferrin decreased with increasing age.

Older participants had more abnormal levels of LDH, α -2-macroglobulin, C3 complement, transferrin, and prothrombin time and were more likely to have hepatitis A than younger participants. Younger participants, however, were more likely to have had abnormal levels of ALT, GGT, alkaline phosphatase, cholesterol, cholesterol-HDL ratio, and triglycerides than older participants.

13.2.1.2 Race

Black participants had higher mean GGT, creatine phosphokinase, and serum amylase levels and lower mean albumin and transferrin levels than did non-Black participants. Non-Black participants had higher mean total bilirubin, triglycerides, and α -2-macroglobulin levels and had lower mean HDL cholesterol, C3 complement, and C4 complement levels than Black participants.

Black participants had a greater percentage of abnormal creatine phosphokinase, serum amylase, and albumin values and had more occurrences of other liver disorders, antibodies for hepatitis A, prior hepatitis B infections, and antibodies for hepatitis C than did non-Black participants. Non-Black participants had a higher percentage of abnormal HDL cholesterol, cholesterol-HDL ratio, and α -2-macroglobulin values.

13.2.1.3 Military Occupation

Enlisted groundcrew had higher mean ALT, GGT, alkaline phosphatase, cholesterol, cholesterol-HDL ratio, triglycerides, creatine phosphokinase, α -1-acid glycoprotein and apolipoprotein B levels, and lower mean HDL levels than officers or enlisted flyers. Mean levels of α -1-antitrypsin, α -2-macroglobulin, and haptoglobin were higher for enlisted flyers than for officers or enlisted groundcrew. Officers had higher mean total bilirubin levels and lower C3 complement, C4 complement, and transferrin levels than enlisted personnel.

Enlisted groundcrew were more likely to have abnormal cholesterol, HDL cholesterol, cholesterol-HDL ratio, and triglyceride values, and were more likely to have antibodies to hepatitis C than officers or enlisted flyers. Enlisted flyers had more abnormal alkaline phosphatase, α -1-antitrypsin, and haptoglobin levels than enlisted groundcrew, and they were more likely to have antibodies to hepatitis A or a prior hepatitis B infection than enlisted groundcrew or officers. Officers had a higher percentage of abnormal C3 complement levels than enlisted personnel.

13.2.1.4 Cumulative Degreasing Chemical Exposure

Participants exposed to degreasing chemicals had higher mean levels of the following: alkaline phosphatase, cholesterol-HDL ratio, triglycerides, α -1-acid glycoprotein, α -1-antitrypsin, apolipoprotein B, and haptoglobin. Mean total bilirubin levels were higher and C3 complement, C4 complement, and transferrin levels were lower in participants not exposed to degreasing chemicals. Mean HDL levels were lower in participants with degreasing chemical exposure.

More abnormalities in cholesterol, HDL cholesterol, cholesterol-HDL ratio, triglycerides, α -1-antitrypsin, and haptoglobin were seen in participants exposed to degreasing chemicals, and more abnormal C3 complement levels were seen in participants who were not exposed.

13.2.1.5 Cumulative Industrial Chemical Exposure

Higher mean levels of cholesterol, cholesterol-HDL ratio, triglycerides, α -1-antitrypsin, and apolipoprotein B, and lower mean levels of HDL cholesterol were seen in participants exposed to industrial chemicals. Mean levels of AST, total bilirubin, and prothrombin time were higher and mean C3 complement and C4 complement levels were lower in participants not exposed to industrial chemicals than in participants with exposure.

Significantly more abnormal cholesterol, HDL cholesterol, cholesterol-HDL ratio, triglycerides, and α -1-antitrypsin levels were seen in participants with industrial chemical exposure, as was a higher prevalence of chronic alcohol-related liver disease and cirrhosis.

13.2.1.6 Body Mass Index

AST, ALT, GGT, LDH, cholesterol-HDL ratio, triglycerides, creatine phosphokinase, C3 complement, C4 complement, haptoglobin, and transferrin increased with body mass index. Cholesterol, HDL cholesterol, amylase, prealbumin, albumin, and α -1-antitrypsin decreased with increasing body mass index.

The percent of abnormal values for amylase, α -1-antitrypsin, and C3 complement, and the prevalence of hepatitis C antibodies was higher in participants who were not obese than in obese participants. Obese participants, however, had more abnormal levels of ALT, LDH, HDL cholesterol, cholesterol-HDL ratio, triglycerides, creatine phosphokinase, and α -2-macroglobulin. Obese participants also were more likely to have chronic liver disease and cirrhosis (nonalcohol-related), other disorders of the liver, and current hepatomegaly than participants who were not obese.

13.2.1.7 Current Alcohol Use

As current alcohol increased, AST, ALT, GGT, total bilirubin, cholesterol, HDL cholesterol, prealbumin, and α -1-acid glycoprotein increased, but the cholesterol-HDL ratio, creatine phosphokinase, amylase, α -2-macroglobulin, and C3 complement levels decreased.

Abnormal levels of HDL cholesterol, cholesterol-HDL ratio, and α -2-macroglobulin were more prevalent in participants consuming no more than one drink per day (in the past 2 weeks) than in participants consuming more than one drink per day. AST, GGT, total bilirubin, and direct bilirubin levels were more likely to be abnormal in participants consuming more than one drink per day over the last 2 weeks.

13.2.1.8 Lifetime Alcohol History

AST, GGT, cholesterol, HDL cholesterol, prealbumin, α -1-acid glycoprotein, α -1-antitrypsin, and haptoglobin levels increased with increasing lifetime alcohol consumption. Cholesterol-HDL ratio and creatine phosphokinase, however, decreased with increasing lifetime alcohol consumption.

Nondrinkers had more abnormal levels of HDL cholesterol, cholesterol-HDL ratio, and α -2-macroglobulin and were more likely to have had uncharacterized hepatitis and hepatitis A antibodies than moderate or heavy drinkers. The heaviest drinkers (>40 drink-years) were more likely to have abnormal GGT, direct bilirubin, α -1-acid glycoprotein, and α -1-antitrypsin levels than moderate drinkers or nondrinkers. Heavy drinkers also were more likely to have chronic liver disease and cirrhosis (alcohol-related), enlarged liver, prior hepatitis B infection, and hepatitis C antibodies than moderate or nondrinkers.

13.2.1.9 Current Cigarette Smoking

As current cigarette smoking increased, GGT, alkaline phosphatase, cholesterol-HDL ratio, α -1-acid glycoprotein, α -1-antitrypsin, and haptoglobin levels increased. AST, ALT, total bilirubin, LDH, creatine phosphokinase, prealbumin, albumin, and prothrombin time decreased with increased current cigarette smoking.

Former cigarette smokers had more abnormal levels of LDH and creatine phosphokinase than nonsmokers or current smokers. Moderate smokers (up to 20 cigarettes per day) were more likely to have hepatitis C antibodies and abnormal levels of alkaline phosphatase and direct bilirubin than heavy smokers, former, or nonsmokers. The heaviest cigarette smokers were more likely to have abnormal cholesterol-HDL ratio, α -1-acid glycoprotein, α -1-antitrypsin, and haptoglobin levels and were more likely to have had a prior hepatitis B infection.

13.2.1.10 Lifetime Cigarette Smoking History

Lifetime cigarette smoking was not significantly associated with any of the dependent variables.

13.2.1.11 Current Wine Consumption

As current wine consumption increased, alkaline phosphatase and α -1-antitrypsin levels decreased. Nonwine drinkers were more likely to have had abnormal alkaline phosphatase and α -1-antitrypsin levels than current wine drinkers.

13.2.1.12 Lifetime Wine History

As lifetime wine consumption increased, alkaline phosphatase levels decreased.

13.2.2 Exposure Analysis

The following section presents results of the statistical analyses of the dependent variables shown in Table 13-1. Dependent variables are grouped into three sections: (1) gastrointestinal variables derived from the questionnaire that was administered at the 2002 follow-up and previous AFHS examinations and subsequently verified from a review of participant medical records, (2) hepatomegaly, as determined at the 2002 physical examination, and (3) gastrointestinal laboratory variables.

13.2.2.1 Medical Records Variables

13.2.2.1.1 Uncharacterized Hepatitis

All Model 1, 2, and 4 unadjusted and adjusted analyses of uncharacterized hepatitis were nonsignificant (Table 13-3(a-d,g,h): $p > 0.21$ for each analysis).

The unadjusted Model 3 analysis revealed a significant difference in occurrences of uncharacterized hepatitis between Ranch Hands in the high dioxin category and Comparisons (Table 13-3(e): Unadjusted Relative Risk [RR]=2.54, $p=0.045$). After adjusting for covariates, however, the results became nonsignificant (Table 13-3(f): $p=0.083$). All other unadjusted and adjusted Model 3 contrasts were nonsignificant (Table 13-3(e,f): $p > 0.23$ for each contrast).

Table 13-3. Analysis of Uncharacterized Hepatitis

13.2.2.1.2 Unspecified Jaundice

The unadjusted and adjusted Model 1 and 2 analyses of jaundice revealed no significant results (Table 13-4(a-d): $p \geq 0.15$ for each analysis).

A significant difference between Ranch Hands in the low and high dioxin categories combined and Comparisons was seen in each of the unadjusted and adjusted Model 3 analyses (Table 13-4(e,f): Unadjusted RR=0.24, $p=0.024$; Adjusted RR=0.24, $p=0.027$). Ranch Hands in the low and high dioxin categories combined had fewer occurrences of unspecified jaundice than Comparisons (0.7% versus 2.9%, respectively). Each of the remaining contrasts in the unadjusted and adjusted Model 3 analyses were nonsignificant (Table 13-4(e,f): $p > 0.07$ for each contrast).

Both the unadjusted and adjusted Model 4 analyses revealed a significant inverse association between 1987 dioxin and unspecified jaundice (Table 13-4(g,h): Unadjusted RR=0.60, $p=0.004$; Adjusted RR=0.59, $p=0.014$). The percentages of Ranch Hands with jaundice in the low, medium, and high 1987 dioxin categories were 3.2, 2.0, and 0.4, respectively.

13.2.2.1.3 Chronic Liver Disease and Cirrhosis (Alcohol-related)

No significant differences between Ranch Hands and Comparisons were revealed in the unadjusted and adjusted Model 1 analyses of alcohol-related chronic liver disease and cirrhosis (Table 13-5(a,b): p>0.23 for each analysis).

A significant positive relation between initial dioxin and alcohol-related chronic liver disease and cirrhosis was revealed in the unadjusted Model 2 analysis (Table 13-5(c): Unadjusted RR=1.46, p=0.029). After adjusting for covariates, the results became nonsignificant (Table 13-5(d): p=0.272).

All unadjusted and adjusted Model 3 and 4 results were nonsignificant (Table 13-5(e-h): p>0.09 for each analysis).

1987 Dioxin Category Summary Statistics			Analysis Results for Log₂ (1987 Dioxin)	
1987 Dioxin	n	Number (%) Yes	Unadjusted Relative Risk (95% C.I.)^a	p-Value
Low	256	5 (2.0)	0.98 (0.69,1.40)	0.913
Medium	257	4 (1.6)		
High	256	3 (1.2)		

^aRelative risk for a twofold increase in 1987 dioxin.

Note: Low = ≤7.8 ppt; Medium = >7.8–19.2 ppt; High = >19.2 ppt.

(h) MODEL 4: RANCH HANDS – 1987 DIOXIN – ADJUSTED			
Analysis Results for Log₂ (1987 Dioxin)			
n	Adjusted Relative Risk (95% C.I.)^a		p-Value
769	0.94 (0.64,1.36)		0.733

^aRelative risk for a twofold increase in 1987 dioxin.

Note: Results were not adjusted for race and military occupation because of the sparse number of Ranch Hands with current hepatomegaly.

13.2.2.3 Laboratory Variables

13.2.2.3.1 AST (Continuous)

No significant relations were revealed in the unadjusted and adjusted Model 1 through 4 analyses of AST in its continuous form (Table 13-11(a-h): $p > 0.05$ for each analysis).

Table 13-11. Analysis of AST (U/L) (Continuous)

13.2.2.3.7 Alkaline Phosphatase (Continuous)

The unadjusted Model 1 analysis of alkaline phosphatase revealed a significant difference between all Ranch Hands and Comparisons (Table 13-17(a): difference of means=2.26 U/L, p=0.048). After adjusting for covariates, the results became nonsignificant (Table 13-17(b): p=0.060). Stratifying by occupation showed no significant results in either the unadjusted or the adjusted Model 1 analyses (Table 13-17(a,b): p>0.05 for each analysis).

All unadjusted and adjusted Model 2 and 4 analyses of alkaline phosphatase were nonsignificant (Table 13-17(c,d,g,h): p>0.13 for each analysis).

The unadjusted Model 3 analysis of alkaline phosphatase revealed a significant difference between Ranch Hands in the high dioxin category and Comparisons (Table 13-17(e): difference of means=3.69 U/L, p=0.048). Also in the unadjusted Model 3 analysis, a significant difference was seen between Ranch Hands in the low and high dioxin categories combined and Comparisons (Table 13-17(e): difference of means=3.34 U/L, p=0.018). After covariate adjustment, no contrasts were significant (Table 13-17(f): p>0.09 for each contrast).

13.2.2.3.8 Alkaline Phosphatase (Discrete)

The unadjusted and adjusted Model 1 analyses of alkaline phosphatase in its discrete form showed no significant overall group differences (Table 13-18(a,b): $p > 0.07$ for each analysis). After stratifying by occupation, however, a significant difference was seen between Ranch Hands and Comparisons in the enlisted groundcrew stratum for both the unadjusted and adjusted analyses (Table 13-18(a,b): Unadjusted $RR = 1.73$, $p = 0.031$; Adjusted $RR = 1.70$, $p = 0.039$). Among the enlisted groundcrew, Ranch Hands had a higher percentage of abnormal alkaline phosphatase values than did the Comparisons (10.6% versus 6.4%).

All unadjusted and adjusted Models 2 through 4 analyses of alkaline phosphatase in its discrete form revealed no significant relation with dioxin (Table 13-18(c-h): $p > 0.05$ for each analysis).

Table 13-18. Analysis of Alkaline Phosphatase (Discrete)

(a) MODEL 1: RANCH HANDS VS. COMPARISONS – UNADJUSTED

^aRelative risk for a twofold increase in 1987 dioxin.

13.2.2.3.9 Total Bilirubin (Continuous)

The unadjusted and adjusted Model 1 and 3 analyses of total bilirubin in its continuous form were nonsignificant (Table 13-19(a,b,e,f): $p > 0.15$ for each analysis).

