14.3 DISCUSSION

Chloracne has very salient diagnostic features in both its distribution and physical findings that differentiates it from other forms of acne and “acne variants.” Chemical workers manufacturing chlorophenol or organochlorine pesticides are most likely to develop chloracne. One of the goals of the AFHS was to evaluate the occurrence of chloracne in participants exposed to herbicides and dioxin. Signs of chloracne were assessed through self-reporting (interviews) and physical examination.

Chloracne distribution usually involves the periorbital and malar areas, temples, posterior auricular sites, extensor aspects of the arms and legs, and, on occasion, the periumbilical and genital regions. According to medical records reviews, no cases of acne on the periumbilical and genital regions were reported for the 2002 physical examination. Lesions that would be key physical findings of chloracne may include closed and open comedones, fluid-filled cysts, and uninflamed papules and nodules. Other cutaneous findings, such as scarring, hyperpigmentation, and depigmentation, are secondary findings and are only indirectly related to chloracne.

As expected, no cases of chloracne were identified at the 2002 physical examination. In fact, no cases of chloracne have been identified over the 20-year examination period of the AFHS. The historical presence of acne, as determined through participant-reported occurrences of acne, was investigated to examine if associations related to herbicide or dioxin exposure may have existed that would be suggestive of chloracne in the past. Because self-reporting of acne is extremely subjective, conditions such as rosacea (in which papules and pustules share clinical features with those observed in acne vulgaris [common acne]); seborrheic dermatitis (a chronic skin disease associated with seborrhea and greasy scales on the scalp or eyelids or other parts of the skin); pseudofolliculitis barbae (an extrafollicular or transfollicular ingrown hair penetration accompanied by inflammation in 45 to 83 percent of Blacks who shave regularly); and Favre-Racouchot syndrome (nodular elastosis with facial cysts and comedones due to aging, sun exposure, or smoking, as seen in 6 percent of people, most commonly Caucasian males aged 40 to 60) may be self-reported as acne (103-106). Tropical acne (inflammatory lesions occurring primarily on the trunk or possibly on the face) (107) is caused by a hot, humid environment and should not be considered a problem that would be newly observed at the 2002 physical examination due to the participants’ advancing ages and their current residences being in less tropical environments than SEA.

Acne vulgaris is a condition that primarily affects younger individuals. It is most severe in the 16- to 24-year-old age group. The reporting of acne after service in SEA and the increased acneiform lesions and acneiform scarring is to be expected in the younger participants. Comedones (Favre-Racouchot syndrome) and hyperpigmentation (poikiloderma of Civatte, hemosiderin deposition in the skin secondary to ecchymoses) are commonly seen in older patients and not necessarily related to acne.

Hyperpigmentation usually occurs in individuals with Type V or VI (Black) skin types and after acne and other inflammatory cutaneous disorders. Black participants reported acne more often than non-Black participants after service in SEA, but the acne was of shorter duration, on average, and with fewer comedones, lesions, scars, and inclusion cysts. These results may be explained if Black participants reported pseudofolliculitis barbae as acne.

If a participant already had acne prior to duty in SEA, it is expected that the dermatology index will be more severe in this group than for participants who did not have acne prior to service in SEA. In addition, environmental factors aggravate already existing acne.

The evaluation of chloracne was based on physical examination only. Occupational history after service in SEA was not used to identify participants who potentially may have been at risk for developing chloracne. No biopsies to confirm the diagnosis of chloracne were deemed necessary by the examining physicians. Chloracne usually appears after a short interval of exposure to dioxin, without a long latency period, and usually persists for 2 to 3 years. Therefore, primary lesions were not expected to be noted upon physical examination. No differences were found between the Ranch Hand and Comparison groups in terms of secondary lesions (scarring, hyperpigmentation, and depigmentation). If secondary lesions had been observed, chloracne might be suggested if the lesions had been found in the typical distribution areas of chloracne. In essence, based on the results of the 2002 physical examination, there were no primary or secondary dermatological findings between the Ranch Hand and Comparison groups that would suggest chloracne.

For Ranch Hands who had a 1987 dioxin measurement of greater than 10 ppt, lipid adjusted serum dioxin levels were extrapolated to an estimated initial dioxin at the end of the last qualifying tour of duty. The median of Ranch Hands with an estimated initial dioxin was 118 ppt, which was less than the serum dioxin levels for which chloracne has been reported (300-400 ppt) in the literature (60).

Self-reported information on acne included the lifetime occurrence, the occurrence in relation to time of duty, and the location. Because the majority of participants who reported acne did not visit a physician for the acne, verification from a medical records review was not feasible. Acneiform lesions, acneiform scars, comedones, and inclusion cysts were used to comprise a dermatology index. Hyperpigmentation and depigmentation were investigated as well. If any of these conditions was present, the result was tabulated as abnormal.

Acne was increased in Ranch Hand enlisted groundcrew, the subgroup with the highest median dioxin level. An increase in acne was also found in the 1992 follow-up examination report. This increase requires more study to determine the relation, if any, between acne and other factors not considered in this report, including the dates of service, the number of days served in the Ranch Hand unit, and occupational exposure history to herbicides and other chemicals. Differences between Ranch Hand enlisted flyers and enlisted groundcrew with regard to these factors may be informative.

Acne was increased in Ranch Hand enlisted groundcrew, in parallel with an increase found at the 1992 physical examination. This occupational category was not separately assessed for the reports of the 1982, 1985, or 1987 examinations, and dermatological conditions were not analyzed for the 1997 follow-up examination report. Further study is required to assess the relation, if any, between this increase and other factors not considered in this report.

The reason for the higher occurrence of acne in Ranch Hand enlisted groundcrew is unknown. Significant findings were present, but they were seen in self-reported data on acne and not substantiated

by findings on the physical examination. In addition, Ranch Hands in the background dioxin category had a higher percentage of acneiform lesions, but not in the low or high dioxin categories.

In conclusion, there does not appear to be a dose-response relation between herbicide exposure or dioxin and acne, based on physical examination findings. In addition, the relatively low amount of serum dioxin makes the increases in the self-reported acne in all Ranch Hand dioxin categories relative to Comparisons difficult to interpret.

14.4 SUMMARY

The dermatology assessment was based on physical examination data and self-reported questionnaire data regarding occurrence, location, and duration of acne. Associations with herbicide exposure (i.e., group – Model 1), initial dioxin (Model 2), categorized dioxin (Model 3), and 1987 dioxin levels (Model 4) were examined for each variable in the dermatology assessment. The significant adjusted results are discussed in the sections below.

14.4.1 Model 1: Group Analysis

Ranch Hands reported acne over their lifetime and acne after service in SEA more often than Comparisons did. This result was also seen for enlisted groundcrew. These significant results were restricted to participants who did not have acne prior to service in SEA. In addition, Ranch Hand officers had fewer comedones than Comparison officers. The results of the group analysis are shown in Table 14-20.

A capital “NS” denotes a nonsignificant positive association. A lowercase “ns” denotes a nonsignificant inverse association.

14.4.3 Model 3: Categorized Dioxin Analysis

Ranch Hands in the background dioxin category, in the low dioxin category, and in the low and high dioxin categories combined reported acne more often than Comparisons did. Upon further investigation, the acne was observed to be after service in SEA and, in particular, for participants who did not have acne prior to service in SEA. Ranch Hands in the high dioxin category without acne prior to service in SEA also reported a longer duration of acne after service in SEA than Comparisons without acne prior to service in SEA. In addition, Ranch Hands in the background dioxin category had more acneiform lesions than Comparisons. The results of all unadjusted and adjusted Model 3 analyses are summarized in Table 14-22.

A capital “NS” denotes a nonsignificant positive association. A lowercase “ns” denotes a nonsignificant inverse association.

14.4.5 Summary of Significant Results

Table 14-24 summarizes the significant results ($p\leq 0.05$) for the adjusted analyses that were performed for the dermatology assessment. The dependent variable and its table reference are listed along with the model and the contrast or description of the model. The p-value is provided along with analysis statistics that correspond to the type of analysis that was performed (either continuous or discrete). A description of the analysis and the statistics that are presented is referenced under the “Note” column and is explained in footnotes.

Table 14-24. Summary of Results from Significant Adjusted Analyses in the Dermatology Assessment

Dependent Variable (Table Reference)	Model	Contrast or Description	p-Value	Analysis Statistics	Adjusted Mean or Percent Abnormal	Note
Occurrence of Acne (Lifetime) (14-3)	1	RH vs. C, All	0.002	1.34 (1.11,1.61)	RH: 47.5% C: 40.6%	(a)

Table 14-24. Summary of Results from Significant Adjusted Analyses in the Dermatology Assessment (Continued)

- (a): Discrete variable: adjusted relative risk and 95% confidence interval were presented; percent abnormal was presented for each exposure group in contrast.
- (b): Discrete variable: adjusted relative risk and 95% confidence interval were presented; percent abnormal was presented for each dioxin category in contrast.
- (c): Continuous variable: slope and standard error were presented and were based on square root of dependent variable versus \log_2 (initial dioxin); adjusted means were transformed to original scale and were presented for each of three initial dioxin categories.
- (d): Continuous variable: difference of adjusted means was presented; confidence interval was not presented because analysis was not performed on original scale; adjusted means were transformed to original scale and were presented for each dioxin category in contrast.
- (e): Continuous variable: slope and standard error were presented and were based on square root of dependent variable versus \log_2 (1987 dioxin); adjusted means were transformed to original scale and were presented for each of three 1987 dioxin categories.

Note: RH = Ranch Hand.
C = Comparison.

Model 2: Low = 32–79 ppt; Medium = >79–199 ppt; High = >199 ppt (Ranch Hands who had a 1987 dioxin measurement greater than 10 ppt).

Model 3: Background (Ranch Hand): 1987 dioxin \leq 10 ppt.
Low (Ranch Hand): 1987 dioxin > 10 ppt, 10 ppt < initial dioxin \leq 118 ppt.
High (Ranch Hand): 1987 dioxin > 10 ppt, initial dioxin > 118 ppt.

Model 4: Low = \leq 7.8 ppt; Medium = >7.8–19.2 ppt; High = >19.2 ppt (Ranch Hands only).

14.5 CONCLUSION

Chloracne is a skin condition recognized as a consequence of exposure to high levels of dioxin and other cyclic organochlorine compounds. It usually appears without long latency after a short interval of exposure to dioxin and persists for about 2 to 3 years. Primary lesions of chloracne were not expected to persist and be noted upon physical examination in 2002. Chloracne might be suggested if the secondary lesions such as scarring, hyperpigmentation, and depigmentation had been observed in the typical distribution areas of chloracne around eyes, temples, and ears. No evidence of chloracne was found in the Ranch Hand or Comparison group.

The dermatology assessment included the occurrence of self-reported acne and physical examination. The occurrence and duration of acne were reported by the participants at the 2002 physical examination. The frequency and occurrence of reported acne after service in SEA were increased in Ranch Hand enlisted groundcrew, the subgroup with the highest median dioxin levels. The frequency of reported acne since SEA service was increased in the background, low, and high dioxin exposure categories. The frequency of acneiform lesions on physical examination was increased only in the background category. The duration of reported acne after service in SEA increased with 1987 dioxin.

The interpretation of the increased frequency of reported acne after service in SEA in Ranch Hand enlisted groundcrew is uncertain because secondary lesions that were observed revealed no association with herbicide or dioxin exposure.

15 CARDIOVASCULAR ASSESSMENT

15.1 INTRODUCTION

15.1.1 Background

15.1.1.1 Organs/Diseases

In the cardiovascular assessment of participants in the Air Force Health Study (AFHS), data regarding cardiac function, vascular cardiac function, and heart disease history were collected based on self-reported information and physical examination. Variables evaluated based on interview data included the lifetime history of essential hypertension, heart disease, myocardial infarction, and stroke or transient ischemic attack. The physical examination included indices of central cardiac function and peripheral vascular function. Assessment of central cardiac function was made by measuring systolic and diastolic blood pressures, heart sounds, and a resting electrocardiograph (ECG). Peripheral vascular function was assessed by presence or absence of carotid bruits, various pulse-point readings, a resting blood pressure index, measures of intermittent claudication and vascular insufficiency, and funduscopic examination of small vessels. Major risk factors for cardiovascular disease include male gender, family history, high blood cholesterol, high blood pressure, diabetes mellitus, cigarette smoking, and physical inactivity (1-3).

15.1.1.2 Toxicology

Animal cardiotoxicology research of dioxin has focused on acute biochemical and functional abnormalities associated with high-level exposure (4). In one study (5), rats were found to have reductions in pulse and blood pressure 6 days after administration of 40 µg/kg of dioxin by gavage and were less responsive to the chronotropic effect of isoproterenol, a beta-agonist. Another study documented changes in myocardial beta-receptors with reduced serum indices of thyroid function and decreased beta-adrenergic responsiveness to isoproterenol in the ventricular papillary muscle of guinea pigs (6). Changes in cardiac function and morphology related to high doses of dioxin also were reported (6, 7). Recently, low doses of dioxin were found to cause myocardial fibrosis in marmosets (4). Other experiments on the effects of dioxin on myocardial contractility in rat (8) and guinea pig (9) atrial muscle, however, have yielded mixed results. Two studies suggested that exposure to dioxin during early chick embryo development was associated with congestive heart failure and increased heart weight (10, 11).

The biochemical effects of dioxin on cardiac muscle were reported in numerous studies. An increase in lipid peroxidation and a decrease in superoxide dismutase activity were noted in the hearts of female rats after dioxin administration (5). Dose-dependent decreases in adipose tissue lipoprotein lipase activity and hepatic low-density lipoprotein binding occurred in rabbits (12) and other laboratory animals (13) in association with elevated serum triglycerides. Other studies documented pre-atherosclerotic lesions in the aortic arch in association with these biochemical abnormalities (12). Dioxin exposure was associated with intravascular thrombosis in rats (7). Two studies provided evidence that the developing vascular endothelium of fish embryos may be a target organ for dioxin toxicity (14, 15).

15.1.1.3 Epidemiology

Epidemiologic studies investigated cardiovascular mortality and morbidity in populations exposed to dioxin through environmental contamination (16-28), occupational exposure (29-57), and in association with service in Southeast Asia (SEA) during the Vietnam War (58-75).

One of the largest human exposures to dioxin occurred as a consequence of an industrial explosion in Seveso, Italy, in 1976 (16-22, 24, 26, 28). In the area closest to the explosion, a median serum dioxin level of 447 parts per trillion (ppt) was measured among residents immediately after the accident (22). In study areas farther away from the accident site, median serum dioxin levels were found to be 94 ppt in a lower-exposed area and 48 ppt in the lowest-exposed area immediately after the accident (22). In the most recent mortality follow-up study of this population through 1996, there was no indication of an increased risk of mortality from all circulatory diseases among residents in the area closest to the explosion (n=804) and in a lower-exposed area (n=5,941) compared to the unexposed population (22). Elevated, but not statistically significant, mortality risks from chronic rheumatic heart disease and hypertension were found among residents in the area closest to the explosion, but not among the populations farther away from the explosion site (22). These findings were similar to earlier mortality follow-up studies of the Seveso population (24, 26). Other studies of environmentally exposed populations also found little indication for a dioxin-related increased risk of cardiovascular disease morbidity or mortality (23, 25, 27).

Cardiovascular mortality and morbidity were evaluated in several worker cohorts occupationally exposed to dioxins in studies conducted by the International Agency for Research on Cancer (IARC) (41, 52) and the National Institute for Occupational Safety and Health (NIOSH) (32, 48), as well as in studies of production workers at Dow Chemical Company (30, 31, 35, 36, 43, 45, 47), Monsanto (34, 42, 49, 54, 55), BASF (44, 46, 50, 56, 57), and in the Netherlands (39), Germany (29, 37, 38, 53), United States (51), and Britain (33, 76). The IARC study included the Dutch, German, and British workers, whereas the NIOSH cohort included workers studied separately in the Dow Chemical Company and Monsanto studies. In addition, a report of Japanese municipal waste incinerator workers was identified (40).

The most recent update of the IARC study evaluated the mortality experience of 21,863 male and female workers exposed to dioxins in 12 countries from 1939 to 1992 (41, 52). No overall increased risk of circulatory system diseases mortality was observed in this cohort compared to national mortality rates (41); however, a more detailed investigation revealed an elevated risk of mortality for all circulatory diseases combined, specifically an elevated risk of mortality for cerebrovascular and ischemic heart disease among those with potential dioxin exposure relative to unexposed workers (52). No consistent patterns with years since first exposure and duration of dioxin exposure were found (52).

Two cohorts included in the IARC study evaluated the risk of cardiovascular disease in relation to serum dioxin levels. In the German study of 1,189 male workers involved in the production of herbicides and insecticides, mortality from circulatory diseases was evaluated from 1952 through 1992 (29, 37, 38). The risk of mortality from cardiovascular disease and ischemic heart disease was highest among workers with the highest estimated exposure to dioxins relative to unexposed workers (38). In a recent update of the Dutch cohort of 1,167 workers from 1955 through 1991, an elevated ischemic heart diseases mortality risk was related to exposure; other circulatory system disease mortality risk was also elevated, but not in an exposure-response manner (39).

As part of the NIOSH Dioxin Registry, cause-specific mortality was initially determined in 5,172 workers exposed to dioxin at 12 U.S. chemical production plants (77). Recent updates of this cohort extended the period of follow-up by 6 years through 1993, and included analyses restricted to 3,538 workers in eight plants for whom qualitative indices of dioxin air levels could be determined and co-exposure to pentachlorophenol could be ruled out (48). Overall mortality from ischemic heart disease in this cohort was elevated and a statistically significant exposure-response relation (Relative Risk [RR] = 1.09, 95% confidence interval: [1.0, 1.2]) with cumulative exposure to dioxin was observed (48). In a cross-sectional study of 281 workers and 260 unexposed controls, NIOSH investigators found little evidence of a long-term effect of high dioxin exposure on adverse cardiovascular outcomes; however, serum dioxin

levels were associated with myocardial infarction risk based on self-report or ECG diagnosis (32). Smaller studies of workers at Dow Chemical Company and Monsanto found little evidence of an elevated risk of mortality from circulatory system diseases among workers potentially exposed to dioxins (30, 31, 34-36, 42, 43, 45, 47, 49, 54, 55).

A follow-up study (1953 to 1992) of 243 German factory workers exposed to dioxin during a chemical explosion in 1953 reported that the median serum dioxin levels ranged from 148 ppt among workers without chloracne to 1,118 ppt among those with severe chloracne (46, 56). No exposure-related increase in mortality from diseases of the circulatory system was observed based on a total of 37 cases (46). Furthermore, there was no association between serum dioxin levels and morbidity from disorders of the circulatory system (56). In a small cross-sectional study of 96 Japanese municipal waste incinerator workers potentially exposed to dioxins, no increased risk of hypertension was found (40).

The AFHS is unique among studies that have examined cardiovascular disease in Vietnam veterans because serial serum dioxin data have been incorporated into longitudinal analyses (65, 66, 72-74, 78-82). Previous AFHS examinations showed mixed results with respect to cardiovascular endpoints. In the baseline and 1987 follow-up examinations, manual examination of the pulses revealed an increased prevalence of pulse deficits in the Ranch Hand cohort relative to Comparisons (72, 81). In the 1985 AFHS follow-up examination, which incorporated Doppler peripheral vascular studies into the protocol, no significant group differences were found (82). When the 1987 follow-up examination data were analyzed relative to serum dioxin levels, Ranch Hand participants in the high exposure category had higher percentages of peripheral pulse abnormalities and were at greater risk of developing systemic arterial hypertension relative to Comparisons (78). In contrast, there was a significant reduction in risk of developing heart disease reported historically or verified by medical records review (78). In the 1992 follow-up examination, surviving Ranch Hands were found to be less at risk of developing heart disease over time than Comparisons, and a significant inverse dose-response effect was noted with respect to the body burden of dioxin as measured in 1987 (79). In the 1997 follow-up examination, circulatory disorders, including myocardial infarction and stroke, were unrelated to dioxin levels or exposure categories (80). A modest increase in the prevalence of hypertension was found related to 1987 dioxin levels. Ranch Hand veterans were also more likely to report heart disease, which was not consistently associated with levels of exposure (80).

A recent follow-up report in 1998 evaluating postservice mortality among Ranch Hands (66) found no evidence of an elevated risk of mortality from circulatory diseases in general. Elevated risks, although not statistically significant, were observed for several specific circulatory disorders, such as atherosclerotic heart disease, cerebrovascular disease, hypertensive disease, and other circulatory diseases in Ranch Hand enlisted groundcrew, the subgroup with the highest median dioxin level (66).

The prevalence of hypertension, vasculopathy, and ischemic and valvular heart disease was found to be higher among Korean Vietnam veterans as compared to Korean nonveterans (75). In addition, prevalence of ischemic heart disease was found to be associated with semi-quantitative indicators of Agent Orange exposure based on military region, duration of service, and type and frequency of contact to Agent Orange (75). Other studies of circulatory disease risk among Vietnam veterans have been inconsistent. Some studies reported increased risks among Vietnam veterans (64, 67, 68), while others found no evidence suggesting an elevated risk (61-63, 69-71).

The Institute of Medicine (IOM) concluded that there is “inadequate or insufficient” evidence to establish an association between dioxin exposure and the occurrence of specific circulatory disorders, including coronary artery disease, myocardial infarction, stroke and hypertension, or circulatory diseases in general (83-87).

15.1.2 Summary of Previous Analyses of the Air Force Health Study

15.1.2.1 1982 Baseline Examination Summary Results

The 1982 baseline examination found no statistically significant differences between the Ranch Hand and Comparison groups in systolic or diastolic blood pressures, the frequency of abnormal ECGs, heart sound abnormalities, abnormal funduscopic findings, or carotid bruits. No statistically significant differences were found between the two groups in the occurrence of reported or verified heart disease or heart attacks.

More than 80 percent of the cardiac conditions reported on the study questionnaire were verified by a detailed review of medical records. There was a strong correlation between the past medical history of cardiac disease and the baseline examination cardiovascular findings, although the differences in peripheral pulse abnormalities occurred primarily in older individuals without a history of cardiovascular disease. Finally, the well-known risk factors of age, smoking, and cholesterol were found to be correlated with each other and with several of the cardiovascular response variables.

15.1.2.2 1985 Follow-up Examination Summary Results

The analysis of cardiovascular disease history did not reveal significant group differences in reported or verified hypertension, reported heart disease, or reported or verified heart attacks. There were no group differences in verified heart disease. The verified cardiovascular history and the central and peripheral cardiovascular abnormalities detected at the physical examination were correlated.

In the analyses of peripheral vascular function, no significant overall group differences were observed for abnormalities involving radial, femoral, popliteal, posterior tibial, dorsalis pedis, or three anatomic aggregates of these pulses (leg pulses, peripheral pulses, and all pulses), either by manual palpation or Doppler techniques. This overall finding was in distinct contrast to the 1982 baseline examination, which, by the manual palpation method, showed significant peripheral pulse deficits in Ranch Hands. This reversal in pulse findings over the two examinations may be attributed to the rigid 4-hour tobacco abstinence applied prior to Doppler testing, although other factors may have been involved.

15.1.2.3 1987 Follow-up Examination Summary Results

The assessment of the central cardiac function found the groups to be similar, although significantly fewer Ranch Hands than Comparisons had bradycardia.

For the peripheral vascular function, Ranch Hands had a higher mean or percent abnormal for diastolic blood pressure (continuous form), carotid bruits, femoral pulses, and dorsalis pedis pulses than did Comparisons. No difference between the two groups was detected in the analysis of the discrete form of diastolic blood pressure.

15.1.2.4 Serum Dioxin Analysis of 1987 Follow-up Examination Summary Results

The cardiovascular evaluation found a significant inverse association with verified history of heart disease. In addition, the analyses of categorized dioxin also indicated a decrease in verified history of heart disease for Ranch Hands with the highest dioxin levels relative to Comparisons with background levels. These Ranch Hands had more essential hypertension by history (after removing the variables body fat and cholesterol from the model).

The analyses of the peripheral vascular function variables displayed significantly higher mean levels of diastolic blood pressure for Ranch Hands in the low and high categories than Comparisons (without

adjustment for body fat). Similar to the analysis of systolic blood pressure, the analysis of diastolic blood pressure in its discrete form did not display a significant association with dioxin within the low and high dioxin categories. Ranch Hands generally exhibited a significantly higher risk of absent femoral, dorsalis pedis, and posterior tibial pulses relative to Comparisons. These observations were thought to represent a subclinical effect of dioxin on the cardiovascular system.

15.1.2.5 1992 Follow-up Examination Summary Results

Similar to the 1987 examination, verified heart disease among Ranch Hands decreased significantly with increasing levels of 1987 dioxin. Ranch Hands also displayed an increased history of essential hypertension for increasing levels of 1987 dioxin.

A few other central cardiac function endpoints, including nonspecific ST- and T-wave changes, right bundle branch block (RBBB), and prior ECG evidence of myocardial infarction, displayed significant positive associations with 1987 dioxin; none of these endpoints displayed any group difference between Ranch Hands and Comparisons. These findings, in conjunction with the increase in the number of deaths caused by diseases of the circulatory system for Ranch Hand nonflying enlisted personnel based on the 1994 AFHS mortality update (88), showed potential associations with dioxin.