A significant inverse relation was seen between initial dioxin and total bilirubin in the unadjusted Model 2 analysis (Table 13-19(c): Slope=-0.035, $p=0.044$). After adjusting for covariates, the results were no longer significant (Table 13-19(d): $p=0.844$).

The unadjusted Model 4 analysis revealed a significant inverse relation between 1987 dioxin and total bilirubin (Table 13-19(g): Slope=-0.022, p=0.040). After covariate adjustment, the results became nonsignificant (Table 13-19(h): p=0.384).

^aRelative risk for a twofold increase in 1987 dioxin.

13.2.2.3.11 Direct Bilirubin (Discrete)

Because of a sparse number of participants with abnormally high direct bilirubin values, the analysis was limited for some of the models.

The unadjusted Model 1 analysis revealed no significant group differences (Table 13-21(a): $p > 0.05$ for each analysis). After adjusting for covariates, a significant overall group difference was seen (Table 13-21(b): Adjusted RR=0.24, $p=0.041$). The percentage of Ranch Hands with abnormally high direct bilirubin values was 0.3 percent versus 1.0 percent for Comparisons. After stratifying by military occupation, no significant difference between Ranch Hands and Comparisons was seen among officers (Table 13-21(b): $p=0.401$). No adjusted Model 1 analyses were performed for enlisted flyers and enlisted groundcrew due to a sparse number of abnormalities.

No Model 2 analyses were performed because there were no abnormally high direct bilirubin values for Ranch Hands with an extrapolated initial dioxin level. All unadjusted and adjusted Model 3 and 4 analyses of direct bilirubin were nonsignificant (Table 13-21(e-h): $p > 0.09$ for each analysis).

Table 13-21. Analysis of Direct Bilirubin (Discrete)

Dioxin Category	n	Adjusted Relative Risk (95% C.I.)^a	p-Value
Comparison	1,149		
Background RH	346	0.64 (0.13,3.27)	0.592
Low RH	207	--	--
High RH	209	--	--
Low plus High RH	416	--	--

^aRelative risk and confidence interval relative to Comparisons.

--: Results were not presented because of the sparse number of participants with an abnormally high direct bilirubin level.

Note: RH = Ranch Hand.

Background (Ranch Hand): 1987 dioxin ≤ 10 ppt.

Low (Ranch Hand): 1987 dioxin > 10 ppt, 10 ppt < initial dioxin ≤ 118 ppt.

High (Ranch Hand): 1987 dioxin > 10 ppt, initial dioxin > 118 ppt.

Results were not adjusted for military occupation because of the sparse number of participants with an abnormally high direct bilirubin level.

(g) MODEL 4: RANCH HANDS – 1987 DIOXIN – UNADJUSTED				
1987 Dioxin Category Summary Statistics			Analysis Results for Log₂ (1987 Dioxin)	
1987 Dioxin	n	Number (%) High	Unadjusted Relative Risk (95% C.I.)^a	p-Value
Low	256	1 (0.4)	0.50 (0.21,1.17)	0.124
Medium	256	1 (0.4)		
High	255	0 (0.0)		

^aRelative risk for a twofold increase in 1987 dioxin.

Note: Low = ≤7.8 ppt; Medium = >7.8–19.2 ppt; High = >19.2 ppt.

(h) MODEL 4: RANCH HANDS – 1987 DIOXIN – ADJUSTED			
Analysis Results for Log₂ (1987 Dioxin)			
n	Adjusted Relative Risk (95% C.I.)^a		p-Value
762	0.53 (0.20,1.40)		0.191

^aRelative risk for a twofold increase in 1987 dioxin.

Note: Results were not adjusted for race, military occupation, cumulative degreasing chemical exposure, and current cigarette smoking because of the sparse number of Ranch Hands with an abnormally high direct bilirubin level.

13.2.2.3.12 LDH (Continuous)

The unadjusted and adjusted Model 1 analyses of LDH in its continuous form showed no significant overall group differences (Table 13-22(a,b): $p > 0.08$ for each analysis). Stratifying by military occupation in the unadjusted Model 1 analysis revealed a significant difference between Ranch Hands and Comparisons among officers (Table 13-22(a): difference of means=4.1 U/L, $p=0.049$). After adjusting for covariates, no significant group differences were seen in any of the occupational strata (Table 13-22(b): $p > 0.05$ for each analysis).

All unadjusted and adjusted analyses of LDH in Models 2 through 4 were nonsignificant (Table 13-22(c-h): $p > 0.07$ for each analysis).

Table 13-22. Analysis of LDH (U/L) (Continuous)

13.2.2.3.13 LDH (Discrete)

No significant relations between LDH in its discrete form and either group or dioxin were seen in the unadjusted and adjusted Model 1, 3, and 4 analyses (Table 13-23(a,b,e-h): $p > 0.08$ for each analysis).

The unadjusted Model 2 analysis revealed a significant inverse relation between initial dioxin and LDH (Table 13-23(c): Unadjusted RR=0.76, $p=0.028$). After covariate adjustment, the results became nonsignificant (Table 13-22(d): $p=0.240$).

Table 13-23. Analysis of LDH (Discrete)

13.2.2.3.15 Cholesterol (Discrete)

All unadjusted and adjusted Model 1, 2, and 4 analyses of cholesterol in its discrete form were nonsignificant (Table 13-25(a-d,g,h): $p > 0.08$ for each analysis).

The unadjusted Model 3 analysis revealed no significant differences between dioxin categories (Table 13-25(e): $p \geq 0.16$ for each contrast). Adjustment for covariates revealed a significant difference between Ranch Hands in the low and high dioxin categories combined and Comparisons (Table 13-25(f): Adjusted RR=0.68, $p=0.039$). Ranch Hands in the low and high dioxin categories combined had a smaller percentage of abnormally high cholesterol values than Comparisons (10.3% versus 13.3%). All remaining contrasts were nonsignificant (Table 13-25(f): $p > 0.06$ for each contrast).

Table 13-25. Analysis of Cholesterol (Discrete)

13.2.2.3.16 HDL Cholesterol (Continuous)

No significant group differences were seen in the unadjusted and adjusted Model 1 analyses of HDL cholesterol in its continuous form (Table 13-26(a,b): $p \geq 0.27$ for each analysis).

As initial dioxin increased, a significant decrease in HDL cholesterol was observed in the unadjusted Model 2 analysis (Table 13-26(c): Slope=-0.024, $p=0.012$). The results of the adjusted Model 2 analysis were nonsignificant (Table 13-26(d): $p=0.494$).

The unadjusted Model 3 analysis revealed a significant difference between Ranch Hands in the high dioxin category and Comparisons (Table 13-26(e): difference of means=-2.55 mg/dL, $p=0.002$), as well as a significant difference between Ranch Hands in the low and high dioxin categories combined and Comparisons (Table 13-26(e): difference of means=-1.34 mg/dL, $p=0.035$). After covariate adjustment, no contrasts were significant (Table 13-26(f): $p > 0.20$ for each contrast).

As 1987 dioxin increased, a significant decrease in HDL cholesterol was observed in the unadjusted Model 4 analysis (Table 13-26(g): Slope=-0.031, $p < 0.001$). The results were no longer significant after adjusting for covariates (Table 13-26(h): $p=0.693$).

13.2.2.3.18 Cholesterol-HDL Ratio (Continuous)

No significant group differences were seen in the unadjusted and adjusted Model 1 analyses of cholesterol-HDL ratio (Table 13-28(a,b): $p > 0.22$ for each analysis).

The unadjusted Model 2 analysis revealed a significant positive association between initial dioxin and cholesterol-HDL ratio (Table 13-28(c): Slope=0.027, $p=0.009$). The relation was no longer significant after adjusting for covariates (Table 13-28(d): $p=0.692$).

The unadjusted Model 3 analysis revealed a significant difference between Ranch Hands in the background dioxin category and Comparisons (Table 13-28(e): difference of means=-0.17, $p=0.020$) as well as a significant difference between Ranch Hands in the high dioxin category and Comparisons (Table 13-28(e): difference of means=0.24, $p=0.010$). After covariate adjustment, however, all contrasts were nonsignificant (Table 13-28(f): $p > 0.35$ for each contrast).

A significant positive association was revealed between 1987 dioxin and cholesterol-HDL ratio in the unadjusted Model 4 analysis (Table 13-28(g): Slope=0.030, $p < 0.001$). The adjusted Model 4 analysis results were nonsignificant (Table 13-28(h): $p=0.956$).

13.2.2.3.19 Cholesterol-HDL Ratio (Discrete)

The unadjusted and adjusted Model 1 and 2 analyses of cholesterol-HDL ratio in its discrete form were nonsignificant (Table 13-29(a-d): $p > 0.16$ for each analysis).

A significant difference between Ranch Hands in the background dioxin category and Comparisons was revealed in the unadjusted Model 3 analysis (Table 13-29(e): Unadjusted RR=0.76, $p=0.045$). The remaining unadjusted contrasts were nonsignificant (Table 13-29(e): $p \geq 0.07$ for each contrast). The adjusted Model 3 analysis revealed no significant relation between dioxin category and dichotomized cholesterol-HDL ratio (Table 13-29(f): $p \geq 0.28$ for each contrast).

The unadjusted Model 4 analysis revealed a significant positive relation between 1987 dioxin and cholesterol-HDL ratio (Table 13-29(g): Unadjusted RR=1.17, $p < 0.001$). The relation was no longer significant after adjusting for covariates (Table 13-29(h): $p=0.866$).

13.2.2.3.20 Triglycerides (Continuous)

No significant association with group or dioxin was revealed in the unadjusted and adjusted Model 1 and 2 analyses of triglycerides in its continuous form (Table 13-30(a-d): $p > 0.08$ for each analysis).

The Model 3 unadjusted analysis revealed three significant contrasts: Ranch Hands in the background dioxin category versus Comparisons (Table 13-30(e): difference of means=-8.2 mg/dL, $p=0.045$), Ranch Hands in the high dioxin category versus Comparisons (Table 13-30(e): difference of means=16.6 mg/dL, $p=0.002$), and Ranch Hands in the low and high dioxin categories combined versus Comparisons (Table 13-30(e): difference of means=10.6 mg/dL). After covariate adjustment, all contrasts were nonsignificant (Table 13-30(f): $p > 0.21$ for each contrast).

The unadjusted Model 4 analysis revealed a significant relation between triglycerides in its continuous form and 1987 dioxin (Table 13-30(g): Slope=0.060, $p < 0.001$). After adjusting for covariates, however, the results were nonsignificant (Table 13-30(h): $p=0.077$).

13.2.2.3.21 Triglycerides (Discrete)

A significant difference between Ranch Hands and Comparisons was seen in the unadjusted and adjusted Model 1 analyses of triglycerides in its dichotomized form (Table 13-31(a,b): Unadjusted RR=1.43, p=0.015; Adjusted RR=1.40, p=0.023). In each of the unadjusted and adjusted Model 1 analyses, stratifying by military occupation revealed a significant difference between Ranch Hands and Comparisons among enlisted groundcrew (Table 13-31(a,b): Unadjusted RR=1.62, p=0.015; Adjusted RR=1.54, p=0.034). For all participants, Ranch Hands had a higher percentage of abnormal triglyceride values than Comparisons (13.4% versus 9.8%). Among enlisted groundcrew, 17.9 percent of Ranch Hands had abnormal triglyceride values versus 11.9 percent of Comparisons.

No significant association was seen between initial dioxin and triglycerides in the unadjusted and adjusted Model 2 analyses (Table 13-31(c,d): p>0.09 for each analysis).

The unadjusted Model 3 analysis of triglycerides revealed three significant contrasts: Ranch Hands in the low dioxin category versus Comparisons, Ranch Hands in the high dioxin category versus Comparisons, and Ranch Hands in the low and high dioxin categories combined versus Comparisons (Table 13-31(e): Unadjusted RR=1.65, p=0.021; Unadjusted RR=2.26, p<0.001; Unadjusted RR =1.93, p<0.001,

respectively). These same contrasts were significant in the adjusted Model 3 analysis: (Table 13-31(f): Adjusted RR=1.72, p=0.015 for Ranch Hands in the low dioxin category versus Comparisons; Adjusted RR=1.70, p=0.012 for Ranch Hands in the high dioxin category versus Comparisons; Adjusted RR=1.71, p=0.001 for Ranch Hands in the low and high dioxin categories combined). The percentages of Ranch Hands with abnormal triglyceride values in the low dioxin category, high dioxin category, and low and high dioxin categories combined were 15.4, 20.4, and 17.9, respectively, versus 9.8 percent for Comparisons.

A significant positive association between 1987 dioxin and dichotomized triglycerides was revealed in each of the unadjusted and adjusted Model 4 analyses (Table 13-31(g,h): Unadjusted RR=1.35, p<0.001; Adjusted RR=1.20, p=0.020). The percentages of abnormally high triglyceride values in the low, medium, and high 1987 dioxin categories were 6.3, 12.9, and 21.2, respectively.

13.2.2.3.22 Creatine Phosphokinase (Continuous)

The unadjusted and adjusted Model 1, 2, and 3 analyses of creatine phosphokinase in its continuous form were nonsignificant (Table 13-32(a-f): $p > 0.18$ for each analysis).

A significant positive association was seen between 1987 dioxin and creatine phosphokinase in the unadjusted Model 4 analysis (Table 13-32(g): Slope=0.028, $p=0.032$). The results of the adjusted Model 4 analysis were nonsignificant (Table 13-32(h): $p=0.654$).

13.2.2.3.24 Serum Amylase (Continuous)

No difference between Ranch Hands and Comparisons was seen among all participants in the unadjusted or adjusted Model 1 analysis of serum amylase (Table 13-34(a,b): $p > 0.26$ for each analysis). Stratifying by military occupation in the unadjusted Model 1 analysis did not reveal any group differences (Table 13-34(a): $p > 0.05$ for each analysis). After stratifying by military occupation in the adjusted Model 1 analysis, a significant difference between Ranch Hand and Comparison officers was revealed (Table 13-34(b): difference of adjusted mean = -3.25 U/L, $p = 0.049$). Ranch Hand officers had an adjusted mean serum amylase value of 57.85 U/L versus 61.10 U/L for Comparison officers.

The unadjusted Model 2 analysis of serum amylase was nonsignificant (Table 13-34(c): $p = 0.080$). After adjusting for covariates, a significant inverse association was revealed between initial dioxin and serum amylase in its continuous form (Table 13-34(d): Adjusted Slope = -0.036, $p = 0.031$). The adjusted mean serum amylase values for Ranch Hands in the low, medium, and high dioxin categories were 63.07 U/L, 57.35 U/L, and 57.06 U/L, respectively.