The analyses of the peripheral vascular function variables displayed significant group differences for the enlisted groundcrew stratum for a few of the pulse endpoints and significant differences between Ranch Hands in the high dioxin category and Comparisons. None of these associations was supported by a significant association with initial or 1987 dioxin. Longitudinal analyses of the pulse endpoints also indicated that Ranch Hands in the enlisted groundcrew stratum and in the high initial dioxin category had a greater prevalence of pulse deficits since the 1985 follow-up examination than Comparisons. Again, these associations were not supported by a significant dose-response effect with initial dioxin.

Overall, the development of cardiovascular disease did not appear to be associated positively with dioxin. Dioxin associations with selected endpoints, as discussed above, together with mortality results, pointed to the need for further evaluation.

15.1.2.6 1997 Follow-up Examination Summary Results

Analyses revealed that Ranch Hands had a significantly higher percentage of participants with a history of heart disease (excluding essential hypertension) than did Comparisons and, in particular, within enlisted flyers. The risk of disease, however, was not significantly increased in Ranch Hand enlisted groundcrew—the military occupation with the highest dioxin levels. The association between heart disease and initial dioxin for Ranch Hands showed a nonsignificant inverse dose-response trend, with heart disease decreasing as initial dioxin increased. Furthermore, Ranch Hands in the background and the low dioxin categories had more heart disease than did Comparisons, but this increase was not seen in Ranch Hands in the high dioxin category. Increases in tachycardia and other ECG findings, such as pre-excitation, were seen for Ranch Hands in the high dioxin category, although the analyses were based on a sparse number of abnormalities. A significant positive association between initial dioxin and evidence of prior myocardial infarction from the ECG was observed in Ranch Hands. A positive association between 1987 dioxin and essential hypertension also was observed in Ranch Hands. In contrast to previous AFHS examinations, no relation was found between peripheral pulses and any measures of exposure.

In contrast to prior examinations, the 1997 follow-up examination documented that Ranch Hands were more likely than Comparisons to have historical evidence for heart disease (excluding essential

hypertension), but were not at greater risk for the occurrence of pulse deficits. By all other indices, the prevalence of cardiovascular disease appeared similar in both cohorts. The verified history of essential hypertension was associated with 1987 dioxin, and the evidence of prior myocardial infarction from the ECG was associated with initial dioxin. These findings, in conjunction with the increase in the number of deaths caused by diseases of the circulatory system for Ranch Hand nonflying enlisted personnel based on the 1994 AFHS mortality update (88), showed associations with dioxin.

15.1.3 Parameters for the 2002 Cardiovascular Assessment

15.1.3.1 Dependent Variables

The analysis of the cardiovascular assessment was based on medical records verification of the data collected from the 2002 questionnaire and data from the 2002 follow-up physical examination. No laboratory examination data were analyzed as cardiovascular dependent variables, although data from the laboratory examination were used as covariates.

15.1.3.1.1 Medical Records Variables

The 2002 questionnaire captured data on the occurrence of heart conditions. Medical records review was accomplished to confirm reported heart conditions and to identify any unreported conditions for each participant that attended the 2002 physical examination. These data from the 2002 physical examination were combined with data from the 1982 baseline examination and the 1985, 1987, 1992, and 1997 follow-up examinations to form a complete history for essential hypertension, heart disease (excluding essential hypertension), myocardial infarction, and stroke or transient ischemic attack for each participant. Each of these conditions was classified as “yes” or “no” and analyzed. The analyses performed in this chapter were based on the 1,951 participants who attended the 2002 follow-up examination.

International Classification of Diseases, 9th Revision, Clinical Modification (ICD-9-CM) codes were used to classify the four conditions described above. The following ICD-9-CM codes were used: essential hypertension (ICD-9-CM codes 401.0-401.9), heart disease (excluding essential hypertension) (ICD-9-CM codes 391.0-391.9, 392.0-392.9, 393.0-398.99, 402.0-402.91, 404.0-404.93, and 410.0-429.9), myocardial infarction (ICD-9-CM codes 410.0-410.92, and 412), and stroke or transient ischemic attack (ICD-9-CM codes 435.0-436).

A large percentage of participants (approximately 82 percent) were determined to have heart disease. The conditions comprising heart disease were numerous, but the predominate ICD-9-CM codes were ICD-9-CM code 426 (conduction disorders) and ICD-9-CM code 427 (cardiac dysrhythmias).

Participants with a verified heart condition prior to service in SEA were excluded from all analyses. A pre-SEA heart condition did not include pre-SEA essential hypertension. Participants with a verified history of essential hypertension prior to service in SEA were also excluded from the analysis of verified history of essential hypertension.

15.1.3.1.2 Physical Examination Variables

Cardiovascular data obtained from the 2002 physical examination were divided into the following two categories for analysis: central cardiac function and peripheral vascular function.

15.1.3.1.2.1 Central Cardiac Function

The assessment of the central cardiac function at the cardiovascular examination was made by measurements of systolic blood pressure, diastolic blood pressure, heart sounds (by auscultation), and an ECG. Systolic and diastolic blood pressures were determined by a Critikon Dinamap 1846SXP[®] automated electronic monitor with the nondominant arm placed at heart level; the lowest diastolic pressure and the corresponding systolic pressure of three measurements taken 3 minutes apart were recorded. Detection of abnormal heart sounds was conducted by standard auscultation. Fourth heart sounds were assessed; murmurs were graded in intensity and location and were judged by the examiners to be functional (normal) or organic (abnormal) in nature.

The standard 12-lead (leads I, aVF, and precordial lead V5) ECG was performed and rhythm strips were obtained for all participants. Participants were asked to abstain from tobacco prior to the ECG because of the constrictive arterial effect of nicotine. Standard PR, QRS, and QT intervals were examined, as was the electrical axis. Morphology of the ECG complex was examined using P-waves, Q-waves, U-waves, QRS morphology, and ST-T morphology. Chamber enlargement using standard criteria was assessed. Evidence of a prior myocardial infarction and arrhythmias were noted. Arrhythmias grouped together for analysis included atrial flutter, atrial fibrillation, A-V dissociation, junctional rhythm, multifocal atrial rhythm, and multifocal or unifocal premature beats. Any A-V nodal blocks were categorized as first-, second-, or third-degree. The overall ECG examination was analyzed, as were the following abnormalities: (1) RBBB, (2) left bundle branch block (LBBB), (3) nonspecific ST- and T-wave changes, (4) bradycardia (a resting pulse rate less than 50 beats per minute), (5) tachycardia (a resting pulse rate greater than 100 beats per minute), (6) arrhythmia, (7) evidence of a prior myocardial infarction, and (8) other diagnoses (ventricular aneurysm and Wolff-Parkinson-White syndrome).

Variables analyzed in the evaluation of the central cardiac function included systolic blood pressure, diastolic blood pressure, heart sounds, and the ECG assessments listed above. Both systolic and diastolic blood pressures were analyzed as continuous and discrete variables. Systolic blood pressure was classified as “normal” (≤ 140 mm Hg) and “abnormal” (> 140 mm Hg), and diastolic blood pressure was classified as “normal” (≤ 90 mm Hg) and “abnormal” (> 90 mm Hg). Participants with a verified pre-SEA heart condition were excluded from all analyses of the central cardiac function variables.

15.1.3.1.2.2 Peripheral Vascular Function

The peripheral vascular function was assessed during the cardiovascular examination by funduscopic examination of small vessels; presence or absence of carotid bruits; determination of the radial, femoral, popliteal, dorsalis pedis, and posterior tibial pulses by Doppler techniques; a measure of intermittent claudication and vascular insufficiency based on participant responses in the health questionnaire; a resting blood pressure index; and two hyperemic indices used as measures of intermittent claudication.

The funduscopic examination was conducted with undilated pupils in a standard manner, with emphasis placed on the detection of arteriovenous nicking (a sign of chronic blood pressure elevation), hemorrhages, exudates, papilledema, diabetic retinopathy, disk pallor, and increased cupping. The presence or absence of carotid bruits was assessed by auscultation over both carotid arteries.

The Doppler procedure for examining pulses was a progressive array of measurements designed to determine whether a pulse abnormality existed, where the obstruction was most likely located, and whether it had functional implications. The determination of a pulse abnormality was based on an analysis of recorded Doppler waveform morphology. Pulsatility, systolic forward flow, diastolic reverse flow, and diastolic oscillations were examined.

The fundusoscopic examination, carotid bruits, and the five pulses were dichotomized as “abnormal” or “normal” (or “presence” or “absence”) and analyzed. Pulses were considered abnormal if no arterial flow or a monophasic arterial flow was present on either side. In addition, two pulse indices were constructed from the radial, femoral, popliteal, dorsalis pedis, and posterior tibial pulse measurements as follows:

- Leg pulses: femoral, popliteal, dorsalis pedis, and posterior tibial pulses
- Peripheral pulses: radial, femoral, popliteal, dorsalis pedis, and posterior tibial pulses.

Each of these indices was considered “normal” if all components were normal and “abnormal” if one or more pulses were abnormal.

Three indices of claudication using peripheral blood pressure measurements were analyzed. Right and left brachial (upper arm) blood pressures were taken during the vascular examination using the Doppler technique. An occluding cuff was placed around the participant's arm. The brachial artery was palpated in the antecubital fossa and acoustic gel was applied to the skin over the artery. An arterial signal was found using the Doppler probe and the cuff was then inflated until the arterial signal disappeared. The cuff was slowly deflated while the operator listened to the Doppler for systolic breakthrough.

After brachial pressures were recorded, the right and left supine ankle pressures were measured. The cuff was placed around the participant's ankle with the lower edge just above the malleolus. The Doppler transducer was placed over the posterior tibial and the dorsalis pedis artery and the vessel with the strongest Doppler signal was chosen and the cuff was inflated. The operator listened for systolic breakthrough as the cuff was deflated.

A resting pressure index was calculated from the resting ankle systolic pressure and brachial systolic pressure using the following equation:

$$\text{Resting Pressure Index} = \frac{\text{Ankle Systolic Pressure}}{\text{Maximum Brachial Systolic Pressure}}.$$

In normal subjects, the ankle systolic pressure should be higher than the brachial pressure; therefore, a normal pressure index should be greater than 1.0 in both legs. Abnormally low ankle pressures may indicate severe arterial occlusive disease. Thus, a complete occlusion in a main arterial pathway can result in an abnormal pressure index evidenced as a pressure index less than 1.0 in either leg (note: <0.97 in either leg for this index was judged abnormal per NIOSH recommendation). An index below 0.30 can suggest severe arterial ischemia.

Two reactive hyperemic indices were determined. These indices were assessed from measurements after participant exercise; in particular, active pedal plantarflexion (APP), or toe raises, were used. APP was demonstrated to the participant by the examiner. With the hands on the side of the examination table to provide balance, the participant was instructed to rise on the balls of the feet until the heels were off the ground to a full extension, then lower the heels back to the ground. This procedure was repeated at a steady pace for 2 minutes or until the patient could no longer tolerate the procedure due to pain (indicating claudication) or excessive discomfort. The participant was then instructed to lie down on the examination table immediately after the APP, and post-exercise pressures were obtained at the ankle and the brachial arteries at the site of the highest pressures before exercise. Brachial and ankle pressures were obtained at 1 minute post-exercise and 2 minutes post-exercise.

Two hyperemic pressure indices of claudication were calculated, one at 1 minute post-exercise and one at 2 minutes post-exercise, from the brachial and hyperemic ankle systolic pressures as follows:

$$\text{Hyperemic Pressure Index} = \frac{\text{Hyperemic Ankle Systolic Pressure}}{\text{Brachial Systolic Pressure}}.$$

The brachial systolic pressures at 1 and 2 minutes after exercise were measured in the arm with the maximum resting brachial systolic pressure. A normal test was defined as the return of the lowest ankle index to greater than 1.0 (note: <0.97 for the hyperemic pressure index after either 1 or 2 minutes was judged abnormal per NIOSH recommendation). The magnitude of the decrease in the ankle index and the time taken to return to the resting index were related to the severity of the arterial occlusive disease.

Post-exercise indices should remain at or above 1.0 in participants judged as normal. These indices should return to resting (pre-exercise) levels within 2 minutes after exercise.

Participants with a verified heart condition prior to service in SEA were excluded from the analyses of the peripheral vascular function variables.

15.1.3.1.3 Self-reported Questionnaire Variable

In the 2002 questionnaire, each participant was asked the following questions:

- Do you get a pain in either or both of your legs while walking?
- Does this pain ever begin when you are standing still or sitting?
- Do you get this pain in either or both of your calf muscles?

The self-reported answers were used to detect intermittent claudication and vascular insufficiency (yes, no), which indicate an insufficient oxygen supply to the leg muscles. A participant was judged to have intermittent claudication and vascular insufficiency if he answered “yes” to the first and third questions and “no” to the second question.

15.1.3.2 Covariates

A number of covariates were examined for inclusion in the adjusted analysis of the cardiovascular assessment. Many of these covariates were considered to be classical risk factors for chronic heart disease. Covariates examined included age, race, military occupation, lifetime cigarette smoking history, current cigarette smoking, lifetime alcohol history, current alcohol use, uric acid, body mass index, waist-to-hip ratio, cholesterol, high-density lipoprotein (HDL), cholesterol-HDL ratio, family history of heart disease, family history of heart disease before the age of 45, diabetic class, current use of blood pressure medication (for systolic and diastolic blood pressures determined during the physical examination), and length of exercise prior to peripheral blood pressure measurements (for the hyperemic pressure indices).

Age, race, and military occupation were determined from military records. Lifetime alcohol history was based on information from the 2002 questionnaire and combined with similar information gathered at the 1987, 1992, and 1997 follow-up examinations. Each participant was asked about his drinking patterns throughout his lifetime. When a participant’s drinking pattern changed, he was asked to describe how his alcohol consumption differed and the duration of time that the drinking pattern lasted. The participant’s average daily alcohol consumption was determined for each of the reported drinking pattern periods throughout his lifetime, and an estimate of the corresponding total number of drink-years was derived. One drink-year was the equivalent of drinking 1.5 ounces of an 80-proof alcoholic beverage, one 12-ounce beer, or one 5-ounce glass of wine per day for 1 year. Current alcohol use was defined as the average number of drinks per day during the 2 weeks prior to completing the physical examination.

Current cigarette smoking and lifetime cigarette smoking history were based on questionnaire data. For lifetime cigarette smoking history, the respondent's average smoking was estimated over his lifetime based on his responses to the 2002 questionnaire, with 1 pack-year defined as 365 packs of cigarettes smoked during a single year.

Uric acid, cholesterol, HDL, and the cholesterol-HDL ratio were based on laboratory measurements at the AFHS 2002 follow-up examination.

Body mass index was calculated as $\text{weight}/(\text{height})^2$, where the weight was measured in kilograms and the height was measured in meters at the physical examination (89). For purposes of covariate associations for discrete dependent variables, body fat was dichotomized as "not obese" ($\leq 30 \text{ kg/m}^2$) and "obese" ($> 30 \text{ kg/m}^2$).

A measurement of each participant's hips and waist (in cm) was taken at the 2002 physical examination. This information was used to construct a waist-to-hip ratio that was used as a covariate for cardiovascular endpoints (90).

Family history of heart disease was defined as "yes" if the participant's mother, father, sister(s), or brother(s) had heart trouble or heart disease and "no" otherwise. Family history of heart disease before the age of 45 was defined as "yes" if the participant's mother, father, sister(s), or brother(s) had heart trouble or heart disease before the age of 45 and "no" otherwise.

Diabetic class was used as a covariate in the analysis of the cardiovascular system for the AFHS 2002 follow-up examination. Diabetes is a known risk factor for cardiovascular disease. In the 2002 questionnaire, a general screening question on diabetes was posed. During the in-person health interview each participant was asked: "Since the date of the last interview, has a doctor told you for the first time that you had diabetes?" Medical records review was accomplished to confirm reported diabetes and to identify any unreported diabetes for each participant that attended the 2002 physical examination. These data from the 2002 physical examination were combined with data from the 1982 baseline examination and the 1985, 1987, 1992, and 1997 follow-up examinations to form a complete history of diabetes for each participant. Participants with a verified history of diabetes, as diagnosed previously by a physician, were combined with those participants with either

- a 2-hour postprandial glucose level of 200 mg/dL or greater on two separate occasions
- a fasting glucose level of 126 mg/dL or greater on two separate occasions, or
- one 2-hour postprandial glucose measurement $\geq 200 \text{ mg/dL}$ and one fasting glucose $\geq 126 \text{ mg/dL}$ on two separate occasions,

and classified as "diabetic" for the diabetic class covariate. Those participants not classified as "diabetic," as defined above, but with a 2-hour postprandial glucose level of at least 140 mg/dL or a fasting glucose level of at least 110 mg/dL at the 2002 physical examination, were classified as "impaired." Those participants not classified as "diabetic" or "impaired" as defined above were classified as "normal."

Blood pressure medication (yes, no) was used as a covariate for the adjusted analyses of the systolic blood pressure and diastolic blood pressure variables only. The participant reported this information during the in-person interview on a self-reported form that listed physicians and medications.

Essential hypertension, heart disease excluding essential hypertension, myocardial infarction, and stroke or transient ischemic attack capture a history of a cardiovascular condition rather than the current state of a participant's life at the time of the physical examination. Consequently, to reflect the historical nature of these dependent variables, lifetime alcohol history and lifetime cigarette smoking history were used as covariates, but current alcohol use and current cigarette smoking were not. Lifetime alcohol history and lifetime cigarette smoking history reflect the cumulative lifetime effects of alcohol use and tobacco, respectively, whereas current alcohol use and current cigarette smoking emphasize the short period of time near the date of the physical examination.

15.1.4 Statistical Methods

Table 15-1 summarizes the statistical analysis performed for the 2002 cardiovascular assessment. The first part of this table lists the dependent variables analyzed, source of the data, form of the data, cutpoints, covariates, exclusions, and statistical methods. The second part of the table further describes the covariates. A covariate was used in its continuous form whenever possible for all adjusted analyses. If the covariate was inherently discrete (e.g., military occupation), or if a categorized form was needed to develop measures of association with the dependent variables, the covariate was categorized as shown in Table 15-1.

Four models were examined for each dependent variable given in Table 15-1. The analyses of these models are presented below. Further details on dioxin and the modeling strategy are found in Chapters 2 and 7, respectively. These analyses were performed both unadjusted and adjusted for covariates. These covariates are given in Table 15-1. Model 1 examined the relation between the dependent variable and group (i.e., Ranch Hand or Comparison). In this model, exposure was defined as “yes” for Ranch Hands and “no” for Comparisons without regard to the magnitude of the exposure. In an attempt to quantify exposure, three contrasts of Ranch Hands and Comparisons were performed along with the overall Ranch Hand versus Comparison contrast. These three contrasts compared Ranch Hands and Comparisons within each military occupational category (i.e., officers, enlisted flyers, and enlisted groundcrew). As described in previous reports and Table 2-4, the median level of exposure to dioxin was highest for enlisted groundcrew, followed by enlisted flyers, then officers.

During the 1987, 1992, 1997, and 2002 examinations, serum dioxin levels were measured by the Centers for Disease Control and Prevention (CDC) using high-resolution gas chromatography and high-resolution mass spectrometry and were reported in ppt on a lipid weight basis (91). These dioxin measurements are referred to as “lipid-adjusted.” All measures of dioxin used in this report were based on lipid-adjusted dioxin measurements.

Model 2 examined the relation between the dependent variable and an extrapolated initial dioxin measure for Ranch Hands who had a 1987 dioxin measurement greater than 10 ppt. The initial dioxin was calculated by extrapolating the 1987 dioxin level back in time to the end of the tour of duty that qualified a Ranch Hand veteran for inclusion in this study. If a Ranch Hand did not have a 1987 dioxin level, then the first dioxin measured, either at 1992, 1997, or 2002, was used to estimate the initial dioxin level. Regardless of when the dioxin was measured, Ranch Hand veterans with a level less than or equal to 10 ppt were excluded from statistical analyses based on Model 2. A statistical adjustment for body mass index at the time of the participant’s blood measurement of dioxin was included in this model to account for body mass index-related differences in elimination rate (92).

Model 3 divided the Ranch Hands examined in Model 2 into two categories based on their initial dioxin measures. These two categories were referred to as “low Ranch Hand” and “high Ranch Hand.” Two additional categories—Ranch Hands with serum dioxin levels at or below 10 ppt and Comparisons—were formed and included in the model. Ranch Hands with serum dioxin levels at or below 10 ppt were assigned to the “background Ranch Hand” category. If a Ranch Hand did not have a 1987 dioxin measurement, the first measured dioxin level was used. Another category was examined by combining the low and high Ranch Hand categories. This combination is referred to in the tables as the “low plus high Ranch Hand” category. These five categories—Comparisons, background Ranch Hands, low Ranch Hands, high Ranch Hands, and low plus high Ranch Hands—were used in Model 3 analyses. The relation between the dependent variable in each of the four Ranch Hand categories and the dependent variable in the Comparison category was examined. As in Model 2, a statistical adjustment for body mass index at the time of the participant's blood measurement of dioxin was included in this model for the unadjusted and adjusted analyses of all dependent variables. One Ranch Hand without a dioxin measure was excluded from statistical analyses based on Model 3.

Model 4 examined the relation between the dependent variable and 1987 dioxin levels in all Ranch Hands with a dioxin measurement. If a Ranch Hand did not have a 1987 dioxin measurement, the first dioxin level obtained, either in 1992, 1997, or 2002, was extrapolated to the date of the 1987 physical examination. If the first dioxin level was not obtained in 1987 and was less than or equal to 10 ppt, it was not extrapolated to 1987 level, but was used at the measured value. One Ranch Hand without a dioxin measurement was excluded from statistical analyses based on Model 4.

The term “unadjusted” was used in the text and tables as follows: Models 1 and 4 did not adjust for any covariates. Models 2 and 3 adjusted only for body mass index at the time of the blood measurement for dioxin. The term “adjusted” was used in the text and tables as follows: Models 1 and 4 adjusted for the covariates shown in Table 15-1 unless otherwise specified by a footnote to the table. Models 2 and 3 additionally adjusted only for body mass index at the time of the blood measurement for dioxin.

Table 15-2 provides a summary of the number of participants with missing dependent variable and covariate data. In addition, the number of participants that were excluded from analyses is given. As noted in Table 15-2, 52 participants did not provide information for family history of heart disease before age 45. Most of these participants did not know the answer to this question. In an attempt not to exclude a substantial number of participants, a limited version of a stepwise procedure was used. If family history of heart disease before age 45 was not significant ($p>0.05$) for the adjusted analysis of a particular model for a dependent variable, this covariate was excluded from the analysis. Excluding family history of heart disease before age 45 from the model allowed these 52 participants to be included in the analysis of the model and thus increased the sample size. The parameters of the model were then re-estimated; these statistics are shown in the tables in this chapter. Those models for which family history of heart disease before age 45 was deleted as a covariate are noted in a footnote to the table.

Table 15-2. Number of Participants Excluded or with Missing Data for the Cardiovascular Assessment

15.2 RESULTS

15.2.1 Dependent Variable-covariate Associations

The cardiovascular dependent variables were tested for associations with each of the covariates used in the adjusted analyses. The complete results are presented in Table F-7. These associations were pairwise between the dependent variable and the covariate and were not adjusted for any other covariates. A brief summary of the pattern of significant ($p \leq 0.05$) dependent variable-covariate associations is described in the following paragraphs.

Age was significantly associated with all dependent variables except diastolic blood pressure (in the discrete form), LBBB, tachycardia and femoral pulses. Among all discrete dependent variables except radial pulses, there was a significantly higher prevalence of a dependent variable abnormality among older participants. An abnormal radial pulse was more prevalent among younger participants than older participants. The continuous form of diastolic blood pressure, resting pressure index, and the hyperemic pressure indices decreased with increasing age. Systolic blood pressure, however, increased as age increased.

Race was significantly associated with the continuous form of diastolic blood pressure and the resting and hyperemic pressure indices and nonspecific ST- and T-wave changes. Black participants had a significantly higher prevalence of abnormal nonspecific ST- and T-wave changes and had a significantly higher mean diastolic blood pressure than non-Blacks. For the continuous form of the pressure indices, Black participants had a significantly lower mean than non-Black participants.

Military occupation was significantly associated with the prevalence of heart disease (excluding essential hypertension), the discrete form of systolic blood pressure, the overall ECG, and the ECG findings of RBBB, nonspecific ST- and T-wave changes, bradycardia, arrhythmia, and evidence of a prior myocardial infarction. For most of these dependent variables, enlisted groundcrew had the lowest prevalence of an abnormality, which may be due to the age difference between enlisted personnel and officers. The mean systolic blood pressure was lowest and the mean diastolic blood pressure was highest in enlisted groundcrew, which also may be due to the age difference between enlisted personnel and officers.

Significant relations also were found between military occupation and the continuous form of all pressure indices. In each case, officers had the highest mean pressure index, indicating better vascular health, on average. A significant association also was found between military occupation and the discrete form of the hyperemic pressure index (1 minute post-exercise). Enlisted flyers were found to have the highest prevalence of a low hyperemic pressure index at 1 minute after exercise.

Lifetime cigarette smoking history was significantly associated with the prevalence of essential hypertension, myocardial infarction, an abnormal overall ECG, evidence of a prior myocardial infarction from the ECG, and an abnormality of all peripheral vascular function variables from the physical examination except radial pulses. In all cases, the prevalence of an abnormality of the dependent variable increased as lifetime cigarette smoking increased. Lifetime cigarette smoking history also was significantly associated with all pressure indices. The presence of low pressure indices increased with increasing lifetime cigarette smoking, and the indices decreased with increasing smoking. In addition, the continuous form of diastolic blood pressure decreased as lifetime cigarette smoking history increased.

Significant associations were found between current cigarette smoking and the ECG measures of LBBB and tachycardia. The heaviest smokers had a higher prevalence of these ECG abnormalities. Significant associations also were found between current cigarette smoking and the peripheral vascular function variables of funduscopic examination, femoral pulses, popliteal pulses, dorsalis pedis pulses, posterior tibial pulses, leg pulses, peripheral pulses, and the pressure indices. The highest prevalence of these abnormalities also was found in the heavier smokers. The continuous form of systolic blood pressure and all pressure indices decreased as current cigarette smoking increased.

Lifetime alcohol history was significantly associated with essential hypertension, heart sounds, overall ECG, and arrhythmia. For all dependent variables, the prevalence of an abnormality was highest for the heaviest drinkers (in terms of drink-years). Significant associations also were found between lifetime alcohol history and dorsalis pedis pulses, posterior tibial pulses, and leg pulses. The highest prevalence of an abnormal pulse also was seen for the heaviest drinkers. All pressure indices (both continuous and discrete forms) were significantly related to lifetime alcohol history. For the continuous measures, the index decreased as lifetime alcohol history increased. For the discrete measures, low pressure indices were highest for the heaviest drinkers. No dependent variables were significantly related to current alcohol use.

The prevalence of essential hypertension, high systolic blood pressure, an abnormal overall ECG, nonspecific ST- and T-wave changes, and arrhythmia was significantly greater for those participants with

higher uric acid levels. In addition, a significant and positive association was found between uric acid and the continuous form of systolic blood pressure. Significant associations were found between uric acid and the prevalence of an abnormality in all peripheral vascular variables except carotid bruits and radial pulses. In each case, a significantly higher prevalence of abnormalities was found for participants with higher uric acid levels. The continuous form of all pressure indices was significantly and inversely related to uric acid.

The prevalence of essential hypertension, high systolic blood pressure and nonspecific ST- and T-wave changes was significantly higher among obese participants. The continuous form of both systolic and diastolic blood pressure was found to have a significant positive relation with body mass index. The presence of an abnormal posterior tibial pulse was significantly higher for participants who were not obese. A significant inverse association was found between body mass index and the continuous form of hyperemic pressure index 1 minute after exercise.

The waist-to-hip ratio was found to have a significant association with essential hypertension, the overall ECG, nonspecific ST- and T-wave changes, bradycardia, funduscopic examination, posterior tibial pulses, and leg pulses. For all dependent variables except bradycardia, the prevalence was significantly higher in participants with a waist-to-hip ratio greater than 1.0. Both the continuous and discrete forms of systolic blood pressure were significantly related to the waist-to-hip ratio. The prevalence of high systolic blood pressure was greater among participants whose waist-to-hip ratio was greater than 1.0. Similarly, systolic blood pressure was higher among those participants with a greater waist-to-hip ratio. All continuous forms of the pressure indices were found to have significant and inverse relations with the waist-to-hip ratio. The discrete form of both hyperemic pressure indices had a significant association with the waist-to-hip ratio. The presence of a low hyperemic pressure index was higher among participants with a waist-to-hip ratio greater than 1.0.

Cholesterol was significantly associated with essential hypertension, heart disease, and myocardial infarction. The prevalence was highest among participants with the lowest cholesterol levels, which may be the result of cholesterol medication use among those participants with these heart conditions. Similar significant relations, where the highest prevalence of an abnormality was found among participants with the lowest cholesterol levels, were seen with the dependent variables of overall ECG, RBBB, evidence of prior myocardial infarction, funduscopic examination, carotid bruits, dorsalis pedis pulses, leg pulses, and the intermittent claudication and vascular insufficiency index. The continuous form of both systolic and diastolic blood pressure was found to have a significant positive relation with cholesterol. Similarly, the greatest percentage of participants with high diastolic blood pressure was seen among participants with the highest cholesterol levels.

Dependent variables found to have significant associations with HDL were essential hypertension, LBBB, and the continuous form of hyperemic pressure index 1 minute after exercise. A significantly higher percentage of participants with low HDL levels were found to have essential hypertension and LBBB. A significant positive relation between HDL and the hyperemic pressure index 1 minute after exercise was observed.

The prevalence of essential hypertension, heart disease, and myocardial infarction was significantly related to the cholesterol-HDL ratio. For each condition, the prevalence was highest among those participants with a low cholesterol-HDL ratio. The continuous forms of systolic blood pressure and diastolic blood pressure showed a significant positive relation to the cholesterol-HDL ratio. Among the ECG measures, significant associations were found between the cholesterol-HDL ratio and the overall ECG, nonspecific ST- and T-wave changes, and bradycardia. The prevalence of these ECG abnormalities was significantly higher among those participants with a low cholesterol-HDL ratio. In addition, a

significant inverse relation was found between the cholesterol-HDL ratio and the continuous form of the hyperemic pressure index 1 minute after exercise.

Family history of heart disease was significantly associated with essential hypertension, heart disease, and myocardial infarction. The prevalence of essential hypertension, heart disease, and myocardial infarction was significantly higher among participants with a family history of heart disease. Family history of heart disease also was significantly associated with both forms of diastolic blood pressure. Mean diastolic blood pressure was higher among participants with no family history of heart disease. Likewise, the prevalence of high diastolic blood pressure was higher among participants with no family history of heart disease. Among the ECG dependent variables, significant associations were found between family history of heart disease and the overall ECG, nonspecific ST- and T-wave changes, and evidence of a prior myocardial infarction. For all three dependent variables, the prevalence of abnormalities was highest among participants with a family history of heart disease.

The prevalences of a myocardial infarction and nonspecific ST- and T-wave changes were highest among participants with a family history of heart disease before age 45. The peripheral vascular function dependent variables of femoral pulses, popliteal pulses, and posterior tibial pulses were significantly higher among participants with family history of heart disease before age 45. A significantly higher percentage of participants with a family history of heart disease before age 45 were found to have a higher prevalence of a low resting pressure index.

Diabetic class was significantly associated with essential hypertension, heart disease, and myocardial infarction. An increasing prevalence of these heart conditions was found with increasing diabetic impairment. Diabetic class was significantly associated with the discrete form of systolic blood pressure and the continuous form of both systolic and diastolic blood pressure. The prevalence of high systolic blood pressure, as well as mean systolic blood pressure, increased with increasing diabetic impairment. In addition, mean diastolic blood pressure was highest in nondiabetics, followed by glucose-impaired participants and diabetics. With the exception of LBBB and tachycardia, all ECG dependent variables had significant associations with diabetic class. With the exception of bradycardia, the prevalence of abnormalities increased with increasing diabetic impairment. Bradycardia was most prevalent among nondiabetics, followed by glucose-impaired participants and diabetics. All peripheral vascular function dependent variables were significantly related to diabetic class except radial pulses and femoral pulses. In each case, the prevalence of abnormalities increased with increasing diabetic impairment. All pressure indices (both continuous and discrete) and the intermittent claudication and vascular insufficiency index were significantly associated with diabetic class. Decreasing mean pressure indices occurred with increasing diabetic impairment. Similarly, for the discrete forms of the pressure indices, prevalence of low pressure indices was highest among those participants classified as diabetic, followed by glucose-impaired participants and nondiabetics.

Current use of blood pressure medication was significantly associated with diastolic blood pressure in the continuous form. Participants who were not taking blood pressure medication were found to have a significantly higher mean diastolic blood pressure.

Length of exercise prior to peripheral blood pressure measurements was significantly associated with all hyperemic pressure indices. Both the hyperemic pressure indices 1 and 2 minutes after exercise were higher as the length of exercise prior to measurement was greater. When analyzing the discrete form of the hyperemic pressure indices, the highest percentage of a low index was found among those with less than 120 seconds of exercise prior to the blood pressure measurements.

15.2.2 Exposure Analysis

The following section presents results of the statistical analyses of the dependent variables shown in Table 15-1. Dependent variables are grouped into three sections: (1) the questionnaire variables, derived from the questionnaire that was administered in the 2002 follow-up and previous AFHS examinations and verified by a medical records review, (2) variables obtained during the 2002 physical examination, and (3) one variable based on self-reported participant information regarding leg muscle pain.

15.2.2.1 Medical Records Variables

15.2.2.1.1 Essential Hypertension

All Model 1, 2, and 3 unadjusted and adjusted analyses of essential hypertension revealed no significant results (Table 15-3(a–f): $p > 0.06$ for all analyses).

The unadjusted Model 4 analysis showed a significant positive association between essential hypertension and 1987 dioxin (Table 14-3(g): Unadjusted RR=1.18, $p < 0.001$). When adjusted for covariates, the relation was not significant (Table 15-3(h): $p = 0.088$).

Table 15-3. Analysis of Essential Hypertension

(a) MODEL 1: RANCH HANDS VS. COMPARISONS – UNADJUSTED

^aRelative risk for a twofold increase in 1987 dioxin.

Note: Family history of heart disease before the age of 45 was not included in the model (see Section 15.1.4).

15.2.2.1.2 Heart Disease (Excluding Essential Hypertension)

The unadjusted and adjusted Model 1 analyses of heart disease (excluding essential hypertension) each showed significant group differences for enlisted flyers (Table 15-4(a,b): Unadjusted RR=2.56, p=0.010; Adjusted RR=2.46, p=0.015, respectively). The percentage of Ranch Hand enlisted flyers with heart

disease was 91.6 versus 81.0 percent for the Comparison enlisted flyers. No differences in heart disease were seen between Ranch Hands and Comparisons overall, in officers, or in enlisted groundcrew ($p>0.10$ for all contrasts).

The Model 3 unadjusted analyses of heart disease revealed a significant difference between Ranch Hands in the background dioxin category and Comparisons (Table 15-4(e): Unadjusted RR=1.50, $p=0.019$). There were no significant differences in the adjusted analyses (Table 15-4(f): $p>0.10$ for all analyses).

Both unadjusted and adjusted analyses of Model 2 and Model 4 did not reveal significant findings (Table 15-4(c,d,g,h): $p>0.15$ for all analyses).

Table 15-4. Analysis of Heart Disease (Excluding Essential Hypertension)

15.2.2.2 Physical Examination Variables – Central Cardiac Function

15.2.2.2.1 Systolic Blood Pressure (Continuous)

Ranch Hand enlisted groundcrew were found to have a significantly lower mean systolic blood pressure than Comparison enlisted groundcrew in the unadjusted analyses of Model 1 (Table 15-7(a): difference of means=-2.4 mm Hg, p=0.045). The adjusted analysis, however, showed no significant difference (p=0.136). All other contrasts in both the unadjusted and adjusted analyses of Model 1 were nonsignificant (Table 15-7(a,b): p>0.06 for all analyses).

The unadjusted Model 3 analyses showed a significant difference between Ranch Hands in the low and high dioxin combined category and Comparisons (Table 15-7(e): difference of means=-2.3 mm Hg, p=0.015). The difference remained significant after adjusting for covariates (Table 15-7(f): difference of adjusted means=-2.3 mm Hg, p=0.022). Ranch Hands in the combined low and high dioxin category had a lower adjusted mean systolic blood pressure (128.2 mm Hg) than Comparisons (130.5 mm Hg). In addition, Ranch Hands in the low dioxin category were found to have a significantly lower mean systolic blood pressure (127.6 mm Hg) than Comparisons in the Model 3 adjusted analyses of systolic blood pressure (Table 15-7(f): difference of adjusted means=-2.9 mm Hg, p=0.025).

All Model 2 and Model 4 unadjusted and adjusted analyses of the continuous form of systolic blood pressure were nonsignificant (Table 15-7(c,d,g,h): p>0.39 for all analyses).

Table 15-7. Analysis of Systolic Blood Pressure (mm Hg) (Continuous)

Note: Low = ≤7.8 ppt; Medium = >7.8–19.2 ppt; High = >19.2 ppt.

Family history of heart disease before the age of 45 was not included in the model (see Section 15.1.4).

15.2.2.2.2 Systolic Blood Pressure (Discrete)

The unadjusted and adjusted Model 1 analyses of the discrete form of systolic blood pressure showed no significant differences between Ranch Hands and Comparisons when examined across all occupations and within each occupation (Table 15-8(a,b): $p > 0.11$ for all analyses). In addition, the unadjusted and adjusted Model 2 analyses showed no significant findings (Table 15-8(c,d): $p > 0.38$ for both analyses).

The unadjusted Model 3 analyses of the discrete form of systolic blood pressure revealed significant differences between Comparisons and Ranch Hands in both the low dioxin category and the combined low and high dioxin category (Table 15-8(e): Unadjusted RR=0.67, $p=0.035$; Unadjusted RR=0.70, $p=0.010$, respectively). In both cases, the percentage of participants with high systolic blood pressure was lower for Ranch Hands (19.4% in the low dioxin category; 20.3% in the low and high dioxin categories combined) than for Comparisons (26.0%). After adjusting for covariates, both analyses remained significant (Table 15-8(f): Adjusted RR=0.63, $p=0.018$ for the low dioxin category contrast; Adjusted RR=0.72, $p=0.023$ for the low and high dioxin categories combined).

The unadjusted Model 4 results were nonsignificant (Table 15-8(g): $p=0.065$). After adjusting for covariates, the results became significant and indicated an inverse relation between the 1987 dioxin level and the presence of high systolic blood pressure (Table 15-8(h): Adjusted RR=0.86, $p=0.023$). The

percentages of participants with high systolic blood pressure in the low, medium, and high 1987 dioxin categories were 26.2, 21.7, and 20.7, respectively.

Table 15-8. Analysis of Systolic Blood Pressure (Discrete)

Note: Low = ≤7.8 ppt; Medium = >7.8–19.2 ppt; High = >19.2 ppt.

Family history of heart disease before the age of 45 was not included in the model (see Section 15.1.4).

15.2.2.2.4 Diastolic Blood Pressure (Discrete)

All unadjusted and adjusted analyses of the discrete form of diastolic blood pressure were nonsignificant in Models 1, 2, and 4 (Table 15-10(a–d,g,h): $p > 0.07$ for all analyses).

The unadjusted Model 3 analysis of the discrete form of diastolic blood pressure revealed a significant difference between Ranch Hands in the high diastolic category and Comparisons (Table 15-10(e): Unadjusted RR=1.92, $p=0.019$). The percentage of participants with high diastolic blood pressure was greater among Ranch Hands in the high diastolic category (9.0%) than Comparisons (4.8%). The difference remained significant after adjusting for covariates (Table 15-10(f): Adjusted RR=1.88, $p=0.036$).

Table 15-10. Analysis of Diastolic Blood Pressure (Discrete)

(a) MODEL 1: RANCH HANDS VS. COMPARISONS – UNADJUSTED

(f) MODEL 3: RANCH HANDS VS. COMPARISONS BY DIOXIN CATEGORY – ADJUSTED			
Dioxin Category	n	Adjusted Relative Risk (95% C.I.)^a	p-Value
Comparison	1,146		
Background RH	344	1.08 (0.65,1.80)	0.774
Low RH	202	1.11 (0.60,2.05)	0.744
High RH	209	1.38 (0.73,2.59)	0.319
Low plus High RH	411	1.24 (0.77,1.99)	0.377

^aRelative risk and confidence interval relative to Comparisons.

Note: RH = Ranch Hand.

Background (Ranch Hand): 1987 dioxin ≤ 10 ppt.

Low (Ranch Hand): 1987 dioxin > 10 ppt, 10 ppt < initial dioxin ≤ 118 ppt.

High (Ranch Hand): 1987 dioxin > 10 ppt, initial dioxin > 118 ppt.

Family history of heart disease before the age of 45 was not included in the model (see Section 15.1.4).

(g) MODEL 4: RANCH HANDS – 1987 DIOXIN – UNADJUSTED				
1987 Dioxin Category Summary Statistics			Analysis Results for Log₂ (1987 Dioxin)	
1987 Dioxin	n	Number (%) Abnormal	Unadjusted Relative Risk (95% C.I.)^a	p-Value
Low	256	17 (6.6)	1.02 (0.86,1.22)	0.801
Medium	253	16 (6.3)		
High	256	19 (7.4)		

^aRelative risk for a twofold increase in 1987 dioxin.

Note: Low = ≤7.8 ppt; Medium = >7.8–19.2 ppt; High = >19.2 ppt.

Table 15-11. Analysis of Heart Sounds (Continued)

(h) MODEL 4: RANCH HANDS – 1987 DIOXIN – ADJUSTED		
Analysis Results for Log ₂ (1987 Dioxin)		
n	Adjusted Relative Risk (95% C.I.)^a	p-Value
755	1.07 (0.86,1.34)	0.526

^aRelative risk for a twofold increase in 1987 dioxin.

Note: Family history of heart disease before the age of 45 was not included in the model (see Section 15.1.4).

15.2.2.2.6 Overall ECG

All unadjusted and adjusted analyses of the overall assessment of the ECG report in Models 1 through 4 were nonsignificant (Table 15-12(a-h): $p > 0.06$ for all analyses).

Table 15-12. Analysis of Overall ECG

(a) MODEL 1: RANCH HANDS VS. COMPARISONS – UNADJUSTED					
Occupational Category	Group	n	Number (%) Abnormal	Unadjusted Relative Risk (95% C.I.)	p-Value
<i>All</i>	<i>Ranch Hand</i>	<i>766</i>	<i>276 (36.0)</i>	<i>1.03 (0.85,1.24)</i>	<i>0.771</i>

Officer	752	0.93 (0.68,1.28)	0.670
Enlisted Flyer	308	1.49 (0.92,2.41)	0.106
Enlisted Groundcrew	842	0.93 (0.67,1.29)	0.653

Note: Family history of heart disease before the age of 45 was not included in the model (see Section 15.1.4).

Table 15-12. Analysis of Overall ECG (Continued)

(c) MODEL 2: RANCH HANDS – INITIAL DIOXIN – UNADJUSTED				
Initial Dioxin Category Summary Statistics			Analysis Results for Log ₂ (Initial Dioxin)	
Initial Dioxin	n	Number (%) Abnormal	Unadjusted Relative Risk (95% C.I.) ^{a,b}	p-Value
Low	136	51 (37.5)	0.86 (0.74,1.01)	0.066
Medium	142	49 (34.5)		
High	140	41 (29.3)		

^aAdjusted for body mass index at the time of the blood measurement of dioxin.

^bRelative risk for a twofold increase in initial dioxin.

Note: Low = 32–79 ppt; Medium = >79–199 ppt; High = >199 ppt.

(d) MODEL 2: RANCH HANDS – INITIAL DIOXIN – ADJUSTED		
Analysis Results for Log ₂ (Initial Dioxin)		
n	Adjusted Relative Risk (95% C.I.) ^a	p-Value
411	1.05 (0.86,1.29)	0.609

^aRelative risk for a twofold increase in initial dioxin.

Note: Family history of heart disease before the age of 45 was not included in the model (see Section 15.1.4).

(e) MODEL 3: RANCH HANDS VS. COMPARISONS BY DIOXIN CATEGORY – UNADJUSTED				
Dioxin Category	n	Number (%) Abnormal	Unadjusted Relative Risk (95% C.I.) ^{a,b}	p-Value
Comparison	1,156	409 (35.4)		
Background RH	347	134 (38.6)	1.24 (0.96,1.59)	0.096
Low RH	206	75 (36.4)	1.03 (0.75,1.40)	0.861
High RH	212	66 (31.1)	0.77 (0.56,1.06)	0.110
Low plus High RH	418	141 (33.7)	0.89 (0.70,1.13)	0.333

^aAdjusted for body mass index at the time of the blood measurement of dioxin.

^bRelative risk and confidence interval relative to Comparisons.

Note: RH = Ranch Hand.

Background (Ranch Hand): 1987 dioxin ≤ 10 ppt.

Low (Ranch Hand): 1987 dioxin > 10 ppt, 10 ppt < initial dioxin ≤ 118 ppt.

High (Ranch Hand): 1987 dioxin > 10 ppt, initial dioxin > 118 ppt.

Table 15-12. Analysis of Overall ECG (Continued)

(f) MODEL 3: RANCH HANDS VS. COMPARISONS BY DIOXIN CATEGORY – ADJUSTED			
Dioxin Category	n	Adjusted Relative Risk (95% C.I.)^a	p-Value
Comparison	1,146		
Background RH	344	1.16 (0.88,1.52)	0.298
Low RH	202	0.86 (0.61,1.20)	0.362
High RH	209	0.96 (0.67,1.36)	0.802
Low plus High RH	411	0.91 (0.70,1.17)	0.453

^aRelative risk and confidence interval relative to Comparisons.

Note: RH = Ranch Hand.

Background (Ranch Hand): 1987 dioxin ≤ 10 ppt.

Low (Ranch Hand): 1987 dioxin > 10 ppt, 10 ppt < initial dioxin ≤ 118 ppt.

High (Ranch Hand): 1987 dioxin > 10 ppt, initial dioxin > 118 ppt.

Family history of heart disease before the age of 45 was not included in the model (see Section 15.1.4).

(g) MODEL 4: RANCH HANDS – 1987 DIOXIN – UNADJUSTED				
1987 Dioxin Category Summary Statistics			Analysis Results for Log₂ (1987 Dioxin)	
1987 Dioxin	n	Number (%) Abnormal	Unadjusted Relative Risk (95% C.I.)^a	p-Value
Low	256	92 (35.9)	0.94 (0.86,1.03)	0.204
Medium	253	97 (38.3)		
High	256	86 (33.6)		

^aRelative risk for a twofold increase in 1987 dioxin.

Note: Low = ≤7.8 ppt; Medium = >7.8–19.2 ppt; High = >19.2 ppt.

(h) MODEL 4: RANCH HANDS – 1987 DIOXIN – ADJUSTED			
Analysis Results for Log₂ (1987 Dioxin)			
n	Adjusted Relative Risk (95% C.I.)^a		p-Value
755	0.96 (0.85,1.08)		0.471

^aRelative risk for a twofold increase in 1987 dioxin.

Note: Family history of heart disease before the age of 45 was not included in the model (see Section 15.1.4).

15.2.2.2.7 ECG: RBBB

All Model 1 through Model 4 unadjusted and adjusted analyses results of RBBB were nonsignificant (Table 15-13(a–h): p>0.14 for all analyses).

Table 15-13. Analysis of ECG: RBBB

(a) MODEL 1: RANCH HANDS VS. COMPARISONS – UNADJUSTED					
Occupational Category	Group	n	Number (%) Yes	Unadjusted Relative Risk (95% C.I.)	p-Value

	<i>Comparison</i>	<i>1,156</i>	<i>42 (3.6)</i>		
Officer	Ranch Hand	301	15 (5.0)	1.53 (0.74,3.18)	0.253
	Comparison	453	15 (3.3)		
Enlisted Flyer	Ranch Hand	131	9 (6.9)	1.06 (0.43,2.59)	0.903
	Comparison	184	12 (6.5)		
Enlisted Groundcrew	Ranch Hand	334	8 (2.4)	0.82 (0.35,1.97)	0.664
	Comparison	519	15 (2.9)		

(b) MODEL 1: RANCH HANDS VS. COMPARISONS – ADJUSTED			
Occupational Category	n	Adjusted Relative Risk (95% C.I.)	p-Value
<i>All</i>	<i>1,902</i>	<i>1.11 (0.68,1.80)</i>	<i>0.680</i>
Officer	752	1.54 (0.72,3.25)	0.263
Enlisted Flyer	308	0.95 (0.37,2.40)	0.910
Enlisted Groundcrew	842	0.82 (0.33,1.99)	0.656

Note: Family history of heart disease before the age of 45 was not included in the model (see Section 15.1.4).

(c) MODEL 2: RANCH HANDS – INITIAL DIOXIN – UNADJUSTED				
Initial Dioxin Category Summary Statistics			Analysis Results for Log ₂ (Initial Dioxin)	
Initial Dioxin	n	Number (%) Yes	Unadjusted Relative Risk (95% C.I.) ^{a,b}	p-Value
Low	136	3 (2.2)	1.08 (0.72,1.61)	0.715
Medium	142	5 (3.5)		
High	140	5 (3.6)		

^aAdjusted for body mass index at the time of the blood measurement of dioxin.

^bRelative risk for a twofold increase in initial dioxin.

Note: Low = 32–79 ppt; Medium = >79–199 ppt; High = >199 ppt.

Table 15-13. Analysis of ECG: RBBB (Continued)

(d) MODEL 2: RANCH HANDS – INITIAL DIOXIN – ADJUSTED		
Analysis Results for Log₂ (Initial Dioxin)		
n	Adjusted Relative Risk (95% C.I.)^a	p-Value
411	1.17 (0.69,1.97)	0.567

^aRelative risk for a twofold increase in initial dioxin.

Note: Family history of heart disease before the age of 45 was not included in the model (see Section 15.1.4).

Results were not adjusted for race because of the sparse number of Ranch Hands with RBBB present.

(e) MODEL 3: RANCH HANDS VS. COMPARISONS BY DIOXIN CATEGORY – UNADJUSTED				
Dioxin Category	n	Number (%) Yes	Unadjusted Relative Risk (95% C.I.)^{a,b}	p-Value
Comparison	1,156	42 (3.6)		
Background RH	347	19 (5.5)	1.52 (0.87,2.66)	0.142
Low RH	206	5 (2.4)	0.66 (0.26,1.69)	0.388
High RH	212	8 (3.8)	1.05 (0.48,2.27)	0.903
Low plus High RH	418	13 (3.1)	0.84 (0.44,1.59)	0.586

^aAdjusted for body mass index at the time of the blood measurement of dioxin.