The unadjusted and adjusted Model 3 analyses of serum amylase were nonsignificant (Table 13-34(e,f): $p > 0.05$ for each analysis). A significant inverse relation was seen between 1987 dioxin and serum amylase in both the unadjusted and adjusted Model 4 analysis (Table 13-34(g,h): Slope = -0.019, $p = 0.029$, and Adjusted Slope = -0.020, $p = 0.048$, respectively). The mean serum amylase level was 63.87 U/L for Ranch Hands in the low dioxin category, compared to 62.03 U/L for the medium dioxin category and 58.26 U/L for the high dioxin category.

13.2.2.3.25 Serum Amylase (Discrete)

No significant group difference for all participants was seen in the unadjusted and adjusted Model 1 analyses of serum amylase in its discrete form (Table 13-35(a,b): p>0.37 for each analysis). After stratifying by military occupation, however, a significant difference was seen between Ranch Hands and Comparisons among officers in both the unadjusted and adjusted Model 1 analyses (Table 13-35(a,b): Unadjusted RR=0.28, p=0.042; Adjusted RR=0.27, p=0.038, respectively). Ranch Hand officers had a lower percentage of abnormally high serum amylase values than did Comparison officers (1.0% for Ranch Hand officers and 3.5% for Comparison officers).

All unadjusted and adjusted Model 2, 3, and 4 analyses of serum amylase in its discrete form were nonsignificant (Table 13-35(c-h): p>0.18 for each analysis).

13.2.2.3.27 Serological Evidence of Prior Hepatitis B Infection

Significant overall group differences were revealed in each of the unadjusted and adjusted Model 1 analyses of serological evidence of prior hepatitis B infection (Table 13-37(a,b): Unadjusted RR=0.56, p<0.001; Adjusted RR=0.53, p<0.001, respectively). Comparisons had a higher percentage of prior hepatitis B infections than Ranch Hands (11.0% versus 6.4%, respectively).

After stratifying by military occupation, significant differences between Ranch Hands and Comparisons in both the unadjusted and adjusted Model 1 analyses of prior hepatitis B infection were seen among

officers (Table 13-37(a,b): Unadjusted RR=0.41, p=0.039, Adjusted RR=0.40, p=0.034), as well as among enlisted groundcrew (Table 13-37(a,b): Unadjusted RR=0.57, p=0.017, Adjusted RR=0.56, p=0.016). Among officers, 5.4 percent of Comparisons had prior hepatitis B infections versus 2.3 percent of Ranch Hands. Comparison enlisted groundcrew had a greater percentage of prior hepatitis B infections than Ranch Hand enlisted groundcrew (13.7% versus 8.3%, respectively).

No significant associations were seen between initial dioxin and prior hepatitis B infection in the unadjusted and adjusted Model 2 analyses (Table 13-37(c,d): p>0.19 for each analysis).

The unadjusted Model 3 analysis revealed a significant difference between Ranch Hands in the background dioxin category and Comparisons (Table 13-37(e): Unadjusted RR=0.38, p<0.001). After adjusting for covariates, three contrasts were significant: Ranch Hands in the background dioxin category versus Comparisons (Table 13-37(f): Adjusted RR=0.44, p=0.004), Ranch Hands in the low dioxin category versus Comparisons (Table 13-37(f): Adjusted RR=0.56, p=0.045), and Ranch Hands in the low and high dioxin categories combined versus Comparisons (Table 13-37(f): Adjusted RR=0.59, p=0.012). The percentages of prior hepatitis B infections for Ranch Hands in the background dioxin category, low dioxin category, and low and high dioxin categories combined were 4.3, 7.1, and 8.3, respectively, versus 11.0 percent for Comparisons.

A significant positive relation between 1987 dioxin and prior hepatitis B infections was seen in the unadjusted Model 4 analysis (Table 13-37(g): Unadjusted RR=1.26, p=0.008). After adjusting for covariates, however, the results were no longer significant (Table 13-37(h): p=0.184).

13.2.2.3.28 Antibodies for Hepatitis C

Both the unadjusted and adjusted Model 1 analyses of hepatitis C antibodies revealed significant overall group differences (Table 13-38(a,b): Unadjusted RR=0.39, p=0.046; Adjusted RR=0.37, p=0.037). A greater percentage of Comparisons had antibodies for hepatitis C than Ranch Hands (1.6% for Comparisons versus 0.6% for Ranch Hands). Stratifying the unadjusted and adjusted Model 1 analyses by military occupation did not reveal any significant results (Table 13-38(a,b): p≥0.17 for each stratum).

All unadjusted and adjusted Model 2, 3, and 4 analyses of hepatitis C antibodies were nonsignificant (Table 13-38(c-h): p>0.05 for each analysis).

n	Adjusted Relative Risk (95% C.I.)^a		p-Value
771	0.62 (0.36,1.09)		0.099

^aRelative risk for a twofold increase in 1987 dioxin.

Note: Results were not adjusted for military occupation because of the sparse number of Ranch Hands with antibodies for hepatitis C.

13.2.2.3.29 Stool Hemocult

No overall group differences were seen between Ranch Hands and Comparisons in the unadjusted and adjusted Model 1 analyses of stool hemocult (Table 13-39(a,b): $p > 0.54$ for each analysis). After stratifying by occupation, a significant group difference was seen among officers in both the unadjusted and adjusted analyses (Table 13-39(a,b): Unadjusted RR=9.12, $p=0.041$; Adjusted RR=8.99, $p=0.043$). Officers in the Ranch Hand group had a higher percentage of positive stool hemocult results than did officers in the Comparison group (2.1% versus 0.2%).

The unadjusted and adjusted Model 2 through 4 analyses did not show any significant associations between dioxin and stool hemocult (Table 13-39(c-h): $p > 0.30$ for each analysis).

Table 13-39. Analysis of Stool Hemocult

Note: Results were not adjusted for race and current cigarette smoking because of the sparse number of Ranch Hands with a positive stool hemocult.

13.2.2.3.30 Protein Profile: Prealbumin (Continuous)

No significant group differences were revealed in the unadjusted and adjusted Model 1 analyses of prealbumin in its continuous form (Table 13-40(a,b): $p > 0.21$ for each analysis).

As initial dioxin increased, a significant decrease in prealbumin was observed in the unadjusted Model 2 analysis (Table 13-40(c): Slope=-0.043, $p=0.042$). After covariate adjustment, however, the results were no longer significant (Table 13-40(d): $p=0.055$).

All unadjusted and adjusted Model 3 and 4 analyses of prealbumin in its continuous form were nonsignificant (Table 13-40(e-h): $p > 0.12$ for each analysis).

13.2.2.3.33 Protein Profile: Albumin (Discrete)

Due to a sparse number of participants with an abnormally low albumin level, the analysis was limited in some of the models.

The unadjusted and adjusted Model 1 analyses of albumin in its discrete form showed no significant group differences (Table 13-43(a,b): $p>0.37$ for each analysis). The Model 2 analysis was not performed since there were no abnormally low albumin values.

Due to a sparse number of abnormalities in the Model 3 analysis, relative risks were only calculated for Ranch Hands in the background dioxin category versus Comparisons. The results of both the unadjusted and adjusted analyses were nonsignificant (Table 13-43(e,f): $p>0.09$ for each contrast).

A significant inverse association between 1987 dioxin and albumin in its discrete form was seen in each of the unadjusted and adjusted Model 4 analyses (Table 13-43(g,h): Unadjusted RR=0.50, $p=0.015$; Adjusted RR=0.37, $p=0.030$). The percentages of participants with abnormally low albumin values in the low, medium, and high 1987 dioxin categories were 1.6, 0.4, and 0.0, respectively.

Table 13-43. Analysis of Protein Profile: Albumin (Discrete)

(a) MODEL 1: RANCH HANDS VS. COMPARISONS – UNADJUSTED					
Occupational Category	Group	n	Number (%) Low	Unadjusted Relative Risk (95% C.I.)	p-Value

762	0.37 (0.15,0.94)		0.030*

^aRelative risk for a twofold increase in 1987 dioxin.

*: Statistically significant (0.010<p-value≤0.050).

Note: Results were not adjusted for race and current cigarette smoking because of the sparse number of Ranch Hands with an abnormally low albumin level.

13.2.2.3.34 Protein Profile: α -1-Acid Glycoprotein (Continuous)

No significant group differences were seen in the unadjusted and adjusted Model 1 analyses of α -1-acid glycoprotein in its continuous form (Table 13-44(a,b): $p>0.19$ for each analysis). The results of the unadjusted Model 2 analysis were nonsignificant (Table 13-44(c): $p=0.145$). After adjusting for covariates, however, a significant inverse association between initial dioxin and α -1-acid glycoprotein was revealed (Table 13-44(d): Adjusted Slope=-0.038, $p<0.001$). The adjusted mean α -1-acid glycoprotein values for Ranch Hands in the low, medium, and high initial dioxin categories were 76.97 mg/dL, 76.46 mg/dL, and 71.12 mg/dL, respectively.

All unadjusted and adjusted Model 3 and 4 analyses of α -1-acid glycoprotein were nonsignificant (Table 13-44(e-h): $p>0.05$ for each analysis).

13.2.2.3.36 Protein Profile: α -1-Antitrypsin (Continuous)

All unadjusted and adjusted Model 1 and 2 analyses of α -1-antitrypsin in its continuous form showed no significant group differences or associations with initial dioxin (Table 13-46(a-d): $p > 0.05$ for each analysis).

The unadjusted Model 3 analysis revealed a significant difference between Ranch Hands in the low dioxin category and Comparisons, as well as a significant difference between Ranch Hands in the low and high dioxin categories combined and Comparisons (Table 13-46(e): difference of means=4.1 mg/dL, $p=0.037$; difference of means=3.6 mg/dL, $p=0.015$, respectively). After adjusting for covariates, however, no contrasts were significant (Table 13-46(f): $p > 0.11$ for each contrast).

No significant associations were seen between 1987 dioxin and α -1-antitrypsin in the unadjusted and adjusted Model 4 analyses (Table 13-46(g,h): $p \geq 0.12$ for each analysis).

13.2.2.3.37 Protein Profile: α -1-Antitrypsin (Discrete)

No significant associations with dioxin were revealed in the unadjusted and adjusted Model 1, 2, and 4 analyses of α -1-antitrypsin in its discrete form (Table 13-47(a-d,g,h): $p > 0.12$ for each analysis).

Three significant contrasts were revealed in the unadjusted Model 3 analysis of abnormally high α -1-antitrypsin values (Table 13-47(e): Unadjusted RR=1.56, $p=0.047$ for Ranch Hands in the low dioxin category versus Comparisons; Unadjusted RR=1.56, $p=0.047$ for Ranch Hands in the high dioxin category versus Comparisons; and Unadjusted RR=1.56, $p=0.010$ for Ranch Hands in the low and high dioxin categories combined versus Comparisons). The adjusted Model 3 analysis of abnormally high α -1-antitrypsin values revealed a significant difference between Ranch Hands in the low dioxin category and Comparisons (Table 13-47(f): Adjusted RR=1.59, $p=0.042$), as well as a significant difference between Ranch Hands in the low and high dioxin categories combined and Comparisons (Table 13-47(f): Adjusted RR=1.48, $p=0.030$, respectively). Abnormally high α -1-antitrypsin values were found in 9.9 percent of the Comparisons, 14.4 percent of the Ranch Hands in the low dioxin category, and 14.1 percent of the Ranch Hands in the low and high dioxin categories combined. Unadjusted and adjusted analyses of associations between dioxin category and the percentage of participants with abnormally low α -1-antitrypsin values were nonsignificant (Table 13-47(e,f): $p > 0.10$ for each contrast).

Table 13-47. Analysis of Protein Profile: α -1-Antitrypsin (Discrete)**(a) MODEL 1: RANCH HANDS VS. COMPARISONS – UNADJUSTED**

^aRelative risk for a twofold increase in 1987 dioxin.

13.2.2.3.42 Protein Profile: C3 Complement (Continuous)

No significant associations between either group or dioxin and C3 complement in its continuous form were seen in the unadjusted and adjusted Model 1 and 2 analyses (Table 13-52(a-d): $p > 0.27$ for each analysis).

The unadjusted Model 3 analysis of C3 complement revealed three significant contrasts (Table 13-52(e): difference of means=4.7 mg/dL, $p=0.003$ for Ranch Hands in the low dioxin category versus Comparisons; difference of means=3.2 mg/dL, $p=0.038$ for Ranch Hands in the high dioxin category versus Comparisons; difference of means=3.9 mg/dL, $p<0.001$ for Ranch Hands in the low and high dioxin categories combined versus Comparisons). The adjusted Model 3 analysis of C3 complement revealed a significant difference between Ranch Hands in the low dioxin category and Comparisons (Table 13-52(f): difference of adjusted means=3.8 mg/dL, $p=0.011$). Ranch Hands in the low dioxin category had a mean C3 complement value of 124.2 mg/dL versus 120.4 mg/dL for Comparisons.

A significant positive relation was seen between 1987 dioxin and C3 complement in the unadjusted Model 4 analysis (Table 13-52(g): Slope=0.126, $p<0.001$). After covariate adjustment, however, the results were no longer significant (Table 13-52(h): $p=0.407$).

13.2.2.3.43 Protein Profile: C3 Complement (Discrete)

All unadjusted and adjusted Model 1 and 2 analyses of C3 complement in its discrete form were nonsignificant (Table 13-53(a-d): p>0.19 for each analysis).

A significant difference between Ranch Hands in the low and high dioxin categories combined and Comparisons was seen in the unadjusted Model 3 analysis of C3 complement (Table 13-53(e): p=0.034). The remaining unadjusted contrasts were nonsignificant (Table 13-53(e): p>0.09 for each contrast). Adjusting for covariates in the Model 3 analysis revealed no significant differences in dioxin category (Table 13-53(f): p>0.54 for each contrast). Adjusted results were not given for the low dioxin category and low and high dioxin categories combined due to a sparse number of abnormalities.

The unadjusted Model 4 analysis revealed a significant relation between 1987 dioxin and C3 complement (Table 13-53(g): Unadjusted RR=0.64, p=0.038). The results were no longer significant, however, after adjusting for covariates (Table 13-53(h): p=0.265).

n	Adjusted Relative Risk (95% C.I.)^a		p-Value
762	0.76 (0.46,1.24)		0.265

^aRelative risk for a twofold increase in 1987 dioxin.