^bRelative risk and confidence interval relative to Comparisons.

Note: RH = Ranch Hand.

Background (Ranch Hand): 1987 dioxin ≤ 10 ppt.

Low (Ranch Hand): 1987 dioxin > 10 ppt, 10 ppt < initial dioxin ≤ 118 ppt.

High (Ranch Hand): 1987 dioxin > 10 ppt, initial dioxin > 118 ppt.

(f) MODEL 3: RANCH HANDS VS. COMPARISONS BY DIOXIN CATEGORY – ADJUSTED			
Dioxin Category	n	Adjusted Relative Risk (95% C.I.)^a	p-Value
Comparison	1,146		
Background RH	344	1.52 (0.84,2.76)	0.169
Low RH	202	0.56 (0.21,1.46)	0.236
High RH	209	1.03 (0.45,2.35)	0.951
Low plus High RH	411	0.76 (0.39,1.49)	0.429

^aRelative risk and confidence interval relative to Comparisons.

Note: RH = Ranch Hand.

Background (Ranch Hand): 1987 dioxin ≤ 10 ppt.

Low (Ranch Hand): 1987 dioxin > 10 ppt, 10 ppt < initial dioxin ≤ 118 ppt.

High (Ranch Hand): 1987 dioxin > 10 ppt, initial dioxin > 118 ppt.

Family history of heart disease before the age of 45 was not included in the model (see Section 15.1.4).

Table 15-13. Analysis of ECG: RBBB (Continued)

(g) MODEL 4: RANCH HANDS – 1987 DIOXIN – UNADJUSTED				
1987 Dioxin Category Summary Statistics			Analysis Results for Log₂ (1987 Dioxin)	
1987 Dioxin	n	Number (%) Yes	Unadjusted Relative Risk (95% C.I.)^a	p-Value
Low	256	14 (5.5)	0.92 (0.74,1.15)	0.472
Medium	253	8 (3.2)		
High	256	10 (3.9)		

^aRelative risk for a twofold increase in 1987 dioxin.

Note: Low = ≤7.8 ppt; Medium = >7.8–19.2 ppt; High = >19.2 ppt.

(h) MODEL 4: RANCH HANDS – 1987 DIOXIN – ADJUSTED			
Analysis Results for Log₂ (1987 Dioxin)			
n	Adjusted Relative Risk (95% C.I.)^a		p-Value
755	0.95 (0.71,1.27)		0.709

^aRelative risk for a twofold increase in 1987 dioxin.

Note: Family history of heart disease before the age of 45 was not included in the model (see Section 15.1.4).

Results were not adjusted for race because of the sparse number of Ranch Hands with RBBB present.

15.2.2.2.8 ECG: LBBB

All Model 1 through Model 4 analyses, both unadjusted and adjusted, of LBBB were nonsignificant (Table 15-14(a-h): $p > 0.06$ for all analyses).

Table 15-14. Analysis of ECG: LBBB

(a) MODEL 1: RANCH HANDS VS. COMPARISONS – UNADJUSTED					
Occupational Category	Group	n	Number (%) Yes	Unadjusted Relative Risk (95% C.I.)	p-Value
<i>All</i>	<i>Ranch Hand</i>	<i>766</i>	<i>8 (1.0)</i>	<i>0.75 (0.32,1.77)</i>	<i>0.507</i>
	<i>Comparison</i>	<i>1,156</i>	<i>16 (1.4)</i>		
Officer	Ranch Hand	301	1 (0.3)	0.15 (0.02,1.16)	0.069
	Comparison	453	10 (2.2)		
Enlisted Flyer	Ranch Hand	131	3 (2.3)	--	0.141 ^a
	Comparison	184	0 (0.0)		
Enlisted Groundcrew	Ranch Hand	334	4 (1.2)	1.04 (0.29,3.70)	0.956
	Comparison	519	6 (1.2)		

^aP-value was determined using a chi-square test with continuity correction because of the sparse number of participants with an LBBB.

--: Results were not presented because of the sparse number of participants with an LBBB.

(b) MODEL 1: RANCH HANDS VS. COMPARISONS – ADJUSTED			
Occupational Category	n	Adjusted Relative Risk (95% C.I.)	p-Value
<i>All</i>	<i>1,902</i>	<i>0.65 (0.27,1.59)</i>	<i>0.337</i>
Officer	752	0.14 (0.02,1.11)	0.062
Enlisted Flyer	308	--	--
Enlisted Groundcrew	842	0.86 (0.23,3.26)	0.826

--: Results were not presented because of the sparse number of participants with an LBBB.

Note: Family history of heart disease before the age of 45 was not included in the model (see Section 15.1.4).

Results were not adjusted for race because of the sparse number of participants with LBBB present.

(c) MODEL 2: RANCH HANDS – INITIAL DIOXIN – UNADJUSTED				
Initial Dioxin Category Summary Statistics			Analysis Results for Log ₂ (Initial Dioxin)	
Initial Dioxin	n	Number (%) Yes	Unadjusted Relative Risk (95% C.I.) ^{a,b}	p-Value

High RH	212	53 (25.0)	1.01 (0.72,1.43)	0.951
Low plus High RH	418	97 (23.2)	0.94 (0.72,1.23)	0.652

^aAdjusted for body mass index at the time of the blood measurement of dioxin.

^bRelative risk and confidence interval relative to Comparisons.

Note: RH = Ranch Hand.

Background (Ranch Hand): 1987 dioxin ≤ 10 ppt.

Low (Ranch Hand): 1987 dioxin > 10 ppt, 10 ppt < initial dioxin ≤ 118 ppt.

High (Ranch Hand): 1987 dioxin > 10 ppt, initial dioxin > 118 ppt.

(f) MODEL 3: RANCH HANDS VS. COMPARISONS BY DIOXIN CATEGORY – ADJUSTED			
Dioxin Category	n	Adjusted Relative Risk (95% C.I.) ^a	p-Value
Comparison	1,128		
Background RH	337	1.13 (0.83,1.53)	0.448
Low RH	192	0.79 (0.54,1.16)	0.235
High RH	206	1.12 (0.77,1.64)	0.544
Low plus High RH	398	0.95 (0.71,1.27)	0.719

^aRelative risk and confidence interval relative to Comparisons.

Note: RH = Ranch Hand.

Background (Ranch Hand): 1987 dioxin ≤ 10 ppt.

Low (Ranch Hand): 1987 dioxin > 10 ppt, 10 ppt < initial dioxin ≤ 118 ppt.

High (Ranch Hand): 1987 dioxin > 10 ppt, initial dioxin > 118 ppt.

Table 15-15. Analysis of ECG: Nonspecific ST- and T-wave Changes (Continued)

(g) MODEL 4: RANCH HANDS – 1987 DIOXIN – UNADJUSTED				
1987 Dioxin Category Summary Statistics			Analysis Results for Log₂ (1987 Dioxin)	
1987 Dioxin	n	Number (%) Yes	Unadjusted Relative Risk (95% C.I.)^a	p-Value
Low	256	53 (20.7)	1.00 (0.90,1.11)	0.971
Medium	253	63 (24.9)		
High	256	63 (24.6)		

^aRelative risk for a twofold increase in 1987 dioxin.

Note: Low = ≤7.8 ppt; Medium = >7.8–19.2 ppt; High = >19.2 ppt.

(h) MODEL 4: RANCH HANDS – 1987 DIOXIN – ADJUSTED			
Analysis Results for Log₂ (1987 Dioxin)			
n	Adjusted Relative Risk (95% C.I.)^a		p-Value
755	0.95 (0.83,1.09)		0.486

^aRelative risk for a twofold increase in 1987 dioxin.

Note: Family history of heart disease before the age of 45 was not included in the model (see Section 15.1.4).

15.2.2.2.10 ECG: Bradycardia

The Model 1 and 2 unadjusted and adjusted analyses of bradycardia did not result in significant findings (Table 15-16(a–d): $p > 0.08$ for all analyses).

The unadjusted Model 3 analyses revealed that bradycardia was present in a significantly higher percentage of Ranch Hands in the background dioxin category than in Comparisons (Table 15-16(e): Unadjusted RR=1.69, $p=0.034$). After covariate adjustment, there were no significant differences (Table 15-16(f): $p=0.051$).

The unadjusted Model 4 analysis of bradycardia revealed a significant inverse association between the presence of bradycardia and 1987 dioxin (Table 15-16(g): Unadjusted RR=0.80, $p=0.024$). The percentages of participants with bradycardia in the low, medium, and high 1987 dioxin categories were 8.6, 5.9, and 2.7, respectively. After covariate adjustment, the results became nonsignificant (Table 15-16(h): $p=0.202$).

Table 15-16. Analysis of ECG: Bradycardia

(a) MODEL 1: RANCH HANDS VS. COMPARISONS – UNADJUSTED					
Occupational Category	Group	n	Number (%) Yes	Unadjusted Relative Risk (95% C.I.)	p-Value

^aRelative risk for a twofold increase in 1987 dioxin.

Note: Family history of heart disease before the age of 45 was not included in the model (see Section 15.1.4).

Results were not adjusted for race, military occupation, current cigarette smoking, diabetic class, and family history of heart disease because of the sparse number of Ranch Hands with tachycardia present.

15.2.2.2.12 ECG: Arrhythmia

All Model 1 and Model 4 unadjusted and adjusted analyses of arrhythmia were nonsignificant (Table 15-18(a,b,g,h): $p > 0.19$ for all analyses).

The unadjusted Model 2 analyses revealed a significant inverse relation between initial dioxin and the presence of arrhythmia (Table 15-18(c): Unadjusted RR=0.63, $p=0.001$). After adjustment for covariates, the relation was not significant (Table 15-18(d): $p=0.092$).

In the unadjusted analyses of Model 3, a significantly lower percentage of Ranch Hands in the high dioxin category displayed the presence of arrhythmia relative to Comparisons (Table 15-18(e): Unadjusted RR=0.49, $p=0.019$). After adjustment for covariates, all results were nonsignificant (Table 15-18(f): $p \geq 0.15$ for all analyses).

Table 15-18. Analysis of ECG: Arrhythmia

<i>All</i>	<i>1,902</i>	<i>0.80 (0.51,1.26)</i>		<i>0.331</i>	
Officer	752	1.05 (0.55,1.98)		0.886	
Enlisted Flyer	308	0.54 (0.21,1.40)		0.201	
Enlisted Groundcrew	842	0.71 (0.31,1.63)		0.416	

Note: Family history of heart disease before the age of 45 was not included in the model (see Section 15.1.4).

(c) MODEL 2: RANCH HANDS – INITIAL DIOXIN – UNADJUSTED				
Initial Dioxin Category Summary Statistics			Analysis Results for Log ₂ (Initial Dioxin)	
Initial Dioxin	n	Number (%) Yes	Unadjusted Relative Risk (95% C.I.) ^{a,b}	p-Value
Low	136	5 (3.7)	1.01 (0.71,1.44)	0.965
Medium	142	8 (5.6)		
High	140	5 (3.6)		

^aAdjusted for body mass index at the time of the blood measurement of dioxin.

^bRelative risk for a twofold increase in initial dioxin.

Note: Low = 32–79 ppt; Medium = >79–199 ppt; High = >199 ppt.

Table 15-19. Analysis of ECG: Evidence of Prior Myocardial Infarction (Continued)

(d) MODEL 2: RANCH HANDS – INITIAL DIOXIN – ADJUSTED		
Analysis Results for Log ₂ (Initial Dioxin)		
n	Adjusted Relative Risk (95% C.I.)^a	p-Value
411	1.57 (0.96,2.59)	0.071

^aRelative risk for a twofold increase in initial dioxin.

Note: Family history of heart disease before the age of 45 was not included in the model (see Section 15.1.4).

Results were not adjusted for race because of the sparse number of Ranch Hands with evidence from the ECG of a prior myocardial infarction.

(e) MODEL 3: RANCH HANDS VS. COMPARISONS BY DIOXIN CATEGORY – UNADJUSTED				
Dioxin Category	n	Number (%) Yes	Unadjusted Relative Risk (95% C.I.)^{a,b}	p-Value
Comparison	1,156	61 (5.3)		
Background RH	347	16 (4.6)	0.90 (0.51,1.60)	0.730
Low RH	206	10 (4.9)	0.91 (0.46,1.80)	0.778
High RH	212	8 (3.8)	0.68 (0.32,1.44)	0.312
Low plus High RH	418	18 (4.3)	0.78 (0.45,1.35)	0.374

^aAdjusted for body mass index at the time of the blood measurement of dioxin.

^bRelative risk and confidence interval relative to Comparisons.

Note: RH = Ranch Hand.

Background (Ranch Hand): 1987 dioxin ≤ 10 ppt.

Low (Ranch Hand): 1987 dioxin > 10 ppt, 10 ppt < initial dioxin ≤ 118 ppt.

High (Ranch Hand): 1987 dioxin > 10 ppt, initial dioxin > 118 ppt.

(f) MODEL 3: RANCH HANDS VS. COMPARISONS BY DIOXIN CATEGORY – ADJUSTED			
Dioxin Category	n	Adjusted Relative Risk (95% C.I.)^a	p-Value
Comparison	1,146		
Background RH	344	0.81 (0.45,1.47)	0.487
Low RH	202	0.75 (0.37,1.52)	0.422
High RH	209	0.82 (0.37,1.84)	0.632
Low plus High RH	411	0.78 (0.44,1.39)	0.406

^aRelative risk and confidence interval relative to Comparisons.

Note: RH = Ranch Hand.

Background (Ranch Hand): 1987 dioxin ≤ 10 ppt.

Low (Ranch Hand): 1987 dioxin > 10 ppt, 10 ppt < initial dioxin ≤ 118 ppt.

High (Ranch Hand): 1987 dioxin > 10 ppt, initial dioxin > 118 ppt.

Family history of heart disease before the age of 45 was not included in the model (see Section 15.1.4).

Table 15-19. Analysis of ECG: Evidence of Prior Myocardial Infarction (Continued)

(g) MODEL 4: RANCH HANDS – 1987 DIOXIN – UNADJUSTED				
1987 Dioxin Category Summary Statistics			Analysis Results for Log₂ (1987 Dioxin)	
1987 Dioxin	n	Number (%) Yes	Unadjusted Relative Risk (95% C.I.)^a	p-Value
Low	256	13 (5.1)	0.97 (0.79,1.21)	0.815
Medium	253	9 (3.6)		
High	256	12 (4.7)		

^aRelative risk for a twofold increase in 1987 dioxin.

Note: Low = ≤7.8 ppt; Medium = >7.8–19.2 ppt; High = >19.2 ppt.

(h) MODEL 4: RANCH HANDS – 1987 DIOXIN – ADJUSTED			
Analysis Results for Log₂ (1987 Dioxin)			
n	Adjusted Relative Risk (95% C.I.)^a		p-Value
755	1.20 (0.88,1.64)		0.252

^aRelative risk for a twofold increase in 1987 dioxin.

Note: Family history of heart disease before the age of 45 was not included in the model (see Section 15.1.4).

15.2.2.2.14 ECG: Other Diagnoses

One participant had an “other” ECG diagnosis, which was an anteroseptal aneurysm. This participant was a non-Black Ranch Hand enlisted groundcrew. Because only one participant had this condition, statistical analysis was not possible.

15.2.2.3 Physical Examination Variables – Peripheral Vascular Function

15.2.2.3.1 Funduscopy Examination

The Model 1 through Model 4 unadjusted and adjusted analyses of the funduscopy examination were nonsignificant (Table 15-20(a-h): $p \geq 0.11$ for all analyses).

Table 15-20. Analysis of Funduscopy Examination

(a) MODEL 1: RANCH HANDS VS. COMPARISONS – UNADJUSTED

n	Adjusted Relative Risk (95% C.I.)^a		p-Value
753	1.05 (0.85,1.29)		0.646

^aRelative risk for a twofold increase in 1987 dioxin.

Note: Family history of heart disease before the age of 45 was not included in the model (see Section 15.1.4).

15.2.2.3.7 Posterior Tibial Pulses

All unadjusted Model 1 analyses of posterior tibial pulses were nonsignificant (Table 15-26(a): $p > 0.06$ for all analyses). When adjusted for covariates, a significant difference in the presence of abnormal posterior tibial pulses was found overall between Ranch Hands and Comparisons (Table 15-26(b): Adjusted RR=0.59, $p=0.027$). The Ranch Hand group had 4.3 percent with an abnormal posterior tibial

pulse, whereas the Comparison group had 5.9 percent abnormal. In addition, the presence of abnormal posterior tibial pulses was found in a significantly lower percentage of Ranch Hand officers (3.6%) than Comparison officers (6.9%) (Table 15-26(b): Adjusted RR=0.46, p=0.047).

There were no significant findings in the unadjusted analyses of Model 3 (Table 15-26(e): p>0.15 for all analyses). In the adjusted analyses of Model 3, a significantly lower percentage of Ranch Hands in the background dioxin category (4.0%) and Ranch Hands in the low dioxin category (3.4%) exhibited abnormal posterior tibial pulses relative to Comparisons (5.9%) (Table 15-27(f): Adjusted RR=0.48, p=0.039 for the background dioxin category contrast; Adjusted RR=0.40, p=0.048 for the low dioxin category contrast).

All unadjusted and adjusted analyses of posterior tibial pulses for Models 2 and 4 were nonsignificant (Table 15-26(c,d,g,h): p>0.07 for all analyses).

Table 15-26. Analysis of Posterior Tibial Pulses

n	Adjusted Relative Risk (95% C.I.) ^a	p-Value
751	1.06 (0.87,1.30)	0.561

^aRelative risk for a twofold increase in 1987 dioxin.

Note: Family history of heart disease before the age of 45 was not included in the model (see Section 15.1.4).

15.2.2.3.9 Peripheral Pulses

All unadjusted and adjusted analyses for Models 1, 2, and 4 were nonsignificant (Table 15-28(a-d,g,h): p>0.06 for all analyses).

The unadjusted analyses of Model 3 were nonsignificant (Table 15-28(e): p>0.06 for all analyses). When adjusted for covariates, a significantly lower percentage of Ranch Hands in the low dioxin category (10.8%) were found to exhibit abnormal peripheral pulses relative to Comparisons (15.9%) (Table 15-28(f): Adjusted RR=0.61, p=0.046).

Table 15-28. Analysis of Peripheral Pulses

(c) MODEL 2: RANCH HANDS – INITIAL DIOXIN – UNADJUSTED						
Initial Dioxin Category Summary Statistics				Analysis Results for Log ₂ (Initial Dioxin)		
Initial Dioxin	n	Unadjusted Mean	Adjusted Mean ^a	R ²	Slope (Standard Error) ^a	p-Value
Low	130	1.187	1.187	0.003	-0.007 (0.007)	0.349
Medium	136	1.168	1.168			
High	133	1.160	1.161			

^aAdjusted for body mass index at the time of the blood measurement of dioxin.

Note: Low = 32–79 ppt; Medium = >79–199 ppt; High = >199 ppt.

(d) MODEL 2: RANCH HANDS – INITIAL DIOXIN – ADJUSTED						
Initial Dioxin Category Summary Statistics				Analysis Results for Log ₂ (Initial Dioxin)		
Initial Dioxin	n	Adjusted Mean		R ²	Adjusted Slope (Standard Error)	p-Value
Low	128	1.140		0.190	-0.011 (0.008)	0.179
Medium	134	1.133				
High	130	1.103				

Note: Family history of heart disease before the age of 45 was not included in the model (see Section 15.1.4).

(e) MODEL 3: RANCH HANDS VS. COMPARISONS BY DIOXIN CATEGORY – UNADJUSTED						
Dioxin Category	n	Unadjusted Mean	Adjusted Mean ^a	Difference of Adjusted Mean vs. Comparisons (95% C.I.) ^a		p-Value
Comparison	1,108	1.172	1.172			
Background RH	340	1.180	1.177	0.005	(-0.017,0.028)	0.642
Low RH	199	1.178	1.179	0.006	(-0.021,0.034)	0.649
High RH	200	1.166	1.169	-0.004	(-0.031,0.024)	0.803
Low plus High RH	399	1.172	1.174	0.001	(-0.020,0.023)	0.893

^aAdjusted for body mass index at the time of the blood measurement of dioxin.

Note: RH = Ranch Hand.

Background (Ranch Hand): 1987 dioxin ≤ 10 ppt.

Low (Ranch Hand): 1987 dioxin > 10 ppt, 10 ppt < initial dioxin ≤ 118 ppt.

High (Ranch Hand): 1987 dioxin > 10 ppt, initial dioxin > 118 ppt.

Table 15-31. Analysis of Hyperemic Pressure Index (1 Minute Post-exercise) (Continuous) (Continued)

(f) MODEL 3: RANCH HANDS VS. COMPARISONS BY DIOXIN CATEGORY – ADJUSTED				
Dioxin Category	n	Adjusted Mean	Difference of Adjusted Mean vs. Comparisons (95% C.I.)	p-Value
Comparison	1,100	1.131		
Background RH	336	1.127	-0.004 (-0.025,0.017)	0.709
Low RH	195	1.153	0.021 (-0.005,0.047)	0.108
High RH	197	1.135	0.004 (-0.023,0.030)	0.784
Low plus High RH	392	1.144	0.012 (-0.007,0.032)	0.219

Note: RH = Ranch Hand.

Background (Ranch Hand): 1987 dioxin \leq 10 ppt.

Low (Ranch Hand): 1987 dioxin $>$ 10 ppt, 10 ppt $<$ initial dioxin \leq 118 ppt.

High (Ranch Hand): 1987 dioxin $>$ 10 ppt, initial dioxin $>$ 118 ppt.

Family history of heart disease before the age of 45 was not included in the model (see Section 15.1.4).

(g) MODEL 4: RANCH HANDS – 1987 DIOXIN – UNADJUSTED					
1987 Dioxin Category Summary Statistics			Analysis Results for Log ₂ (1987 Dioxin)		
1987 Dioxin	n	Unadjusted Mean	R ²	Slope (Standard Error)	p-Value
Low	252	1.195	0.002	-0.005 (0.004)	0.228
Medium	244	1.166			
High	243	1.165			

Note: Low = \leq 7.8 ppt; Medium = $>$ 7.8-19.2 ppt; High = $>$ 19.2 ppt.

(h) MODEL 4: RANCH HANDS – 1987 DIOXIN – ADJUSTED					
1987 Dioxin Category Summary Statistics			Analysis Results for Log ₂ (1987 Dioxin)		
1987 Dioxin	n	Adjusted Mean	R ²	Adjusted Slope (Standard Error)	p-Value

15.3 DISCUSSION

Cardiovascular disorders are among the most common diseases encountered by primary care physicians. Although arbitrary, dividing data collection into central and peripheral cardiovascular functions is convenient and forms a reasonable basis for comparing cohorts under study. In practice, diagnosing cardiovascular disease is based primarily on noninvasive data, as analyzed in this chapter. Specifically, history, physical examination, and a resting ECG serve as highly reliable indices that can alert clinicians to the presence of underlying cardiovascular disease and indicate the need for additional, more-specific, noninvasive or invasive studies.

The limitations of the history in diagnosing cardiovascular disease deserve emphasis. For example, in peripheral vascular disease, signs and symptoms will vary depending on the degree of development of collateral circulatory channels. While hemodynamically significant arterial disease of the lower extremities is usually associated with claudication, severe carotid occlusive disease can be present in the absence of symptoms of transient cerebral ischemia. Further, conclusive evidence shows that advanced coronary artery disease can occur in the absence of angina and be present as “silent” myocardial ischemia. Lastly, it is well recognized that cardiovascular history, as related by patients, is often subject to error. The generic term “heart attack,” for example, can be used to describe any type of cardiac event ranging from an isolated episode of unstable angina or arrhythmia to a myocardial infarction. These imperfections highlight the importance of medical record verification, as conducted in this study.

In the assessment of the cardiovascular system, the physical examination can provide valuable clues to the presence of asymptomatic but significant underlying disease. In this study, steps were taken to simplify

data collection and reduce interobserver variability among the examining physicians. All blood pressure readings, for example, were taken by automated sphygmomanometric instruments. In the cardiovascular examination, murmurs and bruits were auscultory endpoints generated by turbulent blood flow of valvular or vascular origin, respectively. The detection of subtle variation in the frequency, intensity, and radiation of murmurs enables the experienced cardiologist to predict accurately the specific valve of origin and associated hemodynamic significance. Because these skills are usually not acquired by the general internist, and to minimize interobserver variability, the examination protocol specified the recording of the presence or absence of murmurs and the anatomic location on the chest wall. As markers of occult arterial occlusive disease, vascular bruits were relatively easy to detect and were carefully sought over the carotid, abdominal, and femoral vessels.

Dependent variable-covariate analyses confirmed associations that are well established in clinical practice. When correlated with a medical records review, abnormalities noted during physical examinations and in the laboratory confirmed the association of cardiovascular disease with the classic risk factors of age, cigarette use, family history, diabetes, obesity, and alcohol consumption. In the 1997 examinations, obesity proved to be a significant risk factor for the development of heart disease. In the current study, however, the incidence of heart disease was almost identical in participants who were obese and those who were not obese (82.3% versus 82.2%, respectively), and body mass index was most strongly associated with systolic and diastolic hypertension.