Note: Results were not adjusted for race and military occupation because of the sparse number of Ranch Hands with an abnormally low C3 complement level.

13.2.2.3.44 Protein Profile: C4 Complement (Continuous)

No overall group differences were seen between Ranch Hands and Comparisons in the unadjusted and adjusted Model 1 analyses of C4 complement in its continuous form (Table 13-54(a,b): $p > 0.20$ for each analysis). Stratifying the unadjusted and adjusted analyses by military occupation revealed a significant difference between Ranch Hands and Comparisons in the officer stratum (Table 13-54(a,b): difference of means = -0.83 mg/dL, $p = 0.044$ for the unadjusted analysis; difference of adjusted means = -0.91 mg/dL, $p = 0.032$ for the adjusted analysis). All remaining occupational strata in the unadjusted and adjusted analyses were nonsignificant (Table 13-54(a,b): $p > 0.36$ for each stratum). Among officers, Ranch Hands had a lower adjusted mean C4 complement value than Comparisons (23.56 mg/dL and 24.46 mg/dL, respectively).

The unadjusted Model 2 analysis of C4 complement in its continuous form was nonsignificant (Table 13-54(c): $p = 0.230$). As initial dioxin increased, however, a significant decrease in C4 complement was observed in the adjusted Model 2 analysis (Table 13-54(d): Adjusted Slope = -0.053, $p = 0.041$). The adjusted mean C4 complement values in the low, medium, and high initial dioxin categories were 23.52 mg/dL, 24.47 mg/dL, and 22.90 mg/dL, respectively.

All unadjusted and adjusted Model 3 and 4 analyses of C4 complement in its continuous form were nonsignificant (Table 13-54(e-h): $p > 0.08$ for each analysis).

Note: Low = ≤7.8 ppt; Medium = >7.8–19.2 ppt; High = >19.2 ppt.

13.2.2.3.45 Protein Profile: C4 Complement (Discrete)

No significant associations between dioxin and C4 complement in its discrete form were revealed in the unadjusted and adjusted Model 1, 3, and 4 analyses (Table 13-55(a,b,e-h): $p > 0.07$ for each analysis).

A significant positive association between initial dioxin and C4 complement was shown in each of the unadjusted and adjusted Model 2 analyses (Table 13-55(c,d): Unadjusted RR=1.43, $p=0.009$; Adjusted RR=1.80, $p<0.001$). The percentages of participants with abnormally low C4 complement values in the low, medium, and high initial dioxin categories were 5.8, 3.5, and 11.4, respectively.

13.2.2.3.46 Protein Profile: Haptoglobin (Continuous)

A significant overall difference between Ranch Hands and Comparisons was seen in the unadjusted and adjusted Model 1 analyses of haptoglobin in its continuous form (Table 13-56(a,b): difference of means=7.9 mg/dL, $p=0.005$; difference of adjusted means=6.0 mg/dL, $p=0.026$). Among all participants, the adjusted mean haptoglobin value was greater for Ranch Hands than for Comparisons (123.3 mg/dL versus 117.3 mg/dL). Stratifying the unadjusted and adjusted analyses by military occupation revealed a significant difference between Ranch Hand and Comparison enlisted groundcrew (Table 13-56(a,b): difference of means=11.2 mg/dL, $p=0.010$; difference of adjusted means=9.1 mg/dL, $p=0.031$). Ranch Hand enlisted groundcrew had a greater adjusted mean haptoglobin value than Comparison enlisted groundcrew (132.6 mg/dL versus 123.4 mg/dL).

No significant association with initial dioxin was seen in the unadjusted Model 2 analysis of haptoglobin in its continuous form (Table 13-56(c): $p=0.967$). The adjusted Model 2 analysis, however, revealed a significant inverse relation between initial dioxin and haptoglobin (Table 13-56(d): Adjusted Slope=-0.227, $p=0.043$). Ranch Hands in the low, medium, and high dioxin categories had adjusted mean haptoglobin values of 114.7 mg/dL, 120.4 mg/dL, and 107.7 mg/dL, respectively.

The unadjusted Model 3 analysis of haptoglobin revealed three significant contrasts (Table 13-56(e): difference of means=11.4 mg/dL, $p=0.013$ for Ranch Hands in the low dioxin category versus Comparisons; difference of means=13.8 mg/dL, $p=0.003$ for Ranch Hands in the high dioxin category versus Comparisons; difference of means=12.6 mg/dL, $p<0.001$ for Ranch Hands in the low and high dioxin categories combined versus Comparisons). After adjusting for covariates, one contrast remained significant (Table 13-56(f): difference of adjusted means=6.9 mg/dL, $p=0.040$ for Ranch Hands in the low and high dioxin categories combined versus Comparisons). All remaining unadjusted and adjusted contrasts were nonsignificant (Table 13-56(e,f): $p>0.07$ for each contrast). Ranch Hands in the low and

high dioxin categories combined had a higher adjusted mean haptoglobin value than Comparisons (124.2 mg/dL versus 117.3 mg/dL, respectively).

No significant associations between 1987 dioxin and haptoglobin in its continuous form were seen in the unadjusted and adjusted Model 4 analyses (Table 13-56(g,h): $p > 0.07$ for each analysis).

13.2.2.3.47 Protein Profile: Haptoglobin (Discrete)

All unadjusted and adjusted Model 1, 3, and 4 analyses did not show any significant associations between either group or dioxin and haptoglobin in its discrete form (Table 13-57(a,b,e-h): $p > 0.05$ for each analysis).

The unadjusted Model 2 results were nonsignificant (Table 13-57(c): $p = 0.156$). After covariate adjustment, however, a significant inverse relation was revealed between initial dioxin and haptoglobin in its discrete form (Table 13-57(d): Adjusted RR=0.75, $p = 0.026$). The percentages of abnormally high haptoglobin values in the low, medium, and high initial dioxin categories were 13.0, 19.9, and 10.7, respectively.

13.2.2.3.48 Protein Profile: Transferrin (Continuous)

The unadjusted and adjusted Model 1 and 2 analyses of transferrin in its continuous form were nonsignificant (Table 13-58(a-d): $p > 0.24$ for each analysis).

The unadjusted Model 3 analysis of transferrin revealed two significant contrasts (Table 13-58(e): difference of means=6.1 mg/dL, $p=0.046$, for Ranch Hands in the high dioxin category versus Comparisons; difference of means=5.9 mg/dL, $p=0.011$, for Ranch Hands in the low and high dioxin categories combined versus Comparisons). After adjusting for covariates, a significant difference between Ranch Hands in the low dioxin category and Comparisons was revealed (Table 13-58(f): difference of adjusted means=6.7 mg/dL, $p=0.027$). The adjusted mean transferrin level for Ranch Hands in the low dioxin category was 254.3 mg/dL versus 247.6 mg/dL for Comparisons. All remaining unadjusted and adjusted Model 3 contrasts were nonsignificant (Table 13-58(e,f): $p > 0.05$ for each contrast).

The unadjusted Model 4 analysis revealed a significant positive association between 1987 dioxin and the continuous form of transferrin (Table 13-58(g): Slope=0.013, $p < 0.001$). The relation was no longer significant, however, after adjusting for covariates (Table 13-58(h): $p=0.057$).

13.2.2.3.49 Protein Profile: Transferrin (Discrete)

No significant associations between either group or dioxin and transferrin in its discrete form were seen in the unadjusted and adjusted Model 1 and 2 analyses (Table 13-59(a-d): $p>0.14$ for each analysis).

The unadjusted Model 3 analysis showed a significant difference between Ranch Hands in the low and high dioxin categories combined and Comparisons (Table 13-59(e): Unadjusted RR=0.48, $p=0.017$). After adjusting for covariates, two contrasts were significant (Table 13-59(f): Adjusted RR=0.41, $p=0.041$, for Ranch Hands in the low dioxin category versus Comparisons; Adjusted RR=0.50, $p=0.029$, for Ranch Hands in the low and high dioxin categories combined versus Comparisons). Comparisons had a higher percentage of abnormally low transferrin values (6.2%) than Ranch Hands in either the low dioxin category (2.9%) or the low and high dioxin categories combined (3.1%). The remaining unadjusted and adjusted Model 3 contrasts were nonsignificant (Table 13-59(e,f): $p>0.06$ for each contrast).

A significant inverse association was seen between transferrin in its discrete form and 1987 dioxin in the unadjusted Model 4 analysis (Table 13-59(g): Unadjusted RR=0.79, $p=0.021$). The results were nonsignificant in the adjusted Model 4 analysis (Table 13-59(h): $p=0.120$).

^aRelative risk for a twofold increase in 1987 dioxin.

13.2.2.3.50 Prothrombin Time (Continuous)

In the unadjusted and adjusted Model 1 and 2 analyses of continuous prothrombin time, no significant relations with either group or dioxin were seen (Table 13-60(a-d): $p>0.13$ for each analysis).

Both the unadjusted and adjusted Model 3 analysis of prothrombin time revealed a significant difference between Ranch Hands in the background dioxin category and Comparisons (Table 13-60(e,f): difference of means=0.08 seconds, $p=0.025$; difference of adjusted means=0.07 seconds, $p=0.042$). Ranch Hands in the background dioxin category had a higher adjusted mean prothrombin time than Comparisons (10.79 seconds versus 10.72 seconds, respectively). The remaining unadjusted and adjusted Model 3 contrasts were nonsignificant (Table 13-60(e,f): $p\geq 0.40$ for each contrast).

A significant inverse association was seen between 1987 dioxin and prothrombin time in the unadjusted and adjusted Model 4 analyses (Table 13-60(g,h): Slope=-0.002, $p=0.044$; Adjusted Slope=-0.003, $p=0.050$). The adjusted mean prothrombin times in the low, medium, and high 1987 dioxin categories were 10.79 seconds, 10.73 seconds, and 10.66 seconds, respectively.

13.3 DISCUSSION

Digestive symptoms are frequently nonspecific and intermittent; therefore, it is often difficult for physicians to make an accurate diagnosis, particularly with regard to hepatic disease. Liver disorders are commonly asymptomatic; if symptoms are present, they tend to be vague. A physical examination is often misleading or unhelpful. For example, the detection of liver enlargement is often unreliable,

especially in overweight or obese patients. In the case of obstructive airway disease, hyperinflation of the lungs and flattening of the diaphragm may cause the liver's edge to descend abnormally below the right costal margin, resulting in a mistaken diagnosis of hepatomegaly. In addition, detecting the span of the liver using palpation or percussion is often an unreliable index of liver size. If cost is not an issue, the best way to measure liver size is through imaging test screening, such as ultrasound or, preferably, abdominal computed axial tomography (CAT) scan or magnetic resonance imaging (MRI) of the abdomen.

Laboratory testing is the most reliable way to collect data on acute liver disease. The four hepatic enzymes analyzed in the AFHS (AST, ALT, GGT, and LDH) are routinely ordered when evaluating patients who are suspected as having liver disorders. The GGT levels are the most sensitive, although they are typically abnormal in certain circumstances, such as when alcohol is in the patient's system or when the patient is obese. Incidentally, obesity is the single most common cause of abnormal liver tests conducted in the United States (98).

Hepatic enzymes are typically analyzed to detect and follow-up on parenchymal liver diseases, such as alcoholic liver disease, viral hepatitis, and fatty liver due to obesity, diabetes mellitus, or hyperlipidemia. Serum alkaline phosphatase and bilirubin are typically monitored to evaluate cholestatic or obstructive liver diseases, such as those seen in pancreatic cancer, common bile duct stones, or biliary disease in general. Serum alkaline phosphatase levels may be elevated due to other organ dysfunction, primarily attributable to bone-derived alkaline phosphatase. An elevated alkaline phosphatase level is not necessarily indicative of liver disease and may occur in other instances, such as bone growth, Paget's disease (estimated to affect 3% of males over age 40), a neoplasm with metastases to bone, and congestive heart failure.

Similarly, bilirubin measurements can be affected by abnormalities other than intrinsic liver disease. The most common cause of elevated bilirubin is Gilbert's syndrome, which occurs in more than 5 percent of the population and almost 10 percent of males. Gilbert's syndrome causes an elevated indirect bilirubin level, primarily without elevating the direct bilirubin level. The result, then, is an elevated total bilirubin level. In addition, many medications, including over-the-counter drugs, have been implicated in the overproduction of bilirubin that may occur due to hemolysis associated with glucose-six-phosphate dehydrogenase deficiency, a condition that may be present in up to 15 percent of Black males.

Numerous dependent variable-covariate associations that were significant in the AFHS were consistent with associations well recognized in the literature. For instance, older participants in the AFHS had a higher percentage of antibodies for hepatitis A than younger participants. It has been well established that the presence of IgG hepatitis A antibody increases with age in the U.S. population (99). A second important covariate was the increased prevalence of liver disorders, antibodies for hepatitis A, prior hepatitis B infections, and antibodies for hepatitis C in AFHS Black participants compared to non-Black participants. These findings among the U.S. population were reported previously when race was evaluated for liver disease, prevalence of chronic hepatitis C, and prevalence of hepatocellular carcinoma (100, 101). The positive association between race and creatine phosphokinase levels has been well established, with Black participants having higher creatine phosphokinase levels than non-Black participants. This large gap between Black participants and non-Black participants narrows as both cohorts adopt an exercise regimen.

The body mass index covariate revealed a positive association with AST, GGT, C4 complement, haptoglobin, and transferrin. Obese participants showed more occurrences of nonalcohol-related chronic liver disease and cirrhosis, other liver disorders, hepatomegaly, and abnormal α -2-macroglobulin values

than participants who were not obese. The same correlation to obesity has been reported among the general U.S. population (102, 103).

As expected, current alcohol use was associated with elevations of ALT, cholesterol, and other laboratory tests. Heavier drinkers had a greater percentage of abnormally high direct bilirubin values than did lighter drinkers. The GGT level was increased in patients with a lifetime alcohol history; the heaviest lifetime drinkers had the highest percentage of abnormal GGT levels. The frequencies of alcohol-related liver disease and cirrhosis, enlarged liver, prior hepatitis B infection, and antibodies for hepatitis C were all greater among the heaviest lifetime drinkers. All of these findings were reported previously in the general U.S. population (103).