Historically, lifetime alcohol consumption has been strongly associated with hypertension; however, blood pressure determinations made during the 2002 physical examinations did not make this strong association. The increased prevalence of selected pulse deficits associated with alcohol consumption may have been mediated by concomitant cigarette use. Likewise, the finding of significantly lower cholesterol in participants with a history of hypertension, heart disease, and myocardial infarction is counterintuitive, explained perhaps by the use of cholesterol medication by these participants for a heart condition, which was not investigated in these analyses.

In the analyses of verified historical variables, the prevalence of hypertension, myocardial infarction, transient ischemic attack, and stroke was similar in Ranch Hands and Comparisons. At the 1997 examination, in contrast to the 1992 examination, heart disease was more prevalent in Ranch Hands than Comparisons (66.1% versus 60.8%) across all occupational strata. Related to a marked interim increase in heart disease in Comparison relative to Ranch Hand officers, this disparity in prevalence had narrowed (84.0% versus 81.1%) by 2002. The relative risk was statistically significant, though less so, and only in the enlisted flyer category ($p=0.004$ in 1997 versus $p=0.015$ in 2002). The Ranch Hand cohort in the 1992 and 1997 examinations showed a significant inverse dose-response effect between heart disease and either initial dioxin or 1987 serum dioxin. In the 2002 follow-up examination, the prevalence of heart disease was not significantly associated with dioxin within the Ranch Hand group.

During the 20-year course of this longitudinal study, the results of the serum dioxin analyses in the cardiovascular assessment have been variable and inconsistent. In the 1997 examinations, significant positive dose-response effects were noted in the associations of hypertension, ECG evidence of prior myocardial infarction, and tachycardia with 1987 serum dioxin levels. In the current study, only diastolic blood pressure (discrete form) was found to have a positive association with dioxin. In a pattern similar to one found in 1997, but in 2002 more pronounced and statistically significant, an increasing dose-response and relative risk was noted in Ranch Hands in the high dioxin category (in 1997: Adjusted $RR=1.46$, $p=0.221$; in 2002: Adjusted $RR=1.88$, $p=0.036$).

The prevalence of funduscopic abnormalities and intermittent claudication, both more common in Ranch Hands than Comparisons at the 1992 examinations, remained the same in the two cohorts in the current

study as they were in 1997. In several analyses, pulse deficits, also more common in Ranch Hands in 1992 (but not in 1997), were found to be more common in Comparisons in the current study.

At the conclusion of six examinations conducted over 20 years, the prevalence of cardiovascular disease was not significantly increased in the Ranch Hand cohort. In only one analysis, that of diastolic blood pressure noted above, was there any evidence for a dose-response effect in relation to the body burden of dioxin.

15.4 SUMMARY

The cardiovascular assessment was based on questionnaire data, which was subsequently verified by a review of medical records, and physical examination data. Associations with herbicide exposure (i.e., group – Model 1), initial dioxin (Model 2), categorized dioxin (Model 3), and 1987 dioxin levels (Model 4) were examined for each variable in the cardiovascular assessment. The significant adjusted results are discussed in the sections below.

15.4.1 Model 1: Group Analysis

The Model 1 analyses revealed significant findings in the adjusted analyses of heart disease (excluding essential hypertension) and in the adjusted analyses of posterior tibial pulses. The presence of heart disease was found to be significantly higher among Ranch Hands than Comparisons in enlisted flyers. In the adjusted analyses of posterior tibial pulses, Ranch Hands were found to have a significantly lower presence of abnormal pulses than Comparisons. Likewise, in the analysis of officers, a significantly greater percentage of Comparisons were found to have abnormal posterior tibial pulses than Ranch Hands. The results of the group analysis are provided in Table 15-36.

A capital “NS” denotes a nonsignificant positive association. A lowercase “ns” denotes a nonsignificant inverse association.

15.4.3 Model 3: Categorized Dioxin Analysis

Results for the Model 3 adjusted analyses revealed significant findings in both the continuous and discrete forms of systolic blood pressure. In the analyses of the continuous form, Ranch Hands in both the low dioxin category and the low and high dioxin categories combined were found to have a significantly lower mean systolic blood pressure than Comparisons. Similarly, in the analyses of the discrete form of systolic blood pressure, there was a significantly greater percentage of Comparisons with high systolic blood pressure as compared to Ranch Hands in both the low dioxin category and the low and high dioxin categories combined. In the adjusted analyses of the discrete form of diastolic blood pressure, a significantly greater percentage of Ranch Hands in the high dioxin category were found to have high diastolic blood pressure than Comparisons.

Adjusted Model 3 analyses also revealed significant findings for posterior tibial pulses and peripheral pulses. Abnormal posterior tibial pulses were found among a significantly higher percentage of Comparisons than Ranch Hands in both the background dioxin category and the low dioxin category. In addition, abnormal peripheral pulses were found among a significantly higher percentage of Comparisons than Ranch Hands in the low dioxin category.

The results of the categorized dioxin analysis are presented in Table 15-38.

^aA negative difference in means (Ranch Hand mean less than Comparison mean) was considered adverse to Ranch Hands for this variable. A positive difference in means (Comparison mean less than Ranch Hand mean) was considered adverse to Comparisons for this variable.

--: The analysis was not performed because of the sparse number of participants with an abnormality.

Note: NS or ns: Not significant ($p > 0.05$).

C: Continuous form of dependent variable.

D: Discrete form of dependent variable.

The p-value was given if $p \leq 0.05$. The relative risk was given in parentheses for a significant result from the analysis of a discrete dependent variable. The difference in means was given in parentheses for a significant result from the analysis of a continuous dependent variable.

A capital “NS” denotes a nonsignificant positive association. A lowercase “ns” denotes a nonsignificant inverse association.

15.4.4 Model 4: 1987 Dioxin Level Analysis

In the Model 4 adjusted analysis of the discrete form of systolic blood pressure, a significant relation was found between presence of high systolic blood pressure and the 1987 dioxin level. As the 1987 dioxin level increased, the percentage of participants with high systolic blood pressure decreased. The results of the 1987 dioxin analysis are displayed in Table 15-39.

^aA negative slope was considered adverse for this variable.

Table 15-39. Summary of 1987 Dioxin Analysis (Model 4) for Cardiovascular Variables (Ranch Hands Only) (Continued)

Note: NS or ns: Not significant ($p > 0.05$).

C: Continuous form of dependent variable.

D: Discrete form of dependent variable.

The p-value was given if $p \leq 0.05$. The relative risk was given in parentheses for a significant result from the analysis of a discrete dependent variable. The slope was given in parentheses for a significant result from the analysis of a continuous dependent variable.

A capital "NS" denotes a nonsignificant positive association. A lowercase "ns" denotes a nonsignificant inverse association.

15.4.5 Summary of Significant Results

Table 15-40 summarizes the significant results ($p \leq 0.05$) for the adjusted analyses that were performed for the cardiovascular assessment. The dependent variable and its table reference are listed along with the model and the contrast or description of the model. The p-value is provided along with analysis statistics that correspond to the type of analysis that was performed (either continuous or discrete). A description of the analysis and the statistics that are presented is referenced under the "Note" column and is explained in footnotes.

Table 15-40. Summary of Results from Significant Adjusted Analyses in the Cardiovascular Assessment

Dependent Variable (Table Reference)	Model	Contrast or Description	p-Value	Analysis Statistics	Adjusted Mean or Percent Abnormal	Note
Heart Disease (Excluding Essential Hypertension) (15-4)	1	RH vs. C, Enlisted Flyer	0.015	2.46 (1.19,5.11)	RH: 91.6% C: 81.0%	(a)
Systolic Blood Pressure (Continuous) (15-7)	3	Low RH vs. C	0.025	-2.9	RH: 127.6 mm Hg C: 130.5 mm Hg	(b)
	3	Low plus High RH vs. C	0.022	-2.3	RH: 128.2 mm Hg C: 130.5 mm Hg	(b)
Systolic Blood Pressure (Discrete) (15-8)	3	Low RH vs. C	0.018	0.63 (0.43,0.92)	RH: 19.4% C: 26.0%	(c)
	3	Low plus High RH vs. C	0.023	0.72 (0.54,0.96)	RH: 20.3% C: 26.0%	(c)
	4	All RH: 1987 Dioxin	0.023	0.86 (0.75,0.98)	Low: 26.2% Medium: 21.7% High: 20.7%	(d)
Diastolic Blood Pressure (Discrete) (15-10)	3	High RH vs. C	0.036	1.88 (1.04,3.39)	RH: 9.0% C: 4.8%	(c)

Table 15-40. Summary of Results from Significant Adjusted Analyses in the Cardiovascular Assessment (Continued)

Dependent Variable (Table Reference)	Model	Contrast or Description	p-Value	Analysis Statistics	Adjusted Mean or Percent Abnormal	Note
Posterior Tibial Pulses (15-26)	1	RH vs. C, All	0.027	0.59 (0.36,0.95)	RH: 4.3% C: 5.9%	(a)
	1	RH vs. C, Officer	0.047	0.46 (0.22,0.99)	RH: 3.6% C: 6.9%	(a)
	3	Background RH vs. C	0.039	0.48 (0.24,0.96)	RH: 4.0% C: 5.9%	(c)
	3	Low RH vs. C	0.048	0.40 (0.16,0.99)	RH: 3.4% C: 5.9%	(c)
	3	Low RH vs. C	0.046	0.61 (0.37,0.99)	RH: 10.8% C: 15.9%	(c)

- (a): Discrete variable: adjusted relative risk and 95% confidence interval were presented; percent abnormal was presented for each exposure group in contrast.
- (b): Continuous variable: difference of adjusted means was presented; confidence interval was not presented because analysis was not performed on original scale; adjusted means were presented for each dioxin category in contrast.
- (c): Discrete variable: adjusted relative risk and 95% confidence interval were presented; percent abnormal was presented for each dioxin category in contrast.
- (d): Discrete variable: adjusted relative risk and 95% confidence interval were presented for a twofold increase in 1987 dioxin; percent abnormal was presented for each of three 1987 dioxin categories.

Note: RH = Ranch Hand.
C = Comparison.

Model 3: Background (Ranch Hand): 1987 dioxin \leq 10 ppt.
Low (Ranch Hand): 1987 dioxin $>$ 10 ppt, 10 ppt $<$ initial dioxin \leq 118 ppt.
High (Ranch Hand): 1987 dioxin $>$ 10 ppt, initial dioxin $>$ 118 ppt.

Model 4: Low = \leq 7.8 ppt; Medium = $>$ 7.8–19.2 ppt; High = $>$ 19.2 ppt (Ranch Hands only).

15.5 CONCLUSION

The presence of heart disease was found to be higher among Ranch Hands than Comparisons in enlisted flyers. Ranch Hands were found to have a lower presence of abnormal pulses, both in all participants and in the officer stratum. No significant relations between cardiovascular endpoints and initial dioxin were observed.

An increased percentage of Ranch Hands in the high dioxin category were found to have abnormally high diastolic blood pressure. Ranch Hands in both the low dioxin category and the low and high dioxin categories combined were found to have a lower mean systolic blood pressure. Similarly, a smaller percentage of Ranch Hands in both the low dioxin category and the low and high dioxin categories combined had an abnormally high systolic blood pressure.

A lower percentage of Ranch Hands in both the background dioxin category and the low dioxin category had abnormal posterior tibial pulses. In addition, abnormal peripheral pulses were found among a lower

percentage of Ranch Hands in the low dioxin category. As the 1987 dioxin level increased, the percentage of participants with abnormally high systolic blood pressure decreased.

The prevalence of cardiovascular disease was not increased in the Ranch Hand cohort. In only one analysis, that of diastolic blood pressure noted above, was there any evidence for a dose-response effect in relation to the body burden of dioxin.

16 HEMATOLOGY ASSESSMENT

16.1 INTRODUCTION

16.1.1 Background

16.1.1.1 Organs/Diseases

The Air Force Health Study (AFHS) hematology assessment included data from the laboratory examination. Fourteen hematologic variables were examined, including red blood cell (RBC) count, white blood cell (WBC) count, hemoglobin, hematocrit, and platelet count. The following absolute WBC counts were examined: segmented neutrophils, neutrophilic bands, lymphocytes, monocytes, eosinophils, and basophils. Fibrinogen, erythrocyte sedimentation rate (ESR), and RBC morphology were also analyzed.

Several chemical substances, including acetone, acrolein, zinc, acrylonitrile, 1,2-dichloroethene, benzene, and dinitrotoluene have been identified as affecting the hematologic system (1). This chapter discusses findings primarily related to blood cells and platelet counts. Hematologic malignancies are discussed in Chapter 10, while results of blood chemistry tests related to gastrointestinal function are summarized in Chapter 13.

16.1.1.2 Toxicology

Experiments in laboratory animals demonstrated that 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD or dioxin) is directly toxic to the hematopoietic system in several species, although the toxic effects vary depending on the dosage and type of animal species. In many reports, it was difficult to distinguish primary from secondary effects of systemic toxicity.

In one study, dioxin administered to monkeys in low doses by oral gavage resulted in elevated neutrophil counts, while higher doses were associated with lymphocytopenia and thrombocytopenia (2). A decrease in overall cellularity and an increase in the myeloid-erythroid ratio were noted in approximately half of the sternal bone marrow samples examined at the conclusion of the experiment. One study in rats using a range of gavage dioxin doses reported depressed RBC counts and packed cell volumes in the high-dose group (3). Another rat experiment that administered even greater dioxin doses orally found elevated erythrocyte, reticulocyte, and neutrophil counts, with a reduction in mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), platelet counts, and clot retraction times. Authors Weissberg and Zinkl commented that these effects could be attributed to systemic toxicity with terminal dehydration (4). In a multispecies study, mice and guinea pigs given a wide range of dioxin orally were found to have dose-dependent reductions in leukocytes with relative lymphocytopenia within 1 week of dioxin administration, with thrombocytopenia and hemoconcentration occurring in rats (5). Several other animal experiments, although designed primarily to investigate immunologic sequelae of dioxin exposure, focused on selected hematologic elements, particularly macrophages and polymorphonuclear leukocytes. Whether the responses observed were secondary to inflammation or specific to dioxin is not known (4, 6-8).

Additional animal research relevant to the hematopoietic system focused on the altered cellular differentiation associated with dioxin toxicity. In mice, progenitor cells were suppressed following

exposure to dioxin in doses as low as 1.0 µg/kg of body weight, and in vitro studies demonstrated that myelotoxicity occurs by a direct inhibition of proliferating stem cells (9). A subsequent study from the same laboratory demonstrated a direct effect of dioxin on cultured lymphocytes resulting in a selective inhibition of B-cell differentiation into antibody-secreting cells (10). In these and other studies, evidence for the role of the aryl hydrocarbon (Ah) receptor in mediating these myelotoxic and lymphotoxic effects was found (11); however, the relevance of these observations to dioxin hematopoietic toxicity remains to be demonstrated in humans (12).

16.1.1.3 Epidemiology

In general, human observational studies have shown fewer and less consistent hematologic findings than the animal experiments. Mortality and morbidity studies including hematologic data as endpoints have been based on populations exposed to dioxin through environmental contamination (13-26), occupation (27-44), and during military service in Southeast Asia (SEA) (45-55).

16.1.1.3.1 Epidemiology: Blood Chemistry Levels

One of the most severe human environmental exposures to dioxin occurred consequent to an industrial explosion in Seveso, Italy, in 1976. Several medical surveillance reports monitored this heavily exposed population (13-18, 21, 22). According to laboratory tests, no differences in pathological conditions between exposed people and unexposed controls were reported (22). A morbidity study of workers involved in the cleanup of the Seveso environs found no differences in selected hematologic indices (hemoglobin, WBC count, and platelets) between exposed subjects and controls (14).

Several studies were conducted on populations environmentally exposed to dioxin through contaminated soil in the Quail Run (19, 20, 23) and Times Beach (25) residential areas of Missouri. No differences were found in any of the hematologic parameters examined, except for in the Times Beach study, which found a statistically significant increase in the mean platelet count in the exposed cohort relative to the unexposed. The difference, however, was not considered clinically meaningful (25). A follow-up study found no abnormalities in the complete blood count (CBC) related to the adipose tissue levels of dioxin (26).

Hematologic conditions were evaluated in relation to occupational dioxin exposure in several cohorts, including workers in the United States (27, 28, 32, 35, 39-41), Japan (56), Germany (34, 36), and other European countries (29-31, 33, 37, 38, 42, 57). Studies of dioxin-exposed chemical production workers in the United States generally found little indication for hematologic abnormalities (27, 32, 39, 41). In German populations of workers exposed to dioxin after a chemical accident (34) or during the production of resins (36), no differences between exposed subjects and controls were noted in WBC counts, platelet counts, or hemoglobin levels. Furthermore, no indication of hematologic effects was found in other European worker populations (31, 33, 37, 38) or in municipal waste incinerator workers chronically exposed to dioxins in Japan (56).

Studies of Vietnam veterans generally found little evidence for an association between dioxin exposure and hematologic abnormalities (45-54, 58-60). In the Vietnam Experience Study, results of hematologic tests revealed no difference in hemoglobin levels and WBC counts between Vietnam and non-Vietnam veterans (55). In a recent study of Korean Vietnam veterans, WBC counts were similar among veterans compared to non-veterans; however, hemoglobin levels were found to be reduced among veterans (59). Another study of Korean Vietnam veterans found no association between hematologic parameters and veteran status or level of Agent Orange exposure (60). Early investigations found hemoglobin levels to be elevated in the Ranch Hands as compared to the reference group, although this observation was not

considered to be clinically relevant (53). Furthermore, Ranch Hand participants were found to have slightly higher mean platelet counts and a greater percentage of abnormally high platelet counts than Comparisons (48, 49, 54). WBC counts showed associations with dioxin exposure consistent with a dose-response effect (54). Most recently, Ranch Hands with the highest serum dioxin levels had slightly elevated MCVs and platelet counts relative to veterans not involved in Operation Ranch Hand (51). These elevations, however, were determined to be of unknown clinical significance and may not have been related to dioxin exposure (51).

16.1.1.3.2 Epidemiology: Diseases of Blood and Blood-forming Organs

In the Seveso population, an increased risk of mortality from blood diseases was observed among residents classified as exposed (16, 18); however, none of the six cases occurred among those with the highest exposures (16). Occupational cohort studies in the United States and Europe found no evidence of an increased risk of mortality from diseases of the blood and blood-forming organs among dioxin-exposed workers (28, 35, 40, 42). One co-twin case-control study found no association between service in Vietnam and self-reported morbidity from blood disorders (45).

16.1.2 Summary of Previous Analyses of the Air Force Health Study

16.1.2.1 1982 Baseline Examination Summary Results

The functional integrity of the hematopoietic system was assessed at the 1982 baseline examination by the measurement of RBC count, WBC count, hemoglobin, hematocrit, MCV, MCH, mean corpuscular hemoglobin concentration (MCHC), platelet count, and ESR (analyzed as part of the General Health Assessment prior to 2002). These variables were analyzed in the discrete form to detect differences in the percentages of values outside the normal laboratory range, as well as analyzed in the continuous form to detect shifts in mean values between the Ranch Hand and Comparison groups.

The Ranch Hand group had a significantly higher adjusted mean MCV and MCH than the Comparison group ($p=0.05$ and $p=0.04$, respectively), although the magnitude of the difference was small in each case. The Ranch Hand adjusted mean values for RBC count, WBC count, hemoglobin, hematocrit, MCHC, and platelet count were not significantly different from the adjusted mean values of the Comparison group. The percent of abnormal values for these eight variables, as established by the upper and lower limits of normal, did not differ significantly between the two groups.

No overall differences in ESR were found, although a significant interaction between group and age for ESR was noted; younger Ranch Hands had fewer ESR abnormalities than did Comparisons, whereas no difference was found in participants older than 40.

16.1.2.2 1985 Follow-up Examination Summary Results

The same variables (i.e., RBC count, WBC count, hemoglobin, hematocrit, MCV, MCH, MCHC, platelet count, and ESR) were analyzed in the 1985 follow-up examination. The adjusted analyses of the discrete form of these variables showed no statistically significant difference between the Ranch Hand and Comparison groups.

As no subgroup demonstrated consistent patterns of hematologic impairment, biologic relevance was not assigned to the interactions. The significant group differences found for MCV and MCH at the baseline examination were not present in the 1985 follow-up examination analyses. The covariate associations of

age, race, occupation, and lifetime smoking history were highly significant for many of the hematologic variables.

The geometric mean ESRs did not differ significantly between Ranch Hands and Comparisons after adjustment for age, race, occupation, personality score, and an age-by-personality score interaction. In the analysis of the discrete form of ESR, 5.8 percent of the Ranch Hands had ESR abnormalities (>20 mm/hour), contrasted to 3.6 percent in the Comparison group. This difference was significant after adjustment for age and personality score ($p=0.011$).

The longitudinal analyses of platelet count found a significant group difference, with the Ranch Hands having an average decrease in platelet count between the 1982 and 1985 examinations and the Comparisons having an average increase. As a result, the baseline group difference (nonsignificant) in mean values approached equality at the 1985 follow-up examination.

Longitudinal differences between the 1982 baseline and the 1985 follow-up examination were also observed for ESR. The analysis revealed a highly significant group difference ($p=0.002$) because of a reversal of findings between examinations (i.e., a significant adverse association in the [younger] Comparisons at the baseline examination versus a significant adverse association in the Ranch Hands at the follow-up examination).

16.1.2.3 1987 Follow-up Examination Summary Results

The hematologic status of the Ranch Hand and Comparison groups was assessed by the examination of RBC count, WBC count, hemoglobin, hematocrit, MCV, MCH, MCHC, platelet count, and ESR. There were no statistically significant differences between the Ranch Hand and Comparison groups for mean RBC count, hemoglobin, hematocrit, MCV, MCH, and MCHC in analyses adjusted for the covariates of age, race, occupation, current cigarette smoking, and lifetime cigarette smoking history.

Mean platelet counts were significantly greater in Ranch Hands than in Comparisons, as was the percentage of individuals with abnormally high platelet counts. There was little difference in the geometric mean values of ESR in the two groups, but Ranch Hands had a significantly higher percentage of individuals with an abnormal ESR (>20 mm/hour) than Comparisons. Only three participants (two Ranch Hands and one Comparison) were found to have rates in excess of 100 mm/hour; one of these (a Comparison) proved to have lung cancer and died in early 1989. No diagnosis was established for either of the two Ranch Hands during the course of the 1987 examination.

Longitudinal analyses detected a significantly greater decrease in the mean platelet count in Ranch Hands than in Comparisons, despite the higher overall mean count, from the baseline examination to the 1987 follow-up examination. For ESR, there was a significant difference between groups in the change from baseline to the 1987 follow-up examination, with a relatively greater number of Ranch Hands than Comparisons shifting from normal at baseline to abnormal at the follow-up examination.

16.1.2.4 Serum Dioxin Analysis of 1987 Follow-up Examination Summary Results

Hemoglobin and hematocrit were positively associated with dioxin levels in 1987 when time since duty in SEA was no more than 18.6 years and inversely associated with dioxin levels in 1987 when time since duty in SEA was greater than 18.6 years. For the discrete RBC count analysis, the relative risk of an abnormally low count was less than one when time since duty in SEA did not exceed 18.6 years and was greater than one when time since duty in SEA was more than 18.6 years. Because a low RBC count was

considered abnormal for the purpose of these statistical analyses, the trend in relation to 1987 dioxin was similar to that in the analyses of the continuous form of hemoglobin and hematocrit.

In the analysis of the discrete form of prothrombin time, the trend in relation to 1987 dioxin also was similar to that in the analyses of the continuous form of hemoglobin and hematocrit. In the categorized dioxin analyses, whenever the overall contrast showed significant differences among the categories, the mean level or percent abnormal in the three categories of Ranch Hands (i.e., officers, enlisted flyers, and enlisted groundcrew) tended to exceed the corresponding mean level or percent abnormal in the background category that consisted of Comparisons.

ESR exhibited a significant positive association with initial dioxin. The analyses for the four dioxin categories overall exhibited significant contrasts for ESR, and the high versus background contrast and the low versus background contrast were significant with the Ranch Hands exceeding Comparisons.

The longitudinal analyses of MCV, MCH, and platelet count displayed no significant associations with dioxin. In the longitudinal analyses of ESR, the percentages of abnormalities in 1987 were greater for Ranch Hands in the low dioxin category and in the high dioxin category than for Comparisons.

In summary, the results of the previous analysis revealed no meaningful association between hematopoietic toxicity and dioxin. Statistical analyses of WBC count, platelet count, and ESR raised the possibility of subtle biologic effects that cannot be considered clinically meaningful, but did point to the need for follow-up in future AFHS examinations. The increased platelet and WBC counts, in addition to the elevation of ESRs, were thought to indicate the presence of a chronic inflammatory response to dioxin.

16.1.2.5 1992 Follow-up Examination Summary Results

The statistical analyses of MCV, MCH, and MCHC were eliminated for the 1992 follow-up examination and RBC morphology (normal, abnormal), absolute neutrophils (segs), absolute neutrophils (bands), absolute lymphocytes, absolute monocytes, absolute eosinophils, and absolute basophils were added. In the analyses of these variables, platelet count exhibited significant associations with the herbicide exposure indices. Ranch Hands in the enlisted flyer and enlisted groundcrew categories displayed statistically significant higher mean platelet counts than Comparisons. Analyses using extrapolated levels of initial dioxin showed that Ranch Hands with high dioxin levels had significantly greater mean platelet count measurements than Comparisons. ESR also displayed a significant positive association with 1987 dioxin levels. The 1992 follow-up examination results supported the results found in both the 1987 follow-up examination and in the serum dioxin analysis of the 1987 follow-up examination, but the biologic meaning was uncertain.