In the 2002 follow-up examination, after adjusting for covariates, there were significant increases for subsets of Ranch Hands relative to Comparisons in the percentage of abnormally high alkaline phosphatase values, elevated triglyceride values, and abnormally high α -1-antitrypsin values. Mean C4 complement levels were significantly lower in Ranch Hands and mean haptoglobin and prothrombin time levels were significantly higher. Ranch Hand groundcrew had a significantly higher percentage of abnormally elevated alkaline phosphatase levels, as well as abnormally high triglyceride levels, relative to Comparisons. These significant results, when examined collectively, do not appear to represent a significant association with liver disease and do not provide evidence for liver disease associated with herbicide exposure or dioxin body burden. One cannot confirm with certainty, however, the cause of these abnormal alkaline phosphatase and triglyceride values. In general, the alkaline phosphatase level is elevated in infiltrative or cholestatic liver disorders, most commonly fatty liver due to diabetes, obesity, or hyperlipidemia and less commonly due to homeostatic drug injury, primary biliary cirrhosis, or bile duct obstruction.

The elevations of two protein variables— α -1-antitrypsin and haptoglobin—yielded statistically significant overall differences, with Ranch Hands adversely affected. In both instances, however, the prevalence of abnormalities was similar in each cohort. There is no known association between liver disease and high α -1-antitrypsin levels or high haptoglobin levels (low α -1-antitrypsin levels, however, are associated with a hereditary form of a liver disorder).

Likewise, a lower mean C4 complement value was seen in Ranch Hand officers and for extrapolated initial dioxin within Ranch Hands. As initial dioxin increased, C4 complement values decreased. The presence of lower mean C4 complement values has no clinically significant meaning. In general, patients with cirrhosis of the liver may have lower complement values, but these are typically seen in association with overall diminishment of protein albumin and prothrombin production. Therefore, if cirrhosis was present, it is unlikely that lower complement values would be seen as an isolated laboratory value abnormality.

The significantly higher mean prothrombin time seen in Ranch Hands in the background dioxin category was not clinically significant and has no known association with significant liver disease in the range of values noted. Prolongation of a prothrombin time typically has clinical significance if there is an increase of at least 2 seconds and preferably 4 seconds in prothrombin time above control.

Although no overall group differences were defined in analyses of both continuous and discrete forms of the data, previous analysis yielded elevations of ALT, AST, and GGT associated with 1987 dioxin levels. The current analysis shows association with serum alkaline phosphatase levels, triglyceride levels, and protein levels, as described above. The alkaline phosphatase, triglycerides, and protein results, while consistent with a dose-response effect, may be explained on the basis of hyperlipidemia and fatty

infiltration of the liver in association with obesity. A causal relation with prior dioxin exposure remains to be established.

In summary, the dependent variable-covariate associations reported have, in general, also been reported in the U.S. population as a whole. These include the association with current and lifetime alcohol consumption, race differences—especially those seen in Black males, the association of liver test abnormalities with body mass index, and the presence of antibodies against hepatitis A associated with age. There was no clear relation between herbicide exposure or dioxin and any of the abnormalities, although based on the analysis of triglycerides, a subtle relation between dioxin and lipid metabolism cannot be excluded.

13.4 SUMMARY

The gastrointestinal assessment was based on data gathered from the participant questionnaire and subsequently verified by a review of medical records, physical examination, and laboratory. Associations with herbicide exposure (i.e., group – Model 1), initial dioxin (Model 2), categorized dioxin (Model 3), and 1987 dioxin levels (Model 4) were examined for each variable in the gastrointestinal assessment. The significant adjusted results are discussed in the sections below.

13.4.1 Model 1: Group Analysis

Among all participants, Ranch Hands had a significantly greater percentage of abnormal triglyceride values and a higher mean haptoglobin level than did Comparisons. The prevalence of prior hepatitis B infection, hepatitis C, and abnormal direct bilirubin values was lower among Ranch Hands than Comparisons.

Positive stool hemocult results were more prevalent among Ranch Hand officers than Comparison officers. In addition, Ranch Hand officers had a significantly lower mean C4 complement level than did Comparison officers. Ranch Hand officers, however, had a significantly lower mean serum amylase level and significantly fewer abnormal serum amylase values than Comparison officers. Ranch Hand officers also had fewer occurrences of prior hepatitis B infections than did Comparison officers.

Among enlisted groundcrew, Ranch Hands had significantly greater percentages of abnormal alkaline phosphatase and triglyceride values than Comparisons. Ranch Hand enlisted groundcrew had a significantly higher mean haptoglobin level than did Comparison enlisted groundcrew. Fewer occurrences of prior hepatitis B infection were seen among Ranch Hand enlisted groundcrew than among Comparison enlisted groundcrew.

The results of the group analysis are provided in Table 13-62.

^aA negative difference in means (Ranch Hand mean less than Comparison mean) was considered adverse to Ranch Hands for this variable. A positive difference in means (Comparison mean less than Ranch Hand mean) was considered adverse to Comparisons for this variable.

--: The analysis was not performed because of the sparse number of participants with an abnormality.

Note: NS or ns: Not significant ($p > 0.05$).

C: Continuous form of dependent variable.

D: Discrete form of dependent variable.

The p-value was given if $p \leq 0.05$. The relative risk was given in parentheses for a significant result from the analysis of a discrete dependent variable. The difference in means was given in parentheses for a significant result from the analysis of a continuous dependent variable.

A capital "NS" denotes a nonsignificant positive association. A lowercase "ns" denotes a nonsignificant inverse association.

13.4.2 Model 2: Initial Dioxin Analysis

As initial dioxin increased, serum amylase, α -1-acid glycoprotein, C4 complement, and haptoglobin decreased. The percentage of Ranch Hands with abnormally low C4 complement values increased with initial dioxin, but the percentage of Ranch Hands with abnormally high haptoglobin decreased. The results of all unadjusted and adjusted Model 2 analyses are summarized in Table 13-63.

^aA negative slope was considered adverse for this variable.

Note: NS or ns: Not significant (p>0.05).

C: Continuous form of dependent variable.

D: Discrete form of dependent variable.

The p-value was given if p≤0.05. The relative risk was given in parentheses for a significant result from the analysis of a discrete dependent variable. The slope was given in parentheses for a significant result from the analysis of a continuous dependent variable.

A capital “NS” denotes a nonsignificant positive association. A lowercase “ns” denotes a nonsignificant inverse association.

13.4.3 Model 3: Categorized Dioxin Analysis

Ranch Hands in the background dioxin category had a significantly higher mean prothrombin time than did Comparisons. There were fewer occurrences of prior hepatitis B infection, however, in Ranch Hands than in Comparisons.

Ranch Hands in the low dioxin category had greater percentages of abnormally high triglyceride and α -1-antitrypsin values than did Comparisons. There were significantly fewer occurrences of prior hepatitis B infections and abnormally low transferrin levels, however, among Ranch Hands in the low dioxin category than among Comparisons. In addition, Comparisons had significantly lower mean C3 complement and transferrin levels than did Ranch Hands.

Ranch Hands in the high dioxin category had a greater prevalence of abnormally high triglyceride levels than Comparisons.

Ranch Hands in the low and high dioxin categories combined had a higher mean haptoglobin level than Comparisons and a greater percentage of abnormally high triglyceride and α -1-antitrypsin values than Comparisons. Ranch Hands in the low and high dioxin categories combined, however, had fewer occurrences of jaundice and prior hepatitis B infections, as well as fewer abnormally high cholesterol and abnormally low transferrin values than Comparisons.

The results of all unadjusted and adjusted Model 3 analyses are summarized in Table 13-64.

13.4.4 Model 4: 1987 Dioxin Level Analysis

The Model 4 analysis showed that the percentage of Ranch Hands with abnormal triglyceride values significantly increased as 1987 dioxin increased. The prevalence of jaundice and abnormally low albumin values decreased with increasing 1987 dioxin. In addition, mean serum amylase and prothrombin time values significantly decreased with increasing 1987 dioxin. All results for Model 4 unadjusted and adjusted analyses are summarized in Table 13-65.

13.4.5 Summary of Significant Results

Table 13-66 summarizes the significant results ($p\leq 0.05$) for the adjusted analyses that were performed for the gastrointestinal assessment. The dependent variable and its table reference are listed, along with the model and the contrast or description of the model. The p-value is provided along with analysis statistics that correspond to the type of analysis that was performed (either continuous or discrete). A description of the analysis and the statistics that are presented is referenced under the “Note” column and is explained in footnotes.

Table 13-66. Summary of Results from Significant Adjusted Analyses in the Gastrointestinal Assessment (Continued)

- (a): Discrete variable: adjusted relative risk and 95% confidence interval were presented; percent abnormal was presented for each dioxin category in contrast.
- (b): Discrete variable: adjusted relative risk and 95% confidence interval were presented for a twofold increase in 1987 dioxin; percent abnormal was presented for each of three 1987 dioxin categories.
- (c): Discrete variable: adjusted relative risk and 95% confidence interval were presented; percent abnormal was presented for each exposure group in contrast.
- (d): Continuous variable: difference of adjusted means was presented; confidence interval was not presented because analysis was not performed on original scale; adjusted means were presented for each exposure group in contrast.
- (e): Continuous variable: slope and standard error were presented and were based on the natural logarithm of the dependent variable versus \log_2 (initial dioxin); adjusted means were presented for each of three initial dioxin categories.
- (f): Continuous variable: slope and standard error were presented and were based on the natural logarithm of the dependent variable versus \log_2 (1987 dioxin); adjusted means were presented for each of three 1987 dioxin categories.
- (g): Continuous variable: difference of adjusted means was presented; confidence interval was not presented because analysis was not performed on original scale; adjusted means were presented for each dioxin category in contrast.
- (h): Continuous variable: slope and standard error were presented and were based on the square root of the dependent variable versus \log_2 (initial dioxin); adjusted means were presented for each of three initial dioxin categories.
- (i): Discrete variable: adjusted relative risk and 95% confidence interval were presented for a twofold increase in initial dioxin; percent abnormal was presented for each of three initial dioxin categories.

^aA negative difference in means (Ranch Hand mean less than Comparison mean) was considered adverse to Ranch Hands for this variable. A positive difference in means (Comparison mean less than Ranch Hand mean) was considered adverse to Comparisons for this variable.

Note: RH = Ranch Hand.
C = Comparison.

Model 2: Low = 32–79 ppt; Medium = >79–199 ppt; High = >199 ppt (Ranch Hands who had a 1987 dioxin measurement greater than 10 ppt).

Model 3: Background (Ranch Hand): 1987 dioxin \leq 10 ppt.
Low (Ranch Hand): 1987 dioxin > 10 ppt, 10 ppt < initial dioxin \leq 118 ppt.
High (Ranch Hand): 1987 dioxin > 10 ppt, initial dioxin > 118 ppt.

Model 4: Low = \leq 7.8 ppt; Medium = >7.8–19.2 ppt; High = >19.2 ppt (Ranch Hands only).

13.5 CONCLUSION

The gastrointestinal assessment of the AFHS 2002 follow-up examination data consisted of the analysis of (1) 7 categories of liver disorders, which were based on self-reporting by participants and verified by a medical records review, (2) hepatomegaly (enlarged liver), as determined at the 2002 physical examination, and (3) 28 laboratory measurements. Laboratory tests are generally considered the most reliable method for identifying acute liver disease, because digestive symptoms are frequently nonspecific and intermittent and liver disorders are commonly asymptomatic. Furthermore, the detection of liver

enlargement on the sole basis of a physical examination may be confounded by factors such as obesity or obstructive airway disease.

Positive stool hemocult results were increased and mean C4 complement was decreased among Ranch Hand officers. Among enlisted groundcrew, Ranch Hands had greater percentages of abnormal alkaline phosphatase and triglyceride values than Comparisons. Ranch Hand enlisted groundcrew had a higher mean haptoglobin level.

As initial dioxin increased, C4 complement levels decreased and the percentage of Ranch Hands with abnormally low C4 complement values increased.

Ranch Hands in the low dioxin category, high dioxin category, and low and high dioxin categories combined had increased percentages of abnormally high triglyceride values. Ranch Hands in the low dioxin category and low and high dioxin categories combined had an increased prevalence of abnormally high α -1-antitrypsin values than did Comparisons. In the background dioxin category, Ranch Hands had a higher mean prothrombin time than Comparisons. In the low and high dioxin categories combined, Ranch Hands had a higher mean haptoglobin than Comparisons.

The percentage of Ranch Hands with abnormal triglyceride values significantly increased as 1987 dioxin increased.

There was no clear relation between herbicide exposure or dioxin levels and any of the abnormalities, although based on the analysis of triglycerides, a subtle relation between dioxin and lipid metabolism cannot be excluded.

14 DERMATOLOGY ASSESSMENT

14.1 INTRODUCTION

14.1.1 Background

The dermatology assessment of participants in the Air Force Health Study (AFHS) included the occurrence of self-reported acne and physical examination. Of particular interest was the detection of chloracne after exposure to herbicides and dioxin. Chloracne is recognized as a consequence of exposure to high levels of chlorophenols. Chloracne, however, usually appears after a short interval of exposure to dioxin, without a long latency period, and usually persists for 2 to 3 years. Therefore, primary lesions were not expected to be noted at the 2002 physical examination. No biopsies to confirm the diagnosis of chloracne were deemed necessary by the examining dermatologists. Consequently, analysis was limited to secondary lesions, such as scarring, hyperpigmentation, and depigmentation. If secondary lesions had been observed, chloracne might be suggested if the lesions had been found in the typical distribution areas of chloracne. In addition, the occurrence, duration, and location of acne were studied because of the absence of chloracne in AFHS veterans.

The analysis in this chapter is based on the participant-reported lifetime occurrence of acne, the occurrence of acne in relation to time of duty, and the location of acne (e.g., temples, eyes, ears). Acneiform lesions, acneiform scars, comedones, inclusion cysts, depigmentation, and hyperpigmentation, as found by a dermatologist upon a physical examination of the skin, also were studied to investigate whether there were any secondary lesions that could be suggestive of chloracne.

14.1.1.1 Organs/Diseases

Chloracne is a chronic acneiform eruption with a highly specific cutaneous distribution that was first described by Von Bettman in 1897 as an occupational disease in German industrial workers. It was not until 1957 that it became recognizable as a very specific, but not sensitive, consequence of exposure to high levels of chlorophenols (1, 2). Chronic conditions associated with severe chloracne include actinic elastosis, acne scars, and hypertrichosis (3, 4); epidermoid inclusion cysts seen in biopsy specimens are considered pathognomonic (5). The occurrence and severity of chloracne appear to be dose-related, but may depend on other factors, such as the route of administration, age, genetic predisposition, and the presence of acne vulgaris and other dermatoses (3, 6, 7). Literature reviews have described the unique clinical manifestations of chloracne (8-14), and case studies of humans exposed to dioxins have reported dermatologic effects (e.g., chloracne) described earlier in animals (10, 15-21). In one study, patients with chloracne following an industrial accident showed high dioxin serum concentrations, but chloracne did not appear to be a sensitive symptom of dioxin contamination, with some indication of a role of individual susceptibility (22).

14.1.1.2 Toxicology

Some of the first studies assayed the effects of chloracnegenic compounds using the rabbit's ear as a model (23, 24). Other experiments for such effects on hairless mice produced a variety of histopathologic changes, including hyperkeratotic changes in the sebaceous follicle with plugging of the orifice, hyperkeratinization of the stratum corneum, and keratin cyst formation (25-30). Chloracne and other dermal effects as a consequence of dioxin exposure also have been observed in monkeys (31), rats (32),

and domestic animals (33, 34); however, not all animal species appear sensitive to the chloracnegenic effects of dioxin (35).

A genetic basis for the dermal responses to dioxin has been described in selected laboratory animals. In one series of experiments, investigators found strain-specific differences in the cutaneous reactions of haired and hairless mice to the topical application of dioxin (36). The involvement of sebaceous glands and increased transglutaminase activity were noted in both strains, while epidermal proliferation and hyperkeratinization occurred in the responsive (haired) strain only. Furthermore, in a subsequent study at the same laboratory, these dioxin-induced dermal changes were associated with an increased density of Langerhans' cells in mouse skin unique to the responsive strain (37). These and other studies (26, 38, 39) suggest that these strain-specific responses are determined genetically, and evidence exists that they may be mediated by the aryl hydrocarbon (Ah) receptor (27, 40, 41).

14.1.1.3 Epidemiology

Several small case series evaluated dioxin exposure and the development of chloracne (42) and chloracne and serum dioxin levels (43). Other skin conditions sporadically reported in relation to dioxin exposure include red and irritated eyes, hyperpigmentation, actinic elastosis, Peyronie's disease, and porphyria cutanea tarda (14, 44, 45). Studies of dioxin-related chloracne included populations exposed to dioxin through environmental contamination (46-61), occupation (4, 7, 44, 62-68), and during service in Southeast Asia (SEA) (89-98).

One of the most severe human exposures to dioxin occurred consequent to the industrial explosion in Seveso, Italy, in 1976 (22, 46, 48-52, 55, 60, 61). In the area closest to the explosion, a median serum dioxin level of 443 parts per trillion (ppt) was measured immediately after the accident among residents older than 13 years (n=177); in areas farther away from the accident site, median serum dioxin levels were found to be 87 ppt in a lower-exposed area (n=54) and 15 ppt in the lowest-exposed area (n=17) (60). A total of 193 cases of chloracne was observed, including 86 females and 107 males. Eighty-eight percent of the cases were children under 15 years of age; only seven cases were found among adults older than 20 years of age (46). The acnegenic toxic action of dioxin exposure on the skin was thought to last about 2 years (50). The last chloracne cases in the Seveso population were detected in 1978 (50), and all but one case had clinically recovered by 1983 (46). No cases of chloracne were reported among 36 workers exposed to dioxins during the cleanup of a chemical spill in Seveso, Italy (62). In a residential population exposed to dioxins after waste byproducts contaminated with dioxin were mixed with oils and widely sprayed for dust control in residential areas in eastern Missouri, no cases of chloracne were observed (54, 56, 57).

Chloracne has been associated with occupational dioxin exposure in several cohorts, including workers in the United States (4, 64-66, 70, 71, 75, 80), Germany (63, 79, 81), Austria (76-78), China (68, 69), Czech Republic (42), Russia (43, 88), United Kingdom (86), and Italy (62). In a National Institute of Occupational Safety and Health study of 281 workers exposed to chemicals contaminated with dioxin, chloracne was associated with the highest serum dioxin levels (87). In a study of 2,192 Dow Chemical workers potentially exposed to dioxin between 1940 and 1982, almost 16 percent of the workers were found to have chloracne (64-66, 70, 99), and chloracne incidence was positively associated with measures of intensity and cumulative exposure to dioxins (64). Among 73 male employees in a U.S. herbicide production plant, chloracne was found in 18 percent of the workers; however, chloracne was not substantially correlated with indicators of potential dioxin exposure, such as job location within the plant and duration of employment (80). In a 2,4,5-T production facility, clinical evidence of chloracne was found in 55.7 percent of 204 workers exposed to dioxin in a process accident, and no cases of chloracne were observed among 163 unexposed workers (4). Cases of chloracne were not observed among 482 persons potentially exposed to dioxins after an electrical transformer fire in Binghamton, New York (71).

Two small studies (63, 72) of occupationally exposed German chemical plant employees found serum dioxin levels moderately correlated to the occurrence of chloracne (63), and positively correlated with duration of chloracne (72). After a 1953 chemical accident at a BASF facility in Germany, 102 of 158 men exposed to dioxin developed chloracne within 1 year of the accident (83), and estimates of cumulative serum dioxin levels were found to correlate well with the severity of chloracne (79). In a German cohort of chemical workers in six plants, no association overall was reported between chloracne status and serum dioxin levels; however, some positive correlations were observed for several individual plants (82).

A study of nine production workers within a larger cohort found that those with a history of chloracne had significantly higher median serum dioxin levels (340 ppt) compared to workers without chloracne and known occupational exposure (18 ppt), as well as 17 external controls (16 ppt) (76).

Studies of Vietnam veterans generally have not found an association between dioxin exposure and the occurrence of self-reported chloracne, most likely because small numbers of Vietnam veterans were exposed to high levels of dioxin. Dermatology examinations do not appear to reveal any confirmed cases of chloracne (89-97). In one study (91), veterans who served in Vietnam had a higher prevalence of self-reported cutaneous disease compared with controls; however, the diagnosis was not clinically confirmed and the exposure indices were not validated. In the Vietnam Experience Study, the occurrence of dermatologic disorders found upon physical examination was similar in Vietnam and non-Vietnam veterans (90). In a study of Korean Vietnam veterans published in 2003, the frequency of chloracne was similar among Vietnam veterans compared to non-Vietnam veterans, and no trends were seen across semi-quantitative levels of Agent Orange exposure among Vietnam veterans (98). The AFHS is unique among studies that have examined for chloracne in Vietnam veterans because serial serum dioxin data have been incorporated into longitudinal analyses (92-97). At the 1987 AFHS follow-up examination, a higher prevalence of self-reported acne after service in SEA was found among Ranch Hand personnel as contrasted with Comparison subjects (92). No Ranch Hands or Comparison subjects, however, were diagnosed with chloracne based on dermatologic examination, and little evidence for a difference between the Ranch Hands and the Comparison group in the prevalence of other skin conditions was observed (92). Also, in a 1998 publication based on data collected on veterans participating in the AFHS, the risk of acne on the temples, eyes, or ears was not related to serum dioxin levels (96).

In the 1994 report published by the Institute of Medicine (IOM), the Committee to Review the Health Effects in Vietnam Veterans of Exposure to Herbicides concluded that there is sufficient evidence of an association between exposure to dioxin and chloracne (100). This conclusion remained unaltered in the 2002 IOM report (45); however, the committee added a notation in this report that chloracne would appear shortly after dioxin exposure and not after a long latency (45).

14.1.2 Summary of Previous Analyses of the Air Force Health Study

14.1.2.1 1982 Baseline Examination Summary Results

The 1982 baseline examination focused on the diagnosis of chloracne both in historical terms by a detailed questionnaire and in contemporary terms through a comprehensive clinical assessment. The questionnaire data did not demonstrate anatomic, prevalence, or onset-time patterns of acne in the Ranch Hand group that might support an inference of past chloracne, nor did the physical examination detect a case of chloracne. Fourteen biopsies from 11 participants also did not document a chloracne diagnosis, nor did the physical examination detect a case of chloracne. A dermatology index (a composite of the dependent variables comedones, acneiform lesions, acneiform scars, and inclusion cysts) was similar in the Ranch Hand and Comparison groups. No exposure index associations were noted in any occupational

category of the Ranch Hand group. The comprehensive dermatology assessment did not reveal evidence of past or current chloracne in the Ranch Hand group.

14.1.2.2 1985 Follow-up Examination Summary Results

Data from the 1985 follow-up examination participant questionnaire updated information gathered on acne through the 1982 baseline questionnaire, and the physical examination endpoints were similar to the 1982 baseline examination. Data on the occurrence, time, and location of acne were analyzed to assess the possible historical diagnosis of chloracne. No significant difference was observed between groups for reported occurrence or duration of acne.

For participants with acne after the start of the first qualifying tour of duty in SEA, the spatial eyeglass distribution of acne (suggesting chloracne) was observed to be similar for the Ranch Hand and Comparison groups, both for individual sites and the combination of acne on the temples, eyes, or ears. This analysis suggested that the occurrence of skin disease compatible with chloracne was not different in the two groups.

Analyses of the 1985 follow-up physical examination data, as with the baseline examination, placed primary emphasis on six dermatologic disorders: comedones, acneiform lesions, acneiform scars, inclusion cysts, depigmentation, and hyperpigmentation. The adjusted analyses showed no significant difference noted between groups for any variable. Exposure index analyses did not reveal a meaningful pattern of results suggesting a relation between skin disease and herbicide exposure.

Overall, the 1985 follow-up examination results paralleled the 1982 baseline examination findings. The 1985 follow-up examination detected more dermatologic abnormalities than those present at the baseline examination, and slightly more abnormalities were found in the Comparisons, but the contrasts of Ranch Hands and Comparisons were nonsignificant.

14.1.2.3 1987 Follow-up Examination Summary Results

With the exception of more Ranch Hands than Comparisons reporting acne during their lifetime, no significant group differences were detected. Subsequent analysis of the occurrence of acne indicated that, for participants with no history of acne before the start of the first SEA duty, a higher percentage of Ranch Hands than Comparisons reported the occurrence of acne after the start of the first SEA duty. The anatomic distribution of these lesions, however, did not suggest chloracne as a cause. No cases of chloracne were diagnosed in the physical examination. Analyses were conducted on historical occurrence and duration of acne, six dermatologic disorders, a composite variable of other disorders, and a dermatology index combining four disorders. All of these analyses found no significant group differences. The longitudinal analysis, based on the dermatology index, showed no significant differences between groups over time.

14.1.2.4 Serum Dioxin Analysis of 1987 Follow-up Examination Summary Results

For Ranch Hands who reported acne prior to the start of their first qualifying tour of duty in SEA, acne after the start of the first SEA duty increased as initial dioxin increased. Of the physical examination variables, only hyperpigmentation had a significant positive association with initial dioxin.

A significant positive association between 1987 dioxin and the occurrence of reported acne (lifetime) was seen for Ranch Hands who served in SEA during a later qualifying tour of duty. Further stratified analysis suggested that this association was related to acne after the start of the first SEA qualifying tour in Ranch Hands who had a history of acne prior to service in SEA. Lifetime acne was stratified further by

presence of acne prior to service in SEA (“pre-SEA acne” – yes or no), and the presence of acne after the beginning of service in SEA was analyzed separately for each pre-SEA acne stratum. These stratified analyses suggested that this significant positive association between lifetime acne and 1987 dioxin was related to acne after the start of the first SEA qualifying tour in Ranch Hands who had a history of acne prior to service in SEA. Several of the physical examination variables also had significant positive associations with 1987 dioxin levels for Ranch Hands who served in SEA during a later qualifying tour of duty.

No significant differences were found between the low and background dioxin categories or between the high and background categories for any of the variables. No cases of chloracne were identified, nor were there any dermatologic endpoints consistently related to the 1987 dioxin level. Also, the longitudinal analysis of the dermatology index showed no significant associations with dioxin. In summary, there was no consistent evidence in these data to suggest a dioxin association on the dermatologic system.

14.1.2.5 1992 Follow-up Examination Summary Results

In general, the dermatology variables showed no significant differences between Ranch Hands and Comparisons, except for a few significant increases in occurrence of acne for Ranch Hand enlisted groundcrew participants. The analyses of categorized dioxin also indicated a significantly lower occurrence of dermatology index abnormalities for Ranch Hands in the low and high dioxin categories combined than for Comparisons. The analysis of dermatology index exhibited a significant inverse association with 1987 dioxin.

In summary, there was no consistent evidence in these data to suggest an adverse dioxin association on the skin at doses received by U.S. military personnel in SEA.

14.1.2.6 1997 Follow-up Examination Summary Results

Dermatology endpoints were not analyzed statistically for the 1997 AFHS follow-up examination report.

14.1.3 Parameters for the 2002 Dermatology Assessment

14.1.3.1 Dependent Variables

The dermatology assessment was based on physical examination data and information regarding acne, as obtained in a face-to-face interview with the participant.

14.1.3.1.1 Questionnaire Variables

During the health interview conducted as part of the questionnaire, each study participant was asked about occurrences of acne on the face since the date of the last health interview. This information was used to update data gathered through the AFHS 1997 follow-up examination. Information regarding the date and location of each acne occurrence also was collected. In most other clinical areas of the AFHS, data obtained from the health interview underwent verification by requesting medical records from the participants’ physicians. It was expected that the majority of participants who reported acne, however, did not visit a physician for the acne. Consequently, the analysis of acne was based on participant-reported occurrences. The analyses performed in this chapter were based on the 1,951 participants who attended the 2002 follow-up examination.

The variables defined below were constructed from the acne data and analyzed in the dermatology assessment. The following four-cell diagram is used to aid in determining which subsets of participants were used in the analysis and were contrasted with each other.

Pre-SEA Acne	Post-SEA Acne	
	Yes	No
Yes	Cell 1	Cell 2
No	Cell 3	Cell 4

The sample size in each of these four cells is presented below:

Pre-SEA Acne	Post-SEA Acne	
	Yes	No
Yes	n=264	n=400
No	n=180	n=1,106

- Acne (lifetime):
 - Yes: at least one reported occurrence of acne (cells 1, 2, and 3)
 - No: no reported occurrences of acne (cell 4).
- Post-SEA Acne
 - Yes: at least one occurrence of acne that ended after the start of the participant's first qualifying tour of duty in SEA (cells 1 and 3)
 - No: all occurrences of acne ended before the start of the participant's first qualifying tour of duty in SEA (cell 2) or no reported occurrences of acne (cell 4).