16.1.2.6 1997 Follow-up Examination Summary Results

In the analyses of hematologic variables for the 1997 follow-up examination, which mirrored the variables studied for the 1992 follow-up examination, platelet count exhibited significant dose-response associations with the indices of dioxin. Ranch Hand enlisted flyers and groundcrew exhibited slightly but significantly higher mean platelet counts than did Comparisons. Ranch Hands in the high dioxin category also exhibited a significantly higher mean platelet count than Comparisons. No differences in the percentages of abnormal ESRs between Ranch Hands and Comparisons or relations between abnormal ESRs and dioxin levels were observed during the 1997 examination. ESRs increased as 1987 dioxin levels increased.

Longitudinal analyses showed that Ranch Hands, particularly the two enlisted strata, had an increased percentage of abnormal ESRs than did Comparisons over the 15 years of the study since 1982. These analyses also showed that the percentages of abnormalities increased from 1982 to 1997 as dioxin levels increased. This positive association raises the possibility of a subtle inflammatory, infectious, or occult malignant disease process related to the body burden of dioxin.

In general, the results in the 1997 follow-up examination paralleled the findings of the 1987 and 1992 follow-up examinations.

16.1.3 Parameters for the 2002 Hematology Assessment

16.1.3.1 Dependent Variables

The analysis of the hematology assessment consisted of data from the laboratory examination only. No questionnaire or physical examination data were analyzed.

16.1.3.1.1 Laboratory Variables

A total of 14 hematology variables investigated as part of the 2002 laboratory follow-up examination were analyzed statistically. A CBC with a differential WBC count was performed with the differential results reported as absolute counts. Elements of the CBC that were analyzed were RBC count, WBC count, hemoglobin, hematocrit, platelet count, and the following absolute WBC counts: segmented neutrophils, neutrophilic bands, lymphocytes, monocytes, eosinophils, and basophils. Lymphocytes included both reactive and nonreactive lymphocytes. RBC morphology was noted as normal or abnormal. In addition, measurements for ESR and fibrinogen were collected. These variables were determined by routine hematologic procedures. In particular, the cell counts were performed on the Abbott Cell-Dyn 4000® automated instrument, and fibrinogen was measured on the Dade-Behring Blood Coagulation System instrument. The ESR was performed using Vesmatic™ equipment. All dependent variables were analyzed in the continuous form, except for the RBC morphology, which was analyzed as discrete only. ESR and fibrinogen were analyzed continuously and in their discrete forms using Scripps Clinic normal ranges as cutpoints. RBC count, WBC count, hemoglobin, hematocrit, and platelet count were analyzed as continuous and were trichotomized as abnormal low, normal, and abnormal high.

RBC morphology was constructed from a number of laboratory conditions, many of which were minor abnormalities. Participants having at least one of the following conditions at the 2002 follow-up examination were considered to be abnormal for RBC morphology: acanthocytes, rouleaux, Burr cells, spherocytes, moderate microcytes, many microcytes, moderate macrocytes, moderate amount of ovalocytes, hypochromia, anisocytosis, polychromasia, slight baso-stippling, few target cells, Howell-Jolly bodies, and few teardrop cells. Participants with only few ovalocytes, few microcytes, or few macrocytes were considered to be normal for RBC morphology.

Absolute neutrophils (bands), absolute eosinophils, and absolute basophils had a large number of measurements equal to 0 counts per mm³. The nonzero measurements exhibited a positively skewed distribution, so a logarithmic transformation was applied to achieve an approximate normal distribution. The logarithmic transformation, however, could not be applied to the measurements equal to 0 counts per mm³. Consequently, these variables were analyzed in two forms: (1) an analysis of the nonzero measurements and (2) an analysis of the proportion of zero measurements.

Participants with a fever (body temperature greater than or equal to 100 degrees Fahrenheit) at the time of the examination or testing positive for the human immunodeficiency virus (HIV) were excluded from the

analysis of all variables. Participants whose platelet count was inexact because of clumping of the platelets were excluded from the analysis of platelet count.

16.1.3.2 Covariates

Age, race, military occupation, current level of cigarette smoking (cigarettes/day), lifetime cigarette smoking history (pack-years), and body mass index (kg/m^2) were used as covariates in adjusted statistical analyses evaluating the hematologic dependent variables. Age, race, and military occupation were determined from military records. The covariates current cigarette smoking and lifetime cigarette smoking history were based on questionnaire data. For lifetime cigarette smoking history, the respondent's average smoking was estimated over his lifetime based on his responses to the 2002 questionnaire, with 1 pack-year defined as 365 packs of cigarettes smoked during a single year.

Body mass index was calculated as $\text{weight}/(\text{height})^2$, where the weight was measured in kilograms and the height was measured in meters at the physical examination (61). For purposes of covariate associations for discrete dependent variables, body mass index was dichotomized as "not obese" ($\leq 30 \text{ kg}/\text{m}^2$) and "obese" ($> 30 \text{ kg}/\text{m}^2$).

16.1.4 Statistical Methods

Table 16-1 summarizes the statistical analysis performed for the 2002 hematology assessment. The first part of this table lists the dependent variables analyzed, source of the data, form of the data, cutpoints, covariates, exclusions, and statistical methods. The second part of the table further describes the covariates. A covariate was used in its continuous form whenever possible for all adjusted analyses. If the covariate was inherently discrete (e.g., military occupation), or if a categorized form was needed to develop measures of association with the dependent variables, the covariate was categorized as shown in Table 16-1.

Table 16-1. Statistical Analysis for the Hematology Assessment

Dependent Variables

Variable (Units)	Data Source	Data Form	Cutpoints	Covariates ^a	Exclusions ^b	Statistical Analysis and Methods
RBC Count (million/ mm^3)	LAB	C/D	Abnormal Low: < 4.3 Normal: 4.3–5.9 Abnormal High: > 5.9	(1)	(a)	U:PR,CS,GLM,TT A:PR,GLM

Four models were examined for each dependent variable given in Table 16-1. The analyses of these models are presented below. Further details on dioxin and the modeling strategy are found in Chapters 2 and 7, respectively. These analyses were performed both unadjusted and adjusted for covariates. These covariates are given in Table 16-1. Model 1 examined the relation between the dependent variable and group (i.e., Ranch Hand or Comparison). In this model, exposure was defined as “yes” for Ranch Hands and “no” for Comparisons without regard to the magnitude of the exposure. In an attempt to quantify exposure, three contrasts of Ranch Hands and Comparisons were performed along with the overall Ranch Hand versus Comparison contrast. These three contrasts compared Ranch Hands and Comparisons within each military occupational category (i.e., officers, enlisted flyers, and enlisted groundcrew). As described in previous reports and Table 2-4, the median level of exposure to dioxin was highest for enlisted groundcrew, followed by enlisted flyers, then officers.

During the 1987, 1992, 1997, and 2002 examinations, serum dioxin levels were measured by the CDC using high-resolution gas chromatography and high-resolution mass spectrometry and were reported in parts per trillion (ppt) on a lipid weight basis (62). These dioxin measurements are referred to as “lipid-adjusted.” All measures of dioxin used in this report were based on lipid-adjusted dioxin measurements.

Model 2 examined the relation between the dependent variable and an extrapolated initial dioxin measure for Ranch Hands who had a 1987 dioxin measurement greater than 10 ppt. The initial dioxin was calculated by extrapolating the 1987 dioxin level back in time to the end of the tour of duty that qualified a Ranch Hand veteran for inclusion in this study. If a Ranch Hand did not have a 1987 dioxin level, then the first dioxin measured, either at 1992, 1997, or 2002, was used to estimate the initial dioxin level. Regardless of when the dioxin was measured, Ranch Hand veterans with a level less than or equal to 10 ppt were excluded from statistical analyses based on Model 2. A statistical adjustment for body mass index at the time of the participant's blood measurement of dioxin was included in this model to account for body mass index-related differences in elimination rate (63).

Model 3 divided the Ranch Hands examined in Model 2 into two categories based on their initial dioxin measures. These two categories were referred to as "low Ranch Hand" and "high Ranch Hand." Two additional categories—Ranch Hands with serum dioxin levels at or below 10 ppt and Comparisons—were formed and included in the model. Ranch Hands with serum dioxin levels at or below 10 ppt were assigned to the "background Ranch Hand" category. If a Ranch Hand did not have a 1987 dioxin measurement, the first measured dioxin level was used. Another category was examined by combining the low and high Ranch Hand categories. This combination is referred to in the tables as the "low plus high Ranch Hand" category. These five categories—Comparisons, background Ranch Hands, low Ranch Hands, high Ranch Hands, and low plus high Ranch Hands—were used in Model 3 analyses. The relation between the dependent variable in each of the four Ranch Hand categories and the dependent variable in the Comparison category was examined. As in Model 2, a statistical adjustment for body mass index at the time of the participant's blood measurement of dioxin was included in this model for the unadjusted and adjusted analyses of all dependent variables. One Ranch Hand without a dioxin measure was excluded from statistical analyses based on Model 3.

Model 4 examined the relation between the dependent variable and 1987 dioxin levels in all Ranch Hands with a dioxin measurement. If a Ranch Hand did not have a 1987 dioxin measurement, the first dioxin level obtained, either in 1992, 1997, or 2002, was extrapolated to the date of the 1987 physical examination. If the first dioxin level was not obtained in 1987 and was less than or equal to 10 ppt, it was not extrapolated to 1987 level, but was used at the measured value. One Ranch Hand without a dioxin measurement was excluded from statistical analyses based on Model 4.

The term "unadjusted" was used in the text and tables as follows: Models 1 and 4 did not adjust for any covariates. Models 2 and 3 adjusted only for body mass index at the time of the blood measurement for dioxin. The term "adjusted" was used in the text and tables as follows: Models 1 and 4 adjusted for the covariates shown in Table 16-1 unless otherwise specified by a footnote to the table. Models 2 and 3 additionally adjusted only for body mass index at the time of the blood measurement for dioxin.

Table 16-2 provides a summary of the number of participants with missing dependent variable and covariate data. In addition, the number of participants that were excluded from analyses is given.

Table 16-2. Number of Participants Excluded or with Missing Data for the Hematology Assessment

Variable	Variable Use	Group ^a		Dioxin (Ranch Hands Only) ^b		Categorized Dioxin ^c	
		Ranch Hand	Comparison	Initial Dioxin	1987 Dioxin	Ranch Hand	Comparison
Fibrinogen	DEP	1	0	0	1	1	0
Current Cigarette Smoking	COV	0	2	0	0	0	2
Lifetime Cigarette Smoking History	COV	0	3	0	0	0	3
Body Mass Index	COV	1	0	0	1	1	0
Platelet Clumping	EXC	1	3	0	1	1	3
Fever at the Time of the Physical Examination	EXC	3	1	2	3	3	1
HIV Positive	EXC	3	2	3	3	3	2

^a777 Ranch Hands and 1,174 Comparisons for group.

^b424 Ranch Hands for initial dioxin; 776 Ranch Hands for 1987 dioxin.

^c776 Ranch Hands and 1,174 Comparisons for categorized dioxin.

Note: DEP = Dependent variable.

COV = Covariate.

EXC = Exclusion.

16.2 RESULTS

16.2.1 Dependent Variable-covariate Associations

The complete results of covariate associations with each hematologic dependent variable are documented in Appendix F, Table F-8. These associations are pairwise between the dependent variable and the covariate and are not adjusted for any other covariates. The following paragraphs summarize the pattern of significant ($p \leq 0.05$) dependent variable-covariate associations.

Age was associated with RBC count, hemoglobin, hematocrit, fibrinogen, and ESR in both the discrete and continuous forms. RBC count, hemoglobin, and hematocrit decreased with increasing age, while fibrinogen and ESR increased with increasing age. Similarly, abnormally low RBC counts, hemoglobin levels, and hematocrit levels were seen more often in older participants, as were high fibrinogen levels and high ESRs. Platelet counts and absolute lymphocyte counts decreased as the age of the participants increased. Older participants were also more likely to have had an abnormal RBC morphology than younger participants.

Race was associated with the continuous form of WBC count, hemoglobin, hematocrit, platelet count, segmented neutrophils, neutrophilic bands, fibrinogen, and ESR. The mean WBC count, hemoglobin, hematocrit, and absolute neutrophils (segs and bands) were lower in Blacks than non-Blacks. Blacks had a higher mean platelet count, fibrinogen level, and ESR than non-Blacks.

The discrete form of RBC count, WBC count, hemoglobin, hematocrit, RBC morphology, neutrophilic bands, and fibrinogen was also associated with race. Black participants were more likely to have had an abnormally high RBC count than non-Black participants. Blacks were more than twice as likely, however, to have had abnormally low hemoglobin levels and hematocrit levels than non-Blacks. A higher percentage of Blacks had abnormally low WBC counts than non-Blacks. Blacks were more likely to have an abnormal RBC morphology, abnormally high fibrinogen levels, and no neutrophilic bands than non-Blacks.

The continuous form of RBC count, WBC count, hemoglobin, hematocrit, platelet count, fibrinogen, and ESR was associated with military occupation, as were absolute counts of segmented neutrophils, lymphocytes, monocytes, and eosinophils. The discrete form of RBC count, WBC count, and fibrinogen was also found to be associated with military occupation.

Officers were more likely to have had a lower mean RBC count, hemoglobin level, hematocrit, WBC count, platelet count, fibrinogen level, and ESR than enlisted flyers or enlisted groundcrew. Mean absolute counts of segmented neutrophils, lymphocytes, monocytes, and eosinophils were also lower in officers than in enlisted flyers or groundcrew. Fewer officers had abnormally high fibrinogen levels and abnormally high WBC counts than enlisted participants. Officers were more likely to have had abnormally low RBC counts than enlisted participants and were less likely to have had abnormally high RBC counts.

Current cigarette smoking was positively associated with RBC count, WBC count, hemoglobin, hematocrit, platelet count, fibrinogen, and absolute counts of segmented and banded neutrophils, lymphocytes, monocytes, eosinophils, and basophils. While the discrete form of RBC count, WBC count, hemoglobin, hematocrit, and fibrinogen varied with current cigarette smoking, no consistent positive association with current cigarette smoking was apparent.

WBC counts, fibrinogen, ESR, and absolute counts of segmented and banded neutrophils, lymphocytes, monocytes, eosinophils, and basophils increased as lifetime cigarette smoking increased. RBC counts decreased with increasing lifetime cigarette smoking. The heaviest smoker group (in terms of pack-years) had the highest percentage of participants with abnormally high WBC counts and the lowest percentage of participants with abnormally low WBC counts. The heaviest smokers also had the highest percentage of participants with abnormally low RBC counts and abnormally high fibrinogen levels.

Body mass index was positively correlated with RBC count, WBC count, absolute lymphocytes, monocytes, eosinophils, basophils, fibrinogen, and ESR. Platelet counts increased with decreasing body mass index. Fewer obese participants had abnormal low or abnormal high WBC counts than participants who were not obese. Obese participants were more likely to have had abnormally low platelet counts and less likely to have had abnormally high platelet counts than participants who were not obese.

16.2.2 Exposure Analysis

The following section presents results of the statistical analyses of the dependent variables shown in Table 16-1. Dependent variables were based on data from the Scripps Clinic laboratory, which were obtained during the 2002 physical examination.

16.2.2.1 Laboratory Variables

16.2.2.1.1 RBC Count (Continuous)

All unadjusted and adjusted results from the Model 1 through Model 4 analyses of RBC count in the continuous form were nonsignificant (Table 16-3(a–h): $p > 0.06$ for each analysis).

Table 16-3. Analysis of RBC Count (million/mm³) (Continuous)

(a) MODEL 1: RANCH HANDS VS. COMPARISONS – UNADJUSTED					
Occupational Category	Group	n	Unadjusted Mean	Difference of Unadjusted Means (95% C.I.)	p-Value

n	Abnormal Low vs. Normal		Abnormal High vs. Normal	
	Adjusted Relative Risk (95% C.I.) ^a	p-Value	Adjusted Relative Risk (95% C.I.) ^a	p-Value
769	0.98 (0.78,1.24)	0.882	1.04 (0.73,1.48)	0.824

^aRelative risk for a twofold increase in 1987 dioxin.

16.2.2.1.3 WBC Count (Continuous)

No significant associations between exposure group or dioxin levels and WBC count were observed in Model 1 through Model 3 unadjusted and adjusted analyses (Table 16-5(a–f): $p > 0.06$ for each analysis), and no association between 1987 dioxin levels and WBC counts was seen in the unadjusted analysis of Model 4 (Table 16-5(g): $p = 0.341$). After adjustment for the covariates, however, the WBC count significantly decreased as the 1987 dioxin levels increased (Table 16-5(h): Adjusted Slope = -0.014 , $p = 0.047$). The adjusted mean WBC count for the low 1987 dioxin category was 5.98 thousand cells per mm^3 compared to 5.81 thousand cells per mm^3 for the medium category and 5.83 thousand cells per mm^3 for the high category.

16.2.2.1.4 WBC Count (Discrete)

No significant associations with exposure group and dioxin were seen in Model 1, Model 2, or Model 3 unadjusted and adjusted analyses of WBC count in its discrete form (Table 16-6(a–f): $p > 0.10$ for each contrast).

A significant inverse relation was seen between 1987 dioxin levels and abnormally high WBC counts in the unadjusted and adjusted Model 4 analyses (Table 16-6(g, h): Unadjusted Relative Risk [RR] = 0.65 , $p = 0.011$; Adjusted RR = 0.61 , $p = 0.005$). The percentage of Ranch Hands with an abnormally high WBC count was 2.7 percent in the low 1987 dioxin category, 1.9 percent in the medium category, and 1.6 percent in the high category.

Note: Low = ≤7.8 ppt; Medium = >7.8–19.2 ppt; High = >19.2 ppt.

16.2.2.1.6 Hemoglobin (Discrete)

No significant results were seen in the unadjusted or adjusted Model 1 hemoglobin analyses for the officer or the enlisted flyer stratum or for the overall contrast of Ranch Hands and Comparisons (Table 16-8(a,b): $p > 0.15$ for all analyses). A significant difference in the percentage of participants with abnormally high hemoglobin levels was observed between Ranch Hand and Comparison in the enlisted groundcrew stratum (Table 16-8(a): $p = 0.039$ for the unadjusted analysis). Nine Comparison groundcrew (1.7%) had abnormally high hemoglobin levels, and no Ranch Hand groundcrew participants had abnormally high hemoglobin levels. Adjusted analysis was not performed because of the lack of Ranch Hands with abnormally high hemoglobin levels.

No other association between categorized hemoglobin and dioxin levels in Model 2 through Model 4 unadjusted and adjusted analyses was significant (Table 16-8(c-h): $p > 0.25$ for all analyses).

Table 16-8. Analysis of Hemoglobin (Discrete)

(a) MODEL 1: RANCH HANDS VS. COMPARISONS – UNADJUSTED

16.2.2.1.8 Hematocrit (Discrete)

No significant associations were found in Model 1, Model 2, or Model 4 unadjusted and adjusted analyses of hematocrit in its discrete form (Table 16-10(a-d,g,h): $p > 0.08$ for all analyses).

A significant inverse relation was seen in the Model 3 unadjusted and adjusted analyses of abnormally low hematocrit when comparing Ranch Hands in the low dioxin category to the Comparison group (Table 16-10(e,f): Unadjusted RR=0.35, $p=0.044$; Adjusted RR=0.34, $p=0.043$). Abnormally low hematocrit was found in 5.1 percent of the Comparisons and 1.9 percent of the Ranch Hands in the low dioxin category. No other unadjusted or adjusted Model 3 contrast was significant (Table 16-10(e,f): $p > 0.09$ for all analyses).

769	1.02 (0.77,1.37)	0.867	1.12 (0.61,2.07)	0.705

^aRelative risk for a twofold increase in 1987 dioxin.

Note: Results were not adjusted for race because of the sparse number of Ranch Hands with abnormally high hematocrit.

16.2.2.1.9 Platelet Count (Continuous)

The difference in mean platelet count between all Ranch Hands and Comparisons in the Model 1 unadjusted and adjusted analyses was not significant, and no significant difference was seen between Ranch Hands and Comparisons in the officer or enlisted groundcrew strata (Table 16-11(a,b): $p > 0.06$ for all analyses). A significant difference in mean platelet counts was seen, however, between Ranch Hands and Comparisons within the enlisted flyer stratum (Table 16-11(a,b): difference of means = 18.2 thousand/mm³, $p = 0.006$; difference of adjusted means = 18.4 thousand/mm³, $p = 0.005$).

The Model 2 unadjusted analysis of platelet count in its continuous form revealed a significant association with initial dioxin (Table 16-11(c): Slope=0.148, $p = 0.024$). After adjustment for covariates, the association was no longer significant (Table 16-11(d): $p = 0.881$).

Unadjusted Model 3 analyses showed that mean platelet counts were significantly greater for Ranch Hands in the high dioxin category and Ranch Hands in the low and high dioxin categories combined than for Comparisons (Table 16-11(e): difference of means = 13.7 thousand/mm³ for the high dioxin category, $p = 0.002$; difference of means = 6.9 thousand/mm³ for the low and high dioxin categories combined, $p = 0.038$). After adjusting for the covariates, however, the mean platelet counts were no longer significantly different between Comparisons and Ranch Hands in the high category or in the low and high dioxin categories combined (Table 16-11(f): $p > 0.05$ for both analyses). No other contrasts of Ranch Hands and Comparisons in Model 3 were significant (Table 16-11(e,f): $p > 0.60$ for all remaining contrasts).

The unadjusted and adjusted analyses of Model 4 showed no significant association between platelet count and 1987 dioxin levels (Table 16-11(g,h): $p > 0.12$ for both analyses).

16.2.2.1.10 Platelet Count (Discrete)

No significant associations between exposure group or dioxin levels and the categorized form of platelet count were observed in the unadjusted and adjusted analyses for Model 1 through Model 4 (Table 16-12(a-h): $p > 0.09$ for all analyses).

Table 16-11. Analysis of Platelet Count (thousand/mm³) (Continuous)

^aRelative risk for a twofold increase in 1987 dioxin.

Note: Results were not adjusted for race because of the sparse number of Ranch Hands with an abnormally high platelet count.

16.2.2.1.11 RBC Morphology

The percentage of participants with an abnormal RBC morphology was not significantly different between Ranch Hands and Comparisons in the officer or enlisted flyer strata, nor in the overall comparison of Ranch Hands and Comparisons in the Model 1 unadjusted and adjusted analyses (Table 16-13(a,b): $p > 0.13$ for all analyses). The percentage of Ranch Hands with abnormal RBC morphology was significantly greater than Comparisons in the enlisted groundcrew stratum in both the Model 1 unadjusted and adjusted analyses (Table 16-13(a,b): Unadjusted RR=1.88, $p=0.044$; Adjusted RR=2.10, $p=0.022$). Among Ranch Hand enlisted groundcrew, 6.9 percent had an abnormal RBC morphology, while 3.8 percent of Comparison groundcrew had abnormal RBC morphology.

No significant associations between RBC morphology and either initial or 1987 dioxin levels in the unadjusted and adjusted analyses of Model 2 and Model 4 were observed (Table 16-13(c,d,g,h): $p > 0.47$ for all analyses).

The Model 3 unadjusted analysis revealed no significant differences in abnormal RBC morphology between Ranch Hands and Comparisons (Table 16-13(e): $p > 0.05$ for all contrasts). After adjustment for covariates, significant differences were noted between Comparisons and Ranch Hands in the high category and Ranch Hands in the low and high dioxin categories combined (Table 16-13(f): Adjusted RR=1.93 for Ranch Hands in the high category, $p=0.047$; Adjusted RR=1.74 for Ranch Hands in the low and high dioxin categories combined, $p=0.021$). Fewer Comparisons (5.2%) had an abnormal RBC morphology than Ranch Hands in the high dioxin category (6.7%) or the low and high dioxin categories combined (7.6%). No difference was seen between Ranch Hands in the background or low categories and Comparisons in the adjusted Model 3 analyses (Table 16-13(f): $p > 0.12$ for both analyses).

^aRelative risk for a twofold increase in 1987 dioxin.

16.2.2.1.15 Absolute Lymphocytes

No significant differences in mean absolute lymphocyte counts were seen between exposure groups in Model 1 unadjusted or adjusted analyses (Table 16-17(a,b): $p>0.24$ for all analyses) or between absolute lymphocyte counts and 1987 dioxin levels in Model 4 unadjusted and adjusted analyses (Table 16-17(g,h): $p>0.09$ for all analyses).

The unadjusted Model 2 analysis of absolute lymphocytes revealed a significant association between absolute lymphocytes and initial dioxin (Table 16-17(c): Slope=0.039, $p=0.008$). After adjustment for covariates, however, the association was not significant (Table 16-17(d): $p=0.092$).

In the unadjusted Model 3 analyses, a significant difference in absolute lymphocytes was seen between Comparisons and Ranch Hands in the high dioxin category (Table 16-17(e): difference of means = 0.12 thousand/mm³, $p=0.031$). The association was no longer significant after adjustment for covariates (Table 16-17(f): $p=0.592$). No other significant associations were seen in the Model 3 unadjusted or adjusted analyses (Table 16-17(e,f): $p>0.19$ for all contrasts).