Acne after the start of the first SEA duty (post-SEA acne) was further analyzed by examining if the occurrence of acne after duty in SEA may have been affected by whether the participant had acne prior to the start of his first qualifying tour of duty in SEA (pre-SEA acne). In particular, post-SEA acne was analyzed separately for two subsets of participants: (1) participants who had no acne prior to the start of their first qualifying tour of duty in SEA (no pre-SEA acne), and (2) participants who had at least one occurrence of acne prior to the start of their first qualifying tour of duty in SEA (with pre-SEA acne). That is,

- Post-SEA Acne (no pre-SEA acne)
 - Yes: first occurrence of acne began after the start of the participant's first qualifying tour of duty in SEA (cell 3)
 - No: no reported occurrences of acne (cell 4)

and

- Post-SEA Acne (with pre-SEA acne)
 - Yes: first occurrence of acne began before the start of the participant's first qualifying tour of duty in SEA and last occurrence of acne ended after the start of the participant's first qualifying tour of duty in SEA (cell 1)
 - No: all occurrences of acne ended prior to the start of the first duty in SEA (cell 2).

Location and duration of post-SEA acne were analyzed twice. Post-SEA acne, however, may occur with or without the presence of pre-SEA acne. One analysis included participants who had all their

occurrences of acne after the start of their first qualifying tour of duty in SEA (post-SEA acne, but no pre-SEA acne – cell 3) and thus may be a result of herbicide exposure. The second analysis included any participants who had an occurrence of acne after the start of their first qualifying tour of duty in SEA, regardless of whether they had pre-SEA acne (post-SEA acne, cells 1 and 3). Acne for this subset of participants may have been the result of herbicide exposure, but their post-SEA acne may have also been related to the presence of acne before their qualifying tour of duty.

Questions regarding the presence of acne emphasized acne on the temples, eyes, or ears, as acne on these locations may have been related to chloracne. Participant medical records were reviewed to determine if acne had been observed on the periumbilical or scrotal regions, but no occurrences in these regions were observed.

Location of acne was tabulated as follows:

- Temples
- Eyes (or eyelids)
- Ears
- Temples and eyes (or eyelids)
- Temples and ears
- Eyes (or eyelids) and ears
- Temples, eyes (or eyelids), and ears
- Other sites.

Note: If an individual had multiple-site involvement for one or more of the specified sites and for the category “other sites,” then the specified site(s) category was assigned.

Total duration of acne was determined by adding the duration of each reported occurrence of acne from all AFHS questionnaires.

14.1.3.1.2 Physical Examination Variables

Six dermatologic conditions noted at the physical examination and a composite dermatologic index were analyzed. The following conditions were reported: acneiform lesions, acneiform scars, comedones, inclusion cysts, depigmentation, and hyperpigmentation of the skin. Depigmentation and hyperpigmentation were defined as areas of skin that were less or more pigmented relative to the rest of the skin. The dermatology index was created by combining results from the examination for comedones, acneiform lesions, acneiform scars, and inclusion cysts. A participant was defined as abnormal for this dermatology index if any of these conditions was present and defined as normal if none was present. No participants were excluded for medical reasons from the analyses of these variables. Abnormalities relating to skin malignancies were discussed in Chapter 10, Neoplasia Assessment.

14.1.3.2 Covariates

The covariates age, race, and occupation were used in all adjusted statistical analyses. Presence of pre-SEA was used as a covariate for the physical examination variables and was defined as “yes” if at least one occurrence of acne began before the start of the participant’s first qualifying tour of duty in SEA (cells 1 and 2) and “no” otherwise (cells 3 and 4).

14.1.4 Statistical Methods

Table 14-1 summarizes the statistical analysis performed for the 2002 dermatology assessment. The first part of this table lists the dependent variables analyzed, source of the data, form of the data, cutpoints, covariates, exclusions, and statistical methods. The second part of this table further describes the covariates. A covariate was used in its continuous form whenever possible for adjusted analyses. If the covariate was inherently discrete (e.g., military occupation), or if a categorized form was needed to develop measures of association with the dependent variables, the covariate was categorized as shown in Table 14-1.

Table 14-1. Statistical Analysis for the Dermatology Assessment

Dependent Variables

Four models were examined for each dependent variable given in Table 14-1. The analyses of these models are presented below. Further details on dioxin and the modeling strategy are found in Chapters 2 and 7, respectively. These analyses were performed both unadjusted and adjusted for covariates. These covariates are given in Table 14-1. Model 1 examined the relation between the dependent variable and group (i.e., Ranch Hand or Comparison). In this model, exposure was defined as “yes” for Ranch Hands and “no” for Comparisons without regard to the magnitude of the exposure. In an attempt to quantify exposure, three contrasts of Ranch Hands and Comparisons were performed along with the overall Ranch Hand versus Comparison contrast. These three contrasts compared Ranch Hands and Comparisons within each military occupational category (i.e., officers, enlisted flyers, and enlisted groundcrew). As described in previous reports and Table 2-4, the median level of exposure to dioxin was highest for enlisted groundcrew, followed by enlisted flyers, then officers.

During the 1987, 1992, 1997, and 2002 examinations, serum dioxin levels were measured by the Centers for Disease Control and Prevention (CDC) using high-resolution gas chromatography and high-resolution mass spectrometry and were reported in ppt on a lipid weight basis (101). These dioxin measurements are referred to as “lipid-adjusted.” All measures of dioxin used in this report were based on lipid-adjusted dioxin measurements.

Model 2 examined the relation between the dependent variable and an extrapolated initial dioxin measure for Ranch Hands who had a 1987 dioxin measurement greater than 10 ppt. The initial dioxin was calculated by extrapolating the 1987 dioxin level back in time to the end of the tour of duty that qualified a Ranch Hand veteran for inclusion in this study. If a Ranch Hand did not have a 1987 dioxin level, then the first dioxin measured, either at 1992, 1997, or 2002, was used to estimate the initial dioxin level. Regardless of when the dioxin was measured, Ranch Hand veterans with a level less than or equal to 10 ppt were excluded from statistical analyses based on Model 2. A statistical adjustment for body mass index at the time of the participant’s blood measurement of dioxin was included in this model to account for body mass index-related differences in elimination rate (102).

Model 3 divided the Ranch Hands examined in Model 2 into two categories based on their initial dioxin measures. These two categories were referred to as “low Ranch Hand” and “high Ranch Hand.” Two additional categories—Ranch Hands with serum dioxin levels at or below 10 ppt and Comparisons—were formed and included in the model. Ranch Hands with serum dioxin levels at or below 10 ppt were assigned to the “background Ranch Hand” category. If a Ranch Hand did not have a 1987 dioxin measurement, the first measured dioxin level was used. Another category was examined by combining the low and high Ranch Hand categories. This combination is referred to in the tables as the “low plus high Ranch Hand” category. These five categories—Comparisons, background Ranch Hands, low Ranch Hands, high Ranch Hands, and low plus high Ranch Hands—were used in Model 3 analyses. The relation between the dependent variable in each of the four Ranch Hand categories and the dependent variable in the Comparison category was examined. As in Model 2, a statistical adjustment for body mass index at the time of the participant’s blood measurement of dioxin was included in this model for the unadjusted and adjusted analyses of all dependent variables. One Ranch Hand without a dioxin measure was excluded from statistical analyses based on Model 3.

Model 4 examined the relation between the dependent variable and 1987 dioxin levels in all Ranch Hands with a dioxin measurement. If a Ranch Hand did not have a 1987 dioxin measurement, the first dioxin level obtained, either in 1992, 1997, or 2002, was extrapolated to the date of the 1987 physical examination. If the first dioxin level was not obtained in 1987 and was less than or equal to 10 ppt, it was not extrapolated to 1987 level, but was used at the measured value. One Ranch Hand without a dioxin measurement was excluded from statistical analyses based on Model 4.

The term “unadjusted” was used in the text and tables as follows: Models 1 and 4 did not adjust for any covariates. Models 2 and 3 adjusted only for body mass index at the time of the blood measurement for dioxin. The term “adjusted” was used in the text and tables as follows: Models 1 and 4 adjusted for the covariates shown in Table 14-1 unless otherwise specified by a footnote to the table. Models 2 and 3 additionally adjusted only for body mass index at the time of the blood measurement for dioxin.

Table 14-2 provides a summary of the number of participants with missing dependent variable and covariate data. In addition, the number of participants that were excluded from analyses is given.

Table 14-2. Number of Participants with Missing Data for the Dermatology Assessment

Variable	Variable Use	Group ^a		Dioxin (Ranch Hands Only) ^b		Categorized Dioxin ^c	
		Ranch Hand	Comparison	Initial Dioxin	1987 Dioxin	Ranch Hand	Comparison
Time Reference Relative to SEA (pre-SEA or post-SEA)	DEP/EXC	0	1	0	0	0	1
Location of Post-SEA Acne	DEP	3	3	2	3	3	3
Duration of Post-SEA Acne	DEP	3	8	2	3	3	8
Presence of Pre-SEA Acne	COV	0	1	0	0	0	1

^a777 Ranch Hands and 1,174 Comparisons for group.

^b424 Ranch Hands for initial dioxin; 776 Ranch Hands for 1987 dioxin.

^c776 Ranch Hands and 1,174 Comparisons for categorized dioxin.

Note: DEP = Dependent variable.

COV = Covariate.

EXC = Exclusion.

14.2 RESULTS

14.2.1 Dependent Variable-covariate Associations

The dermatology dependent variables were tested for associations with each of the covariates used in the adjusted analyses. The complete results are presented in Appendix F, Table F-6. These associations were pairwise between the dependent variable and the covariate and were not adjusted for any other covariates. A brief summary of the pattern of significant ($p \leq 0.05$) dependent variable-covariate associations is described in the following paragraphs.

Younger participants reported acne at some point in their lifetimes and acne after service in SEA more often than older participants. Younger participants had more acneiform lesions and acneiform scars than older participants. A greater prevalence of comedones and hyperpigmentation was found among older participants than among younger participants.

For participants who reported acne after service in SEA but not prior to service in SEA, Black participants reported acne more often than non-Black participants. On average, non-Black participants reported a longer duration of acne after the start of the first SEA duty than Black participants. Black participants

had more hyperpigmentation than non-Black participants. Non-Black participants had more abnormalities on the dermatology index than Black participants.

Enlisted groundcrew reported more acne after service in SEA than enlisted flyers, and enlisted flyers reported more acne after service in SEA than officers. Enlisted personnel had more acneiform lesions, comedones, and more abnormalities on the dermatology index than officers.

Participants who reported acne prior to service in SEA had more acneiform lesions, acneiform scars, comedones, inclusion cysts, and abnormalities on the dermatology index than participants who did not report acne prior to service in SEA.

14.2.2 Exposure Analysis

The following section presents results of the statistical analyses of the dependent variables shown in Table 14-1. Dependent variables are grouped into two sections: (1) the questionnaire variables, derived from the questionnaire that was administered during the 2002 follow-up and previous AFHS examinations, and (2) variables obtained during the 2002 physical examination.

14.2.2.1 Questionnaire Variables

14.2.2.1.1 Acne (Lifetime)

The unadjusted and adjusted Model 1 analyses of self-reported acne over the lifetime of the participant revealed significant differences between all Ranch Hands and Comparisons (Table 14-3(a,b): Unadjusted Relative Risk [RR]=1.32, $p=0.003$; Adjusted RR=1.34, $p=0.002$). A greater percentage of Ranch Hands reported acne during their lifetime (47.5%) than did Comparisons (40.6%). After stratifying by military occupation, both the unadjusted and adjusted analyses showed a significant difference between Ranch Hand and Comparison enlisted groundcrew (Table 14-3(a,b): Unadjusted RR=1.64, $p<0.001$, Adjusted RR=1.61, $p<0.001$). A greater percentage of Ranch Hand enlisted groundcrew reported an occurrence of acne during their lifetime than Comparison enlisted groundcrew (52.8% versus 40.6%, respectively).

No significant relation between initial dioxin and lifetime occurrence of acne was seen in the unadjusted and adjusted Model 2 analyses (Table 14-3(c,d): $p>0.05$ for each analysis).

The unadjusted Model 3 analysis revealed three significant contrasts: Ranch Hands in the low dioxin category versus Comparisons (Table 14-3(e): Unadjusted RR=1.48, $p=0.010$), Ranch Hands in the high dioxin category versus Comparisons (Table 14-3(e): Unadjusted RR=1.42, $p=0.019$), and Ranch Hands in the low and high dioxin categories combined versus Comparisons (Table 14-3(e): Unadjusted RR=1.45, $p=0.001$). After adjusting for covariates, two contrasts remained significant: Ranch Hands in the low dioxin category versus Comparisons and Ranch Hands in the low and high dioxin categories combined versus Comparisons (Table 14-3(f): Adjusted RR=1.63, $p=0.002$; and Adjusted RR=1.45, $p=0.002$, respectively). The percentage of Ranch Hands in the low dioxin category who reported an occurrence of acne during their lifetime was 50.2 percent compared to 40.6 percent for Comparisons. In the low and high dioxin categories combined, 49.8 percent for Ranch Hands reported an occurrence of acne during their lifetime. All remaining unadjusted and adjusted Model 3 contrasts were not significant (Table 14-3(e,f): $p>0.09$ for each contrast).

All unadjusted and adjusted Model 4 analyses were nonsignificant (Table 14-3(g,h): $p>0.33$ for each analysis).

14.2.2.1.2 Post-SEA Acne

The unadjusted and adjusted Model 1 analyses of acne after service in SEA revealed significant differences between Ranch Hands and Comparisons for all participants (Table 14-4(a,b): Unadjusted RR=1.40, p=0.002; Adjusted RR=1.43, p=0.001). A greater percentage of Ranch Hands reported acne after service in SEA (26.4%) than did Comparisons (20.4%). After stratifying by military occupation, both the unadjusted and adjusted analyses showed a significant difference between Ranch Hand and Comparison enlisted groundcrew (Table 14-4(a,b): Unadjusted RR=1.62, p=0.001, Adjusted RR=1.60, p=0.003). A greater percentage of Ranch Hand enlisted groundcrew reported acne after service in SEA than Comparison enlisted groundcrew (35.0% versus 24.9%, respectively).

All unadjusted and adjusted Model 2 and 4 analyses of acne after service in SEA were nonsignificant (Table 14-4(c,d,g,h): p>0.16 for each analysis).