^aRelative risk for a twofold increase in 1987 dioxin.

16.2.2.1.19 Absolute Basophils (Nonzero Measurements)

For participants who had basophils, no significant relations were observed between the absolute basophil count and exposure group or initial dioxin in Model 1 or Model 2 unadjusted and adjusted analyses (Table 16-21(a–d): $p \geq 0.06$ for all analyses). In Model 3 unadjusted analyses, the mean absolute basophil count was significantly greater for Comparisons than Ranch Hands in the background category (Table 16-21(e): difference of means = -0.006 thousand/mm³, $p=0.030$). This result was no longer significant after adjusting for covariates (Table 16-21(f): $p=0.051$). No other Model 3 unadjusted or adjusted result was significant (Table 16-21(e,f): $p > 0.50$ for all analyses).

In the unadjusted analysis of Model 4, a significant positive relation between absolute basophil count and 1987 dioxin levels was observed (Table 16-21(g): Slope=0.035, $p=0.012$). This result was no longer significant after adjustment for covariates (Table 16-21(h): $p=0.235$).

^aTransformed from natural logarithm scale.

^bSlope and standard error based on natural logarithm of absolute basophils versus log₂ (1987 dioxin).

Note: Low = ≤7.8 ppt; Medium = >7.8–19.2 ppt; High = >19.2 ppt.

16.2.2.1.20 Absolute Basophils (Zero versus Nonzero)

No associations between the percentage of participants with basophils present and either exposure group or dioxin levels were seen in Model 1 through Model 4 unadjusted and adjusted analyses (Table 16-22(a-h): p>0.08 for all analyses).

Table 16-22. Analysis of Absolute Basophils (Zero vs. Nonzero)

(a) MODEL 1: RANCH HANDS VS. COMPARISONS – UNADJUSTED

n	Adjusted Relative Risk (95% C.I.) ^a	p-Value
769	0.95 (0.85,1.05)	0.300

^aRelative risk for a twofold increase in 1987 dioxin.

16.2.2.1.21 Fibrinogen (Continuous)

No significant differences were seen between fibrinogen and exposure group in Model 1 unadjusted and adjusted analyses (Table 16-23(a,b): $p > 0.20$ for all analyses) or between fibrinogen and initial dioxin in Model 2 unadjusted and adjusted analyses (Table 16-23(c,d): $p > 0.48$ for each analyses).

In Model 3 unadjusted analyses, the mean fibrinogen was significantly higher for Ranch Hands in the low dioxin category than for Comparisons (Table 16-23(e): difference of means = 11.3 mg/dL, $p = 0.017$). After adjustment for covariates, the difference was no longer significant (Table 16-23(f): $p = 0.119$). No other contrasts in Model 3 unadjusted and adjusted analyses were significant (Table 16-23(e,f): $p > 0.06$ for all other analyses).

Fibrinogen levels were significantly associated with 1987 dioxin levels in Model 4 unadjusted analysis (Table 16-23(g): Slope=0.009, $p = 0.021$), but were not significantly associated after adjusting for covariates (Table 16-23(h): $p = 0.411$).

Analysis Results for Log₂ (1987 Dioxin)		
n	Adjusted Relative Risk (95% C.I.)^a	p-Value
768	0.98 (0.79,1.22)	0.855

^aRelative risk for a twofold increase in 1987 dioxin.

16.2.2.1.23 ESR (Continuous)

No significant associations were seen between ESR and exposure group in Model 1 unadjusted and adjusted analyses (Table 16-25(a,b): $p > 0.10$ for all analyses) or initial dioxin in Model 2 unadjusted and adjusted analyses (Table 16-25(c,d): $p > 0.53$ for both analyses).

Ranch Hands in the low dioxin category and Ranch Hands in the low and high dioxin categories combined had significantly higher ESRs than Comparisons in the unadjusted Model 3 analyses (Table 16-25(e): difference of means = 1.33 mm/hour for the low dioxin category, $p = 0.018$; difference of means = 1.02 mm/hour for the low and high dioxin categories combined, $p = 0.015$). After adjusting for covariates, the results were significant for the low and high dioxin categories combined (Table 16-25(f): difference of adjusted means = 0.99 mm/hour, $p = 0.027$), but were not significant for the low dioxin category (Table 16-25(f): $p = 0.060$). The adjusted mean ESR was 7.81 mm/hour for Comparisons compared to 8.02 mm/hour for Ranch Hands in the background dioxin category, 8.92 mm/hour for Ranch Hands in the low dioxin category, 8.69 mm/hour for Ranch Hands in the high dioxin category, and 8.80 mm/hour for Ranch Hands in the low and high dioxin categories combined.

The relation between ESR and 1987 dioxin levels was significant in the unadjusted analysis of Model 4 (Table 16-25(g): Slope=0.060, $p = 0.005$), but not significant when adjusted for covariates (Table 16-25(h): $p = 0.086$).

16.3 DISCUSSION

The hematologic dependent variables studied were automated blood cell counts and standardized measurements of hemoglobin concentration, hematocrit, plasma fibrinogen, and ESR obtained from peripheral venous blood samples of AFHS participants. Identification of specific WBC types (e.g., segmented neutrophils, band neutrophils, lymphocytes, monocytes, eosinophils, basophils) was confirmed by visual inspection by trained hematology laboratory technicians of peripheral blood smears stained with Wright-Giemsa reagents.

The observed significant associations between the hematologic dependent variables and the covariates of age, race, and body mass index were all in accordance with known effects that age, genetics, and obesity have on erythrocytes, leukocytes, and platelets. Similarly, all of the significant hematologic dependent variable-covariate associations with cigarette smoking were expected, based on the known hematologic pathophysiology of smokers. Fibrinogen levels, leukocyte counts, and ESRs rise as inflammation increases. As expected and as seen in this study, inflammation increases as age, cigarette smoking, and obesity increase. With the exceptions of segmented neutrophil number, fibrinogen level, and ESR, officers had hematologic differences from enlisted personnel that would be expected due to age because officers were, on average, older than enlisted personnel. Although older, officers had lower fibrinogen levels and ESRs, indicating that they may be healthier than enlisted personnel.

The differences noted between the Ranch Hand and Comparison participants reveal clues, but not answers, to potential hematologic problems among the Ranch Hands. These clues differ in what they point to, depending on the specific hematologic parameter being measured. The statistically significant increase in the number of RBC morphologic abnormalities noted among Ranch Hand enlisted groundcrew relative to Comparison enlisted groundcrew does not constitute evidence for a defined hematologic disorder. It does, however, provide a clue that future hematologic problems, such as hemolysis or myelodysplasia, may emerge in the Ranch Hand enlisted groundcrew.

The statistically significant increase in the mean ESR among Ranch Hands in the low and high dioxin categories combined does not constitute evidence for a defined hematologic disorder. As in the case of RBC morphologic abnormalities, however, it provides a clue that future problems, such as inflammatory disorders or monoclonal gammopathies, may emerge among Ranch Hands.

The finding of a statistically significant increase in mean platelet count among Ranch Hand enlisted flyers relative to Comparison enlisted flyers also does not indicate a definite hematologic disease. Elevated platelet counts can be associated with an inflammatory process, gastrointestinal hemorrhage, or myeloproliferative disorders.

The statistically significant relation between a lower WBC count and higher 1987 dioxin levels in Ranch Hands suggests that there may be a dose-response connection. Disorders such as myelodysplasia and aplastic anemia are associated with a decrease in WBCs. Leukemia, which is also associated with a decrease in WBCs, was analyzed in Chapter 10, Neoplasia Assessment.

In conclusion, the significant hematologic differences noted between the Ranch Hands and Comparisons may point to the possibility of a future emergence of hematologic problems, but they do not point to a specific diagnosis. Hemolysis, myelodysplasia, myeloproliferation, marrow aplasia, and leukemia would be among the disorders that could occur in the future. The increase in ESR for Ranch Hands, an increase that was also associated with increased smoking and increased obesity, also does not point to a specific diagnosis. Based on the results seen at this follow-up examination, careful observation for the development of inflammatory disorders and monoclonal gammopathies should be the focus of any future study of possible hematologic disorders on Ranch Hands.

16.4 SUMMARY

The hematology assessment was based only on laboratory data. Associations with herbicide exposure (i.e., group – Model 1), initial dioxin (Model 2), categorized dioxin (Model 3), and 1987 dioxin levels (Model 4) were examined for each variable in the hematology assessment. The significant adjusted results are discussed in the sections below.

16.4.1 Model 1: Group Analysis

As shown in Table 16-27, the analysis of the continuous form of platelet count demonstrated a significant difference between Ranch Hands and Comparisons in the enlisted flyer stratum. The mean platelet count was higher for Ranch Hand enlisted flyers than for Comparison enlisted flyers. The only other significant difference between Ranch Hands and Comparisons in Model 1 analyses was in the enlisted groundcrew stratum for RBC morphology. Ranch Hand enlisted groundcrew were more likely to have an abnormal RBC morphology than Comparison enlisted groundcrew.

A capital "NS" denotes a nonsignificant positive association. A lowercase "ns" denotes a nonsignificant inverse association.

16.4.2 Model 2: Initial Dioxin Analysis

No significant relations were seen between initial dioxin and any of the hematology variables after adjustment for covariates in Model 2 analyses. Table 16-28 shows the results of the initial dioxin analysis.

Table 16-28. Summary of Initial Dioxin Analysis (Model 2) for Hematology Variables (Ranch Hands Only)

ESR (D)	ns	NS

Note: NS or ns: Not significant ($p>0.05$).

C: Continuous form of dependent variable.

D: Discrete form of dependent variable.

The p-value was given if $p\leq 0.05$. The slope was given in parentheses for a significant result from the analysis of a continuous dependent variable.

A capital “NS” denotes a nonsignificant positive association. A lowercase “ns” denotes a nonsignificant inverse association.

16.4.3 Model 3: Categorized Dioxin Analysis

A significant difference in abnormally low hematocrit levels was seen between Comparisons and Ranch Hands in the low dioxin category in the Model 3 analyses. Comparisons were significantly more likely to have abnormally low hematocrit levels than Ranch Hands in the low dioxin category. In addition, Ranch Hands in the high dioxin category and in the low and high dioxin categories combined had a significantly higher percentage of abnormal RBC morphology results than did Comparisons. Ranch Hands in the low and high dioxin categories combined also had a significantly higher mean ESR than Comparisons. Table 16-29 presents the results of the categorized dioxin analysis.

--: The analysis was not performed because of the sparse number of participants with an abnormality.

Note: NS or ns: Not significant ($p > 0.05$).

C: Continuous form of dependent variable.

D: Discrete form of dependent variable.

The p-value was given if $p \leq 0.05$. The relative risk was given in parentheses for a significant result from the analysis of a discrete dependent variable. The difference in means was given in parentheses for a significant result from the analysis of a continuous dependent variable.

A capital "NS" denotes a nonsignificant positive association. A lowercase "ns" denotes a nonsignificant inverse association.

16.4.4 Model 4: 1987 Dioxin Level Analysis

In the Model 4 analyses, only the WBC count varied significantly with 1987 dioxin levels. In analysis of both the continuous and discrete forms of WBC count, a significant inverse relation between WBC counts and 1987 dioxin levels was observed. Table 16-30 displays the results of the 1987 dioxin analysis.

Note: NS or ns: Not significant ($p>0.05$).

C: Continuous form of dependent variable.

D: Discrete form of dependent variable.

The p-value was given if $p\leq 0.05$. The relative risk was given in parentheses for a significant result from the analysis of a discrete dependent variable. The slope was given in parentheses for a significant result from the analysis of a continuous dependent variable.

A capital "NS" denotes a nonsignificant positive association. A lowercase "ns" denotes a nonsignificant inverse association.

16.4.5 Summary of Significant Results

Table 16-31 summarizes the significant results ($p \leq 0.05$) for the adjusted analyses that were performed for the hematology assessment. The dependent variable and its table reference are listed, along with the model and the contrast or description of the model. The p-value is provided along with analysis statistics that correspond to the type of analysis that was performed (either continuous or discrete). A description of the analysis and the statistics that are presented is referenced under the “Note” column and is explained in footnotes.

Table 16-31. Summary of Results from Significant Adjusted Analyses in the Hematology Assessment

Dependent Variable (Table Reference)	Model	Contrast or Description	p-Value	Analysis Statistics	Adjusted Mean or Percent Abnormal	Note
WBC Count (16-5)	4	All RH: 1987 Dioxin	0.047	-0.014 (0.007)	Low: 5.98 thousand/mm ³ Medium: 5.81 thousand/mm ³ High: 5.83 thousand/mm ³	(a)
WBC Count (16-6)	4	All RH: 1987 Dioxin — Abnormal High vs. Normal	0.005	0.61 (0.43,0.86)	Low: 2.7% Medium: 1.9% High: 1.6%	(b)
Hematocrit (16-10)	3	Low RH vs. C: Abnormal Low vs. Normal	0.043	0.34 (0.12,0.97)	RH: 1.9% C: 5.1%	(c)
Platelet Count (16-11)	1	RH vs. C, Enlisted Flyer	0.005	18.4	RH: 249.5 thousand/mm ³ C: 231.1 thousand/mm ³	(d)
RBC Morphology (16-13)	1	RH vs. C, Enlisted Groundcrew	0.022	2.10 (1.12,3.97)	RH: 6.9% C: 3.8%	(e)
	3	High RH vs. C	0.047	1.93 (1.01,3.70)	RH: 6.7% C: 5.2%	(c)
	3	Low plus High RH vs. C	0.021	1.74 (1.09,2.78)	RH: 7.6% C: 5.2%	(c)
ESR (16-25)	3	Low plus High RH vs. C	0.027	0.99	RH: 8.80 mm/hour C: 7.81 mm/hour	(f)

- (a): Continuous variable: slope and standard error were presented and were based on natural logarithm of dependent variable versus \log_2 (initial dioxin); adjusted means were presented for each of three 1987 dioxin categories.
- (b): Discrete variable: adjusted relative risk and 95% confidence interval were presented for a twofold increase in 1987 dioxin; percent abnormal was presented for each of three 1987 dioxin categories.
- (c): Discrete variable: adjusted relative risk and 95% confidence interval were presented; percent abnormal was presented for each dioxin category in contrast.
- (d): Continuous variable: difference of adjusted means was presented; confidence interval was not presented because analysis was not performed on original scale; adjusted means were presented for each exposure group in contrast.

Table 16-31. Summary of Results from Significant Adjusted Analyses in the Hematology Assessment (Continued)

- (e): Discrete variable: adjusted relative risk and 95% confidence interval were presented; percent abnormal was presented for each exposure group in contrast.
- (f): Continuous variable: difference of adjusted means was presented; confidence interval was not presented because analysis was not performed on original scale; adjusted means were presented for each dioxin category in contrast.

Note: RH = Ranch Hand.
C = Comparison.

Model 3: Background (Ranch Hand): 1987 dioxin \leq 10 ppt.
Low (Ranch Hand): 1987 dioxin $>$ 10 ppt, 10 ppt $<$ initial dioxin \leq 118 ppt.
High (Ranch Hand): 1987 dioxin $>$ 10 ppt, initial dioxin $>$ 118 ppt.

Model 4: Low = \leq 7.8 ppt; Medium = $>$ 7.8–19.2 ppt; High = $>$ 19.2 ppt (Ranch Hands only).

16.5 CONCLUSION

A few statistically significant findings were observed in the statistical analysis of the hematologic system. The mean platelet count was increased among Ranch Hand enlisted flyers. Ranch Hand enlisted groundcrew experienced an increased risk of abnormal RBC morphology. Ranch Hands in the low dioxin category had a decreased risk of abnormally low hematocrit levels. Ranch Hands in the high dioxin category and in the low and high dioxin categories combined had a significantly higher percentage of abnormal RBC morphology results. In addition, Ranch Hands in the low and high dioxin combined category had a higher mean ESR than did Comparisons. In analyses of both the continuous and discrete forms of WBC, a significant inverse relation between WBC counts and 1987 dioxin levels was observed.

The significant hematologic differences noted between the Ranch Hands and Comparisons may point to the possibility of a future emergence of hematologic problems, but they do not point to a specific diagnosis. Hemolysis, myelodysplasia, myeloproliferation, marrow aplasia, and leukemia would be among the disorders that could occur in the future. Hematologic malignancies are discussed in Chapter 10, Neoplasia Assessment.

The increase in ESR for Ranch Hands also does not point to a specific diagnosis. Based on the results seen at this follow-up examination, careful observation for the development of inflammatory disorders and monoclonal gammopathies should be the focus of any future study of possible hematologic disorders on Ranch Hands.

In conclusion, these data did not suggest an association between dioxin and any hematologic condition.

17 RENAL ASSESSMENT

17.1 INTRODUCTION

17.1.1 Background

17.1.1.1 Organs/Diseases

The Air Force Health Study (AFHS) examinations included several laboratory measures of renal function and a questionnaire to ascertain historic renal disease among participants. The laboratory assessment quantified urinary protein, urine specific gravity, hematuria, leukocyturia, serum creatinine, urinary creatinine, blood urea nitrogen, and microalbumin. The questionnaire provided data that identified participants with a history of kidney disease, defined as kidney trouble, kidney stones, or kidney infections. Similar parameters were investigated in the few epidemiologic studies that assessed dioxin-related renal disease. Occupational and environmental toxins have been associated with acute and chronic renal damage. Heavy metals, such as lead and cadmium, and organic solvents, such as ethylene glycol, have been linked to renal effects ranging from subclinical proteinuria to chronic renal failure (1).

17.1.1.2 Toxicology

In humans, there is little or no evidence that the kidney is a target organ for 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD or dioxin) toxicity. Although renal excretion of phenoxy herbicides (dioxin and 2,4,5-trichlorophenoxyacetic acid [2,4,5-T]) has been well established in animals (2) and humans (3, 4), other studies indicate that it may be of secondary importance to intestinal elimination (5, 6). In addition, more recent reports indicate that the primary route for elimination of dioxin is feces, with only small amounts excreted in urine (7, 8).

Several studies have focused on the renal sequelae of dioxin toxicity in laboratory animals (9-13). In a study of dioxin toxicity in guinea pigs, a decrease in kidney weight was noted relative to controls, and histopathologic examination revealed focal mineralization changes in the renal parenchyma (9). Developmental renal anomalies, including hydronephrosis in mice (10-12) and hamsters (13), occurred after maternal dioxin exposure at toxic levels. In one study, these effects were limited to an aryl hydrocarbon (Ah) receptor-responsive strain (10).

Bowes and Ramos (14) studied rat kidney in vitro cytotoxic responses to several aromatic hydrocarbons, including dioxin, and found that exposed glomerular mesangial cells showed increased deoxyribonucleic acid (DNA) synthetic rates. A subsequent study reported that dioxin-induced mitochondrial membrane injury in both glomerular mesangial cells and tubular epithelial cells of rat kidney demonstrated alterations in glutathione (GSH) status, which is an integral part of cellular antioxidant defense mechanisms (15). Mice exposed to subchronic low doses of dioxin exhibited depletion of GSH in renal tissue, indicative of oxidative stress (16). Other researchers have reported dioxin-stimulated prostaglandin synthesis in canine kidney, which suggests a role in immunotoxicity (17). A report by the Institute of Medicine (IOM) (18) states that the kidney does not appear to be a target organ for dioxin toxicity in animals.

17.1.1.3 Epidemiology

Morbidity studies of humans exposed to dioxin have not emphasized nonmalignant renal and urinary tract disease, although an isolated case of hemorrhagic cystitis occurred in a child exposed to high concentrations of dioxin in soil (19). Epidemiologic studies of populations heavily exposed to dioxin through environmental contamination in Missouri and Seveso, Italy (20-23), including recent updates of the Seveso cohort that evaluated long-term effects (24-26), failed to document any adverse renal effects.

A small study of Times Beach, Missouri, area residents who were exposed to dioxin through contaminated waste oil sprayed at various sites for dust control included various laboratory tests that compared a high-risk group to a low-risk group (27). The high-risk group reported more urinary tract problems than the low-risk group and had higher levels of both occult blood (red blood cells [RBCs]) and white blood cells (WBCs) in urine, though none of the differences reached statistical significance. Another study focusing on residents of the most highly contaminated sites reported no differences on routine urinalysis parameters when compared to an unexposed group (28).

The mortality experience of several cohorts occupationally exposed to dioxin found no indication of excess mortality due to nonmalignant renal disease (29-33). Fewer occupational studies have investigated morbidity outcomes. Clinical examinations were conducted on 204 U.S. workers exposed to dioxin as a contaminant in the manufacturing process of 2,4,5-T from 1948 to 1969, including workers exposed during an industrial accident in 1949 (34). Investigators compared exposed workers to unexposed workers and reported no evidence of renal damage. Zober and colleagues (35) assessed the long-term morbidity experience of 158 German men exposed to dioxin during an accident in 1953, as well as during the subsequent cleanup. When dioxin-exposed workers were compared to unexposed workers, no significant differences were found in the frequency of nephritis and nephrosis or kidney and ureter calculi. A study of persistent health effects of dioxin exposure among 159 Austrian workers exposed 30 years earlier to dioxin did not report any long-term renal effects (36).

Studies of veterans potentially exposed to dioxin in Southeast Asia (SEA) have yielded similarly negative findings. One large study of Vietnam veterans who served in SEA reported that these veterans did not differ in the frequency of kidney disease when compared to veterans who served elsewhere (37). Another large study conducted by the Centers for Disease Control and Prevention (CDC) compared the physical health of Vietnam veterans to non-Vietnam veterans, finding no differences in urinary tract complaints at medical examination (38). Mortality studies of Vietnam-era veterans have not reported excess mortality due to nonmalignant renal disease (39-42), including the mortality update of the Ranch Hand cohort published in 1998 (43).

Prior AFHS reports, which established the body burden of dioxin by serum levels, found no significant differences in standard indices of renal function between the Ranch Hand and Comparison cohorts (44, 45). Routine microscopic urinalysis, however, revealed that there was a higher prevalence of microhematuria among Ranch Hands in the high initial serum dioxin category than among Comparison participants (44), a finding that persisted in the 1992 examination results (46). Though in clinical practice such hematuria is usually of benign origin, the possibility of occult dioxin-induced renal disease was raised.

A recent review of the human health effects of dioxin concluded that there was little evidence that dioxin exposure is related to adverse renal or bladder effects in humans or animals (47). Nonmalignant renal disease in humans has not been evaluated in the IOM's series of *Veterans and Agent Orange* reports (18, 48-51).

17.1.2 Summary of Previous Analyses of the AFHS

17.1.2.1 1982 Baseline Examination Summary Results

The 1982 baseline examination assessed renal disease and function by questionnaire and laboratory testing. Based on questionnaire information, the Ranch Hand group reported significantly more kidney disease than the Comparison group ($p=0.039$), but this finding was not substantiated by laboratory test results, even when all abnormalities in blood urea nitrogen, creatinine clearance, presence of occult blood, five or more urinary WBCs per high-powered field (HPF), and the presence of urine protein were summed. The distributions of creatinine clearance levels were similar for the two groups, as were the means of blood urea nitrogen, urine specific gravity, and urine WBC count. Difficulty in assessing the degree and significance of hidden noncompliance to the full 24-hour urine collection made the interpretation of the creatinine clearance test results somewhat problematic. Known noncompliance to urine collection, as determined by direct questioning at the end of the sample collection, was much more frequent ($p<0.001$) in the older participants.

Overall, the baseline examination renal assessment suggested an excess of historical kidney disease in the Ranch Hand group not corroborated by laboratory urinalysis testing.

17.1.2.2 1985 Follow-up Examination Summary Results

A historical assessment of kidney disease and kidney stones by a review-of-systems questionnaire showed no significant differences between the Ranch Hand and Comparison groups. Current renal function was evaluated by five laboratory variables: urine protein, urinary occult blood, urine WBC counts, blood urea nitrogen, and urine specific gravity. Invasive procedures were not used.

The prevalence rates for hematuria were similar for both the Ranch Hand and Comparison groups. The approximate tenfold increase in hematuria in both groups over that observed at the baseline examination was most likely due to different laboratory techniques (reagent-strip testing versus microscopic observation). Similar results were found for leukocyturia. The blood urea nitrogen results were similar to those observed at the baseline examination.

In contrast to the baseline examination values, the 1985 follow-up examination urine specific gravities were lower, a finding most likely attributable to differences in laboratory methodology (falling drop method versus multistick procedure).

In conclusion, all renal measurements, except reported kidney disease, revealed group-by-covariate interactions in the adjusted analyses. These interactions were often complex, making it impossible to reach a firm conclusion as to the presence of a group difference.

17.1.2.3 1987 Follow-up Examination Summary Results

In general, none of the variables of reported history of kidney disease or kidney stones, urinary protein, urinary occult blood, urinary WBCs, blood urea nitrogen, and urine specific gravity showed a significant difference between the two groups for adjusted analyses in the 1987 follow-up examination. Examination of the group-by-covariate interactions did not yield a consistent pattern to suggest renal detriment to either the Ranch Hands or the Comparisons. Lack of a group difference in the reported history of kidney disease or kidney stones (consistent with the 1985 examination results) was in contrast with the baseline examination findings, in which Ranch Hands reported significantly more disease. In the longitudinal analysis of blood urea nitrogen, no difference in the change over time was detected.