The unadjusted Model 3 analysis revealed significant differences in acne after service in SEA between Ranch Hands in the low dioxin category and Comparisons (Table 14-4(e): Unadjusted RR=1.47, p=0.023), between Ranch Hands in the high dioxin category and Comparisons (Table 14-4(e): Unadjusted RR=1.58, p=0.006), and between Ranch Hands in the low and high dioxin categories combined and Comparisons (Table 14-4(e): Unadjusted RR=1.53, p=0.001). After covariate adjustment, the contrast between Ranch Hands in the high dioxin category and Comparisons was no longer significant (Table 14-4(f): p=0.332). The contrast between Ranch Hands in the background dioxin category and Comparisons, however, became significant (Table 14-4(f): Adjusted RR=1.49, p=0.009). The difference between Ranch Hands in the low dioxin category and Comparisons, as well as the difference between Ranch Hands in the low and high dioxin categories combined and Comparisons, remained significant (Table 14-4(f): Adjusted RR=1.68, p=0.003; and Adjusted RR=1.41, p=0.011, respectively). The percentage of participants reporting acne after service in SEA was 23.9 percent for Ranch Hands in the background dioxin category, 27.5 percent for Ranch Hands in the low dioxin category, 29.1 percent for

Ranch Hands in the high dioxin category, 28.3 percent for Ranch Hands in the low and high dioxin categories combined, and 20.4 percent for Comparisons.

Table 14-4. Analysis of Post-SEA Acne

(a) MODEL 1: RANCH HANDS VS. COMPARISONS – UNADJUSTED					
Occupational Category	Group	n	Number (%) Yes	Unadjusted Relative Risk (95% C.I.)	p-Value
<i>All</i>	<i>Ranch Hand</i>	777	205 (26.4)	<i>1.40 (1.13,1.73)</i>	<i>0.002**</i>
	<i>Comparison</i>	1,173	239 (20.4)		
Officer	Ranch Hand	307	53 (17.3)	1.09 (0.74,1.61)	0.649
	Comparison	462	74 (16.0)

14.2.2.1.3 Post-SEA Acne (No Pre-SEA Acne)

In an attempt to determine whether self-reported acne after service in SEA was related to the presence of acne prior to duty in SEA, two analyses were performed: reported acne after service in SEA without the presence of acne prior to service (this section), and reported acne after service in SEA along with the presence of acne prior to service in SEA (Section 14.2.2.1.4).

For participants who did not report acne prior to service in SEA, the unadjusted and adjusted Model 1 analyses of acne after service in SEA revealed a significant group difference between all Ranch Hands and Comparisons (Table 14-5(a,b): Unadjusted RR=1.70, p=0.001; Adjusted RR=1.78, p<0.001). After stratifying by military occupation, a significant difference in reported acne was observed between Ranch Hand and Comparison enlisted groundcrew in both the unadjusted and adjusted analyses (Table 14-5(a,b): Unadjusted RR=2.14, p<0.001; Adjusted RR=2.15, p<0.001). For all participants who did not report acne prior to service in SEA, Ranch Hands had a greater percentage of reported acne after service in SEA than Comparisons (18.0% versus 11.4%). Among enlisted groundcrew who did not report acne prior to service in SEA, Ranch Hands had a greater percentage of acne after service in SEA than Comparisons (26.3% versus 14.2%).

All unadjusted and adjusted Model 2 and 4 analyses of acne after service in SEA (for participants with no report of acne prior to service in SEA) were nonsignificant (Table 14-5(c,d,g,h): p>0.08 for each analysis).

The unadjusted Model 3 analysis revealed three significant contrasts for acne after service in SEA: Ranch Hands in the low dioxin category versus Comparisons (Table 14-5(e): Unadjusted RR=1.99, p=0.005), Ranch Hands in the high dioxin category versus Comparisons (Table 14-5(e): Unadjusted RR=2.19, p<0.001), and Ranch Hands in the low and high dioxin categories combined versus Comparisons (Table 14-5(e): Unadjusted RR=2.09, p<0.001).

After adjusting for covariates, all four Model 3 contrasts were significant (Table 14-5(f): Adjusted RR=1.60, p=0.046 for Ranch Hands in the background dioxin category versus Comparisons; Adjusted RR=2.19, p=0.002 for Ranch Hands in the low dioxin category versus Comparisons; Adjusted RR=1.72, p=0.026 for Ranch Hands in the high dioxin category versus Comparisons; and Adjusted RR=1.93, p<0.001 for Ranch Hands in the low and high dioxin categories combined versus Comparisons). Among participants who did not report acne prior to service in SEA, the percentages of Ranch Hands reporting acne after service in SEA in the background dioxin category, low dioxin category, high dioxin category, and low and high dioxin categories combined were 14.1, 20.5, 22.1, and 21.3, respectively. Among Comparisons who did not report acne prior to service in SEA, 11.4 percent reported acne after service in SEA.

14.2.2.1.4 Post-SEA Acne (with Pre-SEA Acne)

For participants who did report acne prior to service in SEA, all unadjusted and adjusted Model 1 through 4 analyses of reported acne after service in SEA were nonsignificant (Table 14-6(a-h): $p > 0.15$ for each analysis). In comparing the results of this section and Section 14.2.2.1.3, it can be seen that the significant relations between either group or dioxin and the reporting of acne after service in SEA were confined to participants who did not report acne prior to service in SEA (see Tables 14-4 and 14-5).

14.2.2.1.5 Location of Post-SEA Acne (Excluding Participants with Pre-SEA Acne)

The number of participants who reported acne after service in SEA is presented by location in Table 14-7. This table includes data on those participants who reported acne only after service in SEA.

Table 14-7. Location of Post-SEA Acne (Excluding Participants with Pre-SEA Acne)

Location	Group Sample Size	
	Ranch Hand	Comparison
Temples Only	11	14
Eyes (or Eyelids) Only	1	2
Ears Only	2	5
Temples and Eyes (or Eyelids)	3	0
Temples and Ears	2	2
Eyes (or Eyelids) and Ears	2	1
Temples, Eyes (or Eyelids), and Ears	5	2
Other Sites	62	63
Total	88	89

Location	Initial Dioxin Sample Size	1987 Dioxin Sample Size
Temples Only	7	11
Eyes (or Eyelids) Only	1	1
Ears Only	2	2
Temples and Eyes (or Eyelids)	2	3
Temples and Ears	1	2
Eyes (or Eyelids) and Ears	1	2
Temples, Eyes (or Eyelids), and Ears	3	5
Other Sites	39	62
Total	56	88

**Table 14-7. Location of Post-SEA Acne (Excluding Participants with Pre-SEA Acne)
(Continued)**

Location	Comparison	Dioxin Category			
		Background Ranch Hand	Low Ranch Hand	High Ranch Hand	Low plus High Ranch Hand
Temples Only	14	4	4	3	7
Eyes (or Eyelids) Only	2	0	0	1	1
Ears Only	5	0	2	0	2
Temples and Eyes (or Eyelids)	0	1	1	1	2
Temples and Ears	2	1	0	1	1
Eyes (or Eyelids) and Ears	1	1	0	1	1
Temples, Eyes (or Eyelids), and Ears	2	2	0	3	3
Other Sites	63	23	19	20	39
Total	89	32	26	30	56

The percentage of participants who reported acne on the temples, eyes, or ears after service in SEA was compared to the percentage of participants who reported acne after service in SEA on other sites. This analysis was restricted to participants who reported acne only after service in SEA. The relation between this comparison and either group or dioxin is given in Table 14-8. No significant results were seen in the unadjusted and adjusted Model 1 through 4 analyses of location of acne after service in SEA, where participants who reported acne prior to service in SEA were excluded (Table 14-8(a-h): $p > 0.13$ for each analysis).

14.2.2.1.6 Location of Post-SEA Acne (All Post-SEA Occurrences)

The number of participants who reported acne after service in SEA is presented by location in Table 14-9. Participants who reported acne after service in SEA are included in this table, regardless of whether they reported acne prior to service in SEA.

Table 14-9. Location of Post-SEA Acne (All Post-SEA Occurrences)

Location	Group Sample Size	
	Ranch Hand	Comparison
Temples Only	28	37
Eyes (or Eyelids) Only	3	4
Ears Only	9	13
Temples and Eyes (or Eyelids)	5	2
Temples and Ears	13	16
Eyes (or Eyelids) and Ears	3	2
Temples, Eyes (or Eyelids), and Ears	13	8
Other Sites	128	154

Temples, Eyes (or Eyelids), and Ears	8	4	4	5	9
Other Sites	154	52	36	40	76
Total	236	83	57	61	118

The percentage of participants who reported acne on the temples, eyes, or ears after service in SEA was compared to the percentage of participants who reported acne after service in SEA on other sites. This analysis included all participants who reported acne after service in SEA regardless of whether they reported acne prior to service in SEA. The relation between this comparison and either group or dioxin is given in Table 14-10. The unadjusted and adjusted Model 1 through 4 analyses of location of reported acne after service in SEA revealed no significant results (Table 14-10(a-h): $p > 0.45$ for each analysis).

14.2.2.1.7 Duration of Post-SEA Acne (Excluding Participants with Pre-SEA Acne)

No significant group differences were revealed in the unadjusted and adjusted Model 1 analyses of duration of acne after service in SEA (excluding participants who reported acne prior to service in SEA) (Table 14-11(a,b): $p > 0.08$ for each analysis).

Both the unadjusted and adjusted Model 2 analyses revealed significant positive associations between initial dioxin and duration of acne after service in SEA (Table 14-11(c,d): Slope=1.991, $p < 0.001$; Adjusted Slope=1.808, $p < 0.001$). The adjusted mean duration of acne after service in SEA in the low,

medium, and high initial dioxin categories was 17.75 months, 33.79 months, and 102.59 months, respectively.

The unadjusted Model 3 analysis revealed a significant difference in the duration of acne after service in SEA between Ranch Hands in the high dioxin category and Comparisons (Table 14-11(e): difference of means=63.97 months, $p<0.001$), as well as a significant difference between Ranch Hands in the low and high dioxin categories combined and Comparisons (Table 14-11(e): difference of means=27.75 months, $p=0.032$). After covariate adjustment, a significant difference was seen between Ranch Hands in the high dioxin category and Comparisons (Table 14-11(f): difference of adjusted means=54.28, $p=0.002$). Excluding participants who reported acne prior to service in SEA, the adjusted mean duration of acne after service in SEA was 104.25 months for Ranch Hands in the high dioxin category and 49.97 months for Comparisons. All remaining unadjusted and adjusted Model 3 contrasts were nonsignificant (Table 14-11(e,f): $p>0.07$ for each contrast).

The unadjusted and adjusted Model 4 analyses each revealed a significant positive association between 1987 dioxin and duration of acne after service in SEA (Table 14-11(g): Slope=1.103, $p<0.001$; Adjusted Slope=0.964, $p=0.002$). Excluding participants who reported acne prior to service in SEA, the adjusted mean duration of acne after service in SEA in the low, medium, and high 1987 dioxin categories was 29.90 months, 27.36 months, and 65.97 months, respectively.

14.2.2.1.8 Duration of Post-SEA Acne (All Post-SEA Occurrences)

All unadjusted and adjusted Model 1, 3, and 4 analyses of duration of acne after service in SEA were nonsignificant (Table 14-12(a,b,e-h): p>0.08 for each analysis).

The unadjusted Model 2 analysis showed a significant positive association between initial dioxin and duration of acne after service in SEA (when all participants with acne after service in SEA were included) (Table 14-12(c): Slope=0.903, p=0.034). After adjusting for covariates, however, the results were no longer significant (Table 14-12(d): p=0.067).

In comparing the results of this section and Section 14.2.2.1.7, it appears as if the significant relation between dioxin and the duration of acne after service in SEA appears to be confined to participants who did not report acne prior to service in SEA.

14.2.2.2 Physical Examination Variables

14.2.2.2.1 Acneiform Lesions

No significant group differences were seen in the unadjusted and adjusted Model 1 analyses of acneiform lesions (Table 14-13(a,b): $p > 0.15$ for each analysis).

A significant positive relation between initial dioxin and acneiform lesions was seen in the unadjusted Model 2 analysis (Table 14-13(c): Unadjusted RR=1.36, $p=0.050$). After adjusting for covariates, however, the results were nonsignificant (Table 14-13(d): $p=0.467$).

The unadjusted Model 3 analysis did not show any significant relation between dioxin category and acneiform lesions (Table 14-13(e): $p > 0.16$ for each contrast). After covariate adjustment, a significant difference was seen between Ranch Hands in the background dioxin category and Comparisons (Table 14-13(f): Adjusted RR=1.72, $p=0.042$). The percentage of acneiform lesions was greater among Ranch Hands in the background dioxin category (6.5%) than Comparisons (4.9%).

The unadjusted and adjusted Model 4 analyses showed no significant associations between acneiform lesions and 1987 dioxin (Table 14-13(g,h): $p > 0.15$ for each analysis).

Table 14-13. Analysis of Acneiform Lesions

14.2.2.2.3 Comedones

No significant group differences were revealed in the unadjusted Model 1 analysis of comedones (Table 14-15(a): $p > 0.05$ for each analysis). Adjusting for covariates showed no group differences over all participants (Table 14-15(b): $p = 0.131$). After stratifying the adjusted analysis by military occupation, a significant difference between Ranch Hand and Comparison officers was seen (Table 14-15(b): Adjusted RR=0.46, $p = 0.049$). Fewer Ranch Hand officers had comedones than Comparison officers (2.9% versus 6.1%, respectively). Other Model 1 adjusted contrasts were nonsignificant (Table 14-15(b): $p > 0.26$ for all remaining contrasts).

All unadjusted and adjusted Model 2, 3, and 4 analyses were nonsignificant (Table 14-15(c-h): $p > 0.05$ for each analysis).

Table 14-15. Analysis of Comedones

^aRelative risk for a twofold increase in 1987 dioxin.

14.2.2.2.7 Dermatology Index

The dermatology index was constructed from the results of the physical examination of comedones, acneiform lesions, acneiform scars, and inclusion cysts. All unadjusted and adjusted Model 1, 3, and 4 analyses showed no significant associations with dermatology index (Table 14-19(a,b,e-h): $p > 0.08$ for each analysis).

A significant positive relation with initial dioxin was seen in the unadjusted Model 2 analysis of dermatology index (Table 14-19(c): Unadjusted RR=1.20, $p=0.034$). After adjusting for covariates, however, the results were no longer significant (Table 14-19(d): $p=0.115$).

Table 14-19. Analysis of Dermatology Index

(a) MODEL 1: RANCH HANDS VS. COMPARISONS – UNADJUSTED					
Occupational Category	Group	n	Number (%) Abnormal	Unadjusted Relative Risk (95% C.I.)	p-Value