17.1.2.4 Serum Dioxin Analysis of 1987 Follow-up Examination Summary Results

The different sets of statistical analyses performed for the renal assessment did not indicate that an association existed between the serum dioxin levels of AFHS participants and their 1987 examination health status. No significant associations with dioxin were observed in the longitudinal analyses of blood urea nitrogen. For some adjusted analyses, diabetic class was a significant covariate in the model. Because dioxin may influence diabetic status, ancillary models without diabetic class also were examined. For the most part, deletion of diabetic class from an adjusted model had no appreciable effect on the outcome of the analysis.

17.1.2.5 1992 Follow-up Examination Summary Results

The analysis of renal health endpoints revealed isolated statistically significant findings, but did not reveal consistent evidence for any detriment related to group membership, estimated initial dioxin exposure, or 1987 serum dioxin levels. One finding that deserved scrutiny was the higher prevalence of urinary occult blood (microhematuria) for Ranch Hands in the high dioxin category relative to the Comparison group. This was consistent with the significant positive dose-response relation between microhematuria and initial dioxin levels (Ranch Hands only) noted in the results of the 1987 examination. None of the other 1992 exposure analysis results, however, was statistically significant for urinary occult blood, and the longitudinal analyses indicate that the prevalence of microhematuria has decreased in the Ranch Hand cohort at each of the last two follow-up examinations. Clinically, the detection of urinary occult blood may signal the presence of silent renal calculi or neoplastic disease. The analyses of kidney stones did not support the presence of silent renal calculi.

17.1.2.6 1997 Follow-up Examination Summary Results

Renal endpoints were not analyzed statistically for the 1997 AFHS follow-up examination report.

17.1.3 Parameters for the 2002 Renal Assessment

17.1.3.1 Dependent Variables

The renal assessment was based on laboratory data collected at the 2002 physical examination, as well as a verified history of kidney stones and kidney disease, as reported by the participant and subsequently verified by a medical records review.

17.1.3.1.1 Medical Records Variables

In the self-administered family and personal history questionnaire, each AFHS participant was asked whether he had ever experienced kidney trouble or kidney stones in the years prior to the 2002 physical examination. Medical records review was accomplished to confirm reported problems with kidney function and to identify any unreported kidney problems for each participant that attended the 2002 physical examination. These data from the 2002 physical examination were combined with data from the 1982 baseline examination and the 1985, 1987, 1992, and 1997 follow-up examinations to form a complete history of kidney problems for each participant. Based on the verified data, occurrence of kidney stones (International Classification of Diseases, 9th Revision, Clinical Modification [ICD-9-CM] codes 592.0 - 592.1) and occurrence of past kidney disease (ICD-9-CM codes 271.4, 580.0 - 593.9, 753.0 - 753.4, 788.0, 791.0 - 791.3, 791.6 - 791.9, and operations or procedures 55.01 - 56.99) were classified as “yes” or “no.” Predominate conditions for past kidney disease included kidney stone, unspecified disorders of the kidney and ureter, and nonspecific findings on the examination of the urine.

The analyses performed in this chapter were based on the 1,951 participants who attended the 2002 follow-up examination.

Participants with occurrences of kidney disease or kidney stones before duty in SEA were excluded from the analyses of the respective variables.

17.1.3.1.2 Laboratory Variables

Renal variables were quantified by laboratory tests to assess nonspecific renal system function. Urinary protein and urine specific gravity were determined by accepted dipstick methods using Bayer Atlas[®] equipment. Hematuria and leukocyturia were measured by high-powered microscopic examination. Serum creatinine, urinary creatinine, and blood urea nitrogen were assayed using Dade Behring Dimension[®] RxL equipment. Urinary microalbumin was assayed using the Beckman Coulter IMAGE[®] system.

An empirical formula, based on age, body weight, and serum creatinine, was used to estimate creatinine clearance without using a timed collection of urine. The formula used was

$$[(140 - \text{age (years)}) \times \text{weight (kg)}] / [\text{serum creatinine (mg/dL)} \times 72] \text{ (52-54).}$$

Low creatinine clearance was considered to be undesirable because of the inverse relation with high serum creatinine levels. Blood urea nitrogen (mg/dL), serum creatinine (mg/dL), creatinine clearance, and urine specific gravity were analyzed as continuous variables. Hematuria (urinary RBCs per HPF) (≤ 2 , > 2), leukocyturia (urinary WBCs per HPF) (≤ 2 , > 2), and urinary protein (absent, present) were analyzed as dichotomous variables.

A urinary microalbumin to urinary creatinine ratio helps adjust the microalbumin measure for the factors that lead to variability. This ratio also is substantially better than a microalbumin measure alone for identifying patients at risk for early kidney damage secondary to diabetes. The urinary microalbumin to urinary creatinine ratio ($\mu\text{g}/\text{mg}$) had a large number of measurements (87%) equal to 0, indicating no microalbumin in the participant's urine. The nonzero measurements exhibited a positively skewed distribution, so a logarithmic transformation was applied to achieve an approximate normal distribution. The logarithmic transformation, however, could not be applied to the measurements equal to 0. Consequently, this variable was analyzed in two forms: (1) an analysis based on the continuous form of the nonzero measurements and (2) an analysis based on a discrete form of the urinary microalbumin to urinary creatinine ratio, where the proportion of nonzero measurements was analyzed.

No participants were excluded for medical reasons from the analysis of these variables.

17.1.3.2 Covariates

Age, race, military occupation, and diabetic status were used as covariates in adjusted statistical analyses evaluating all renal dependent variables. Age, race, and military occupation were determined from military records.

In the 2002 questionnaire, a general screening question on diabetes was posed. During the in-person health interview each participant was asked: "Since the date of the last interview, has a doctor told you for the first time that you had diabetes?" Medical records review was accomplished to confirm reported diabetes and to identify any unreported diabetes for each participant that attended the 2002 physical examination. These data from the 2002 physical examination were combined with data from the 1982

baseline examination and the 1985, 1987, 1992, and 1997 follow-up examinations to form a complete history of diabetes for each participant. The analyses performed in this chapter were based on the 1,951 participants who attended the 2002 follow-up examination. Participants with a verified history of diabetes, as diagnosed previously by a physician, were combined with those participants with either

- a 2-hour postprandial glucose level of 200 mg/dL or greater on two separate occasions
- a fasting glucose level of 126 mg/dL or greater on two separate occasions, or
- one 2-hour postprandial glucose measurement ≥ 200 mg/dL and one fasting glucose ≥ 126 mg/dL on two separate occasions,

and classified as “diabetic” for the diabetic class covariate. Those participants not classified as “diabetic,” as defined above, but with a 2-hour postprandial glucose level of at least 140 mg/dL or a fasting glucose level of at least 110 mg/dL at the 2002 physical examination, were classified as “impaired.” Those participants not classified as “diabetic” or “impaired” as defined above were classified as “normal.”

Analyses of the urinary microalbumin to urinary creatinine ratio included four additional covariates: taking a calcium channel blocker (yes/no), taking an angiotensin converting enzyme (ACE) inhibitor (yes/no), taking an alpha- or beta-adrenergic blocking agent (yes/no), and taking a diuretic (yes/no) at the time of the 2002 AFHS physical examination.

17.1.4 Statistical Methods

Table 17-1 summarizes the statistical analysis performed for the 2002 renal assessment. The first part of this table lists the dependent variables analyzed, source of the data, form of the data, cutpoints, covariates, exclusions, and statistical methods. The second part of the table further describes the covariates. A covariate was used in its continuous form whenever possible for all adjusted analyses. If the covariate was inherently discrete (e.g., military occupation), or if a categorized form was needed to develop measures of association with the dependent variables, the covariate was categorized as shown in Table 17-1.

Four models were examined for each dependent variable given in Table 17-1. The analyses of these models are presented below. Further details on dioxin and the modeling strategy are found in Chapters 2 and 7, respectively. These analyses were performed both unadjusted and adjusted for covariates. These covariates are given in Table 17-1. Model 1 examined the relation between the dependent variable and group (i.e., Ranch Hand or Comparison). In this model, exposure was defined as “yes” for Ranch Hands and “no” for Comparisons without regard to the magnitude of the exposure. In an attempt to quantify exposure, three contrasts of Ranch Hands and Comparisons were performed along with the overall Ranch Hand versus Comparison contrast. These three contrasts compared Ranch Hands and Comparisons within each military occupational category (i.e., officers, enlisted flyers, and enlisted groundcrew). As described in previous reports and Table 2-4, the median level of exposure to dioxin was highest for enlisted groundcrew, followed by enlisted flyers, then officers.

During the 1987, 1992, 1997, and 2002 examinations, serum dioxin levels were measured by the CDC using high-resolution gas chromatography and high-resolution mass spectrometry and were reported in

parts per trillion (ppt) on a lipid weight basis (55). These dioxin measurements are referred to as “lipid-adjusted.” All measures of dioxin used in this report were based on lipid-adjusted dioxin measurements.

Model 2 examined the relation between the dependent variable and an extrapolated initial dioxin measure for Ranch Hands who had a 1987 dioxin measurement greater than 10 ppt. The initial dioxin was calculated by extrapolating the 1987 dioxin level back in time to the end of the tour of duty that qualified a Ranch Hand veteran for inclusion in this study. If a Ranch Hand did not have a 1987 dioxin level, then the first dioxin measured, either at 1992, 1997, or 2002, was used to estimate the initial dioxin level. Regardless of when the dioxin was measured, Ranch Hand veterans with a level less than or equal to 10 ppt were excluded from statistical analyses based on Model 2. A statistical adjustment for body mass index at the time of the participant’s blood measurement of dioxin was included in this model to account for body mass index-related differences in elimination rate (56).

Model 3 divided the Ranch Hands examined in Model 2 into two categories based on their initial dioxin measures. These two categories were referred to as “low Ranch Hand” and “high Ranch Hand.” Two additional categories—Ranch Hands with serum dioxin levels at or below 10 ppt and Comparisons—were formed and included in the model. Ranch Hands with serum dioxin levels at or below 10 ppt were assigned to the “background Ranch Hand” category. If a Ranch Hand did not have a 1987 dioxin measurement, the first measured dioxin level was used. Another category was examined by combining the low and high Ranch Hand categories. This combination is referred to in the tables as the “low plus high Ranch Hand” category. These five categories—Comparisons, background Ranch Hands, low Ranch Hands, high Ranch Hands, and low plus high Ranch Hands—were used in Model 3 analyses. The relation between the dependent variable in each of the four Ranch Hand categories and the dependent variable in the Comparison category was examined. As in Model 2, a statistical adjustment for body mass index at the time of the participant’s blood measurement of dioxin was included in this model for the unadjusted and adjusted analyses of all dependent variables. One Ranch Hand without a dioxin measure was excluded from statistical analyses based on Model 3.

Model 4 examined the relation between the dependent variable and 1987 dioxin levels in all Ranch Hands with a dioxin measurement. If a Ranch Hand did not have a 1987 dioxin measurement, the first dioxin level obtained, either in 1992, 1997, or 2002, was extrapolated to the date of the 1987 physical examination. If the first dioxin level was not obtained in 1987 and was less than or equal to 10 ppt, it was not extrapolated to 1987 level, but was used at the measured value. One Ranch Hand without a dioxin measurement was excluded from statistical analyses based on Model 4.

The term “unadjusted” was used in the text and tables as follows: Models 1 and 4 did not adjust for any covariates. Models 2 and 3 adjusted only for body mass index at the time of the blood measurement for dioxin. The term “adjusted” was used in the text and tables as follows: Models 1 and 4 adjusted for the covariates shown in Table 17-1 unless otherwise specified by a footnote to the table. Models 2 and 3 additionally adjusted only for body mass index at the time of the blood measurement for dioxin.

Table 17-2 provides a summary of the number of participants with missing dependent variable and covariate data. In addition, the number of participants that were excluded from analyses is given.

Table 17-2. Number of Participants Excluded or with Missing Data for the Renal Assessment

Variable	Variable Use	Group ^a		Dioxin (Ranch Hands Only) ^b		Categorized Dioxin ^c	
		Ranch Hand	Comparison	Initial Dioxin	1987 Dioxin	Ranch Hand	Comparison
Pre-SEA History of Kidney Stones	EXC	9	12	5	9	9	12
Pre-SEA History of Kidney Disease	EXC	14	21	7	13	13	21
Creatinine Clearance	DEP	1	0	0	1	1	0

^a777 Ranch Hands and 1,174 Comparisons for group.

^b424 Ranch Hands for initial dioxin; 776 Ranch Hands for 1987 dioxin.

^c776 Ranch Hands and 1,174 Comparisons for categorized dioxin.

Note: DEP = Dependent variable.

EXC = Exclusion.

17.2 RESULTS

17.2.1 Dependent Variable-covariate Associations

The renal dependent variables were tested for associations with each of the covariates used in the adjusted analyses. The complete results are presented in Appendix F, Table F-9. These associations were pairwise between the dependent variable and the covariate and were not adjusted for any other covariates. The following paragraphs summarize the pattern of significant ($p \leq 0.05$) dependent variable-covariate associations. In the discussion of the results, low levels were considered adverse for creatinine clearance.

Older participants had more occurrences of kidney stones and kidney disease than did younger participants. Creatinine clearance and urine specific gravity each decreased with age. Blood urea nitrogen and serum creatinine increased with age. For participants with urinary microalbumin present, the urinary microalbumin to urinary creatinine ratio increased with age.

All dependent variables except for the continuous form of the urinary microalbumin to urinary creatinine ratio were associated with race. Non-Black participants had more occurrences of kidney stones than did Black participants, but fewer occurrences of kidney disease than Black participants. Black participants had higher mean values for serum creatinine and urine specific gravity than Non-Black participants. A higher percentage of Black participants had urinary microalbumin present than did non-Black participants. In addition, Black participants had a higher prevalence of abnormal results for urinary occult blood, urinary WBC count, and urinary protein than non-Black participants. Mean blood urea nitrogen and creatinine clearance levels were higher for Non-Black participants than Black participants.

Military occupation was associated with blood urea nitrogen, serum creatinine, creatinine clearance, urine specific gravity, and the ratio of urinary microalbumin to urinary creatinine in its discrete form. Officers had higher mean blood urea nitrogen and serum creatinine levels than enlisted personnel, but a lower mean creatinine clearance and urine specific gravity. A larger percentage of enlisted personnel than officers had urinary microalbumin present.

Diabetic participants had the highest mean blood urea nitrogen and serum creatinine levels. For participants with urinary microalbumin present, diabetic participants also had the highest mean urinary

microalbumin to urinary creatinine ratio. In addition, diabetic participants had the highest prevalence of kidney disease and urinary protein, and the greatest proportion of participants with urinary microalbumin present was found among diabetics. Participants in the impaired diabetic class had the most occurrences of kidney stones, followed by diabetic participants, then participants with normal glucose levels.

Use of calcium channel blockers, ACE inhibitors, and diuretics at the time of the physical examination were associated with the percentage of participants with urinary microalbumin present. For participants with urinary microalbumin present, these medications also were associated with the urinary microalbumin to urinary creatinine ratio. Urinary microalbumin was present more often in participants taking these medications than in participants who were not taking these medications. In addition, a higher mean urinary microalbumin to urinary creatinine ratio was observed for participants taking these medications than for participants who were not. The mean urinary microalbumin to urinary creatinine ratio was higher in participants who used alpha- or beta-adrenergic blocking agents at the time of the physical exam than for participants who did not use this type of medication.

17.2.2 Exposure Analysis

The following section presents results of the statistical analyses of the dependent variables shown in Table 17-1. Dependent variables are grouped into two sections: (1) the questionnaire variables, derived from the questionnaire that was administered in the 2002 follow-up and previous AFHS examinations, and (2) the laboratory examination variables, obtained during the 2002 physical examination.

17.2.2.1 Medical Records Variables

17.2.2.1.1 Occurrence of Kidney Stones

Model 1 showed no significant difference in occurrence of kidney stones between Ranch Hands and Comparisons in either the unadjusted or adjusted analysis (Table 17-3(a,b): $p > 0.13$ for all contrasts). A significant inverse association between the occurrence of kidney stones and initial dioxin was seen in the unadjusted Model 2 analysis (Table 17-3(c): Unadjusted Relative Risk [RR]=0.72, $p=0.008$). After adjusting for covariates, the results were nonsignificant (Table 17-3(d): $p=0.059$).

The unadjusted Model 3 analysis of occurrence of kidney stones showed a significant difference between Ranch Hands in the low dioxin category and Comparisons (Table 17-3(e): Unadjusted RR=1.58, $p=0.033$). The same contrast was nonsignificant after adjusting for covariates (Table 17-3(f): $p=0.053$). No significant differences in the occurrence of kidney stones were found between Ranch Hands in the high dioxin category or low and high dioxin categories combined and Comparisons in the unadjusted and adjusted Model 3 analyses (Table 17-3(e,f): $p > 0.40$ for each analysis). No significant relations were shown between occurrence of kidney stones and 1987 dioxin in the unadjusted or adjusted Model 4 analyses (Table 17-3(g,h): $p > 0.39$ for each analysis).

17.2.2.2 Laboratory Variables

17.2.2.2.1 Blood Urea Nitrogen

The unadjusted and adjusted Model 1 and Model 2 analyses of blood urea nitrogen showed no significant results (Table 17-5(a-d): $p > 0.05$ for each analysis).

The unadjusted Model 3 analysis revealed a significant difference between Ranch Hands in the high dioxin category and Comparisons (Table 17-5(e): difference of means = -0.70 mg/dL, $p = 0.044$). After adjusting for covariates, no contrasts were significant (Table 17-5(f): $p > 0.22$ for each contrast).

The unadjusted and adjusted Model 4 analyses revealed no significant associations between blood urea nitrogen and 1987 dioxin (Table 17-5(g,h): $p > 0.59$ for each analysis).

17.2.2.2.2 Serum Creatinine

Both the unadjusted and adjusted Model 1 analyses of serum creatinine revealed significant overall group differences (Table 17-6(a,b): difference of means=-0.02 mg/dL, $p=0.038$; difference of adjusted means=-0.02, $p=0.031$). The overall adjusted mean serum creatinine values were 1.17 mg/dL for Ranch Hands and 1.19 mg/dL for Comparisons. After stratifying by military occupation, unadjusted and adjusted analyses revealed group differences within the officer stratum (unadjusted: difference of means=-0.03 mg/dL, $p=0.025$; adjusted: difference of adjusted means=-0.04 mg/dL, $p=0.010$). Among the officers, the Ranch Hands had an adjusted mean serum creatinine value of 1.16 mg/dL versus 1.20 mg/dL for the Comparisons.

The unadjusted Model 2 analysis revealed a significant inverse association between initial dioxin and serum creatinine (Table 17-6(c): Slope=-0.016, $p=0.010$). After adjusting for covariates, the relation became nonsignificant (Table 17-6(d): $p=0.392$).

Ranch Hands in the high dioxin category had a significantly lower mean serum creatinine level than Comparisons in the unadjusted Model 3 analysis (Table 17-6(e): difference of means=-0.05 mg/dL, $p=0.003$). After adjusting for covariates, all contrasts were nonsignificant (Table 17-6(f): $p>0.09$ for all contrasts).

No significant associations were seen in the unadjusted and adjusted Model 4 analyses of serum creatinine (Table 17-6(g,h): $p>0.32$ for each analysis).

17.2.2.2.3 Creatinine Clearance

The unadjusted and adjusted Model 1 analyses of creatinine clearance showed no group differences between Ranch Hands and Comparisons (Table 17-7(a,b): $p > 0.05$ for each analysis). A significant association between creatinine clearance and initial dioxin was seen in the unadjusted Model 2 analysis (Table 17-7(c): Slope=0.132, $p=0.001$). After adjusting for covariates, however, the relation became nonsignificant (Table 17-7(d): $p=0.509$).

The unadjusted Model 3 analysis of creatinine clearance revealed two significant contrasts: Ranch Hands in the high dioxin category versus Comparisons and Ranch Hands in the low and high dioxin categories combined versus Comparisons (Table 17-7(e): difference of means=7.06, $p < 0.001$; difference of means=3.56, $p=0.003$, respectively). After covariate adjustment, the Model 3 analysis of creatinine clearance revealed a significant difference between Ranch Hands in the low dioxin category and Comparisons (Table 17-7(f): difference of adjusted means=2.92, $p=0.015$) as well as a significant difference between Ranch Hands in the low and high dioxin categories combined and Comparisons (Table 17-7(f): difference of adjusted means=2.26, $p=0.014$). The contrast of Ranch Hands in the high dioxin category versus Comparisons was no longer significant (Table 17-7(f): $p=0.188$). The adjusted mean creatinine clearance values in the low, combined low and high, and Comparison dioxin categories were 85.27, 84.61, and 82.35, respectively.

The unadjusted and adjusted analyses for Model 4 each showed significant positive associations between creatinine clearance and 1987 dioxin (Table 17-7(g,h): Slope=0.173, $p < 0.001$, unadjusted; adjusted Slope=0.118, $p < 0.001$, adjusted). The adjusted mean creatinine clearance values in the low, medium, and high 1987 dioxin categories were 79.36, 85.48, and 86.92, respectively.

17.2.2.2.4 Urinary Microalbumin to Urinary Creatinine Ratio (Nonzero Measurements)

Both the unadjusted and adjusted Model 1 analyses of nonzero urinary microalbumin to urinary creatinine ratio values revealed significant overall group differences (Table 17-8(a,b): difference of means=-11.93 µg/mg, p=0.008; difference of adjusted means=-12.69 µg/mg, p=0.037). The overall adjusted mean ratio of the nonzero values was 27.44 µg/mg and 40.13 µg/mg for Ranch Hands and Comparisons, respectively. After stratifying by military occupation, unadjusted and adjusted analyses revealed group differences within the enlisted groundcrew stratum (unadjusted: difference of means=-17.48 µg/mg, p=0.002; adjusted: difference of adjusted means=-19.06 µg/mg, p=0.024). Within the enlisted groundcrew stratum, the Ranch Hands had an adjusted mean urinary microalbumin to urinary creatinine ratio value of 23.85 µg/mg versus 42.91 µg/mg for the Comparisons.

The association between initial dioxin and the urinary microalbumin to urinary creatinine ratio examined in the unadjusted and adjusted Model 2 analyses revealed nonsignificant results (Table 17-8(c,d): p≥0.30 for each analysis). The unadjusted Model 3 analysis revealed two significant contrasts: Ranch Hands in the low dioxin category versus Comparisons and Ranch Hands in the low and high dioxin categories

combined versus Comparisons (Table 17-8(e): difference of means=-12.49 µg/mg, p=0.039; difference of means=-11.26 µg/mg, p=0.024, respectively). After covariate adjustment, the Model 3 analysis revealed a significant difference between Ranch Hands in the low dioxin category and Comparisons (Table 17-8(f): difference of adjusted means=-16.47 µg/mg, p=0.033). Ranch Hands in the low dioxin category had a lower mean urinary microalbumin to urinary creatinine ratio than Comparisons (22.00 µg/mg and 38.47 µg/mg, respectively).

The unadjusted and adjusted Model 4 analyses did not reveal a significant association between urinary microalbumin to urinary creatinine ratio and 1987 dioxin (Table 17-8(g,h): $p \geq 0.39$ for each analysis).

17.2.2.2.6 Urine Specific Gravity

The unadjusted and adjusted Model 1 through 3 analyses of urine specific gravity did not show any significant group differences (Table 17-10(a-f): $p > 0.05$ for each analysis). The unadjusted Model 4 analysis revealed a significant positive association between 1987 dioxin and urine specific gravity (Table 17-10(g): Slope=0.0003, $p=0.033$). After adjusting for covariates, however, the relation became nonsignificant (Table 17-10(h): $p=0.807$).

17.3 DISCUSSION

The AFHS evaluated renal (kidney) disorders based on the medical histories and laboratory measures. The clinical histories and laboratory values were measured in accordance with the Kidney Disease Outcomes Quality Initiative (K/DOQI) guidelines recently established by the National Kidney Foundation (57). The Foundation published the guidelines to assist clinicians in evaluating, classifying, and stratifying persons with chronic kidney disease.

The K/DOQI guidelines stress the importance of assessing the glomerular filtration rate (GFR) and urinary composition (albuminuria, proteinuria, abnormal cells) of an individual to determine the presence of kidney disease. The AFHS assessed the GFR using standard laboratory measures recommended by the K/DOQI, including the serum creatinine test and the Cockcroft-Gault (52-54) equation, which estimates creatinine clearance based on age, weight, and gender. A person with a low GFR is at a higher risk of progressive loss of kidney function and complications due to kidney disease (e.g., uremia, anemia, metabolic bone disease) than a person with a high GFR. The AFHS assessment of urinary composition also was consistent with the guidelines, focusing on the presence of albuminuria, proteinuria, and formed elements (RBCs and WBCs) in the urine. The use of the urinary albumin or protein-to-creatinine ratio as an index of total albumin or protein excretion has been approved and adopted by the K/DOQI as the screening measure of choice, particularly when validating diabetic nephropathy.

The AFHS cutpoints for hematuria and pyuria (two cells per HPF) will miss few cases of disease, but may cause inclusion of more healthy subjects than would a higher cutpoint. Abnormalities based on the AFHS cutpoints are considered a minor abnormality, which are not always a sign of renal parenchymal disease, and will frequently resolve spontaneously without the need for an indepth evaluation. Other measures, such as the urine specific gravity and the blood urea nitrogen, were of lesser value in the assessment of kidney disease than the other parameters studied in this evaluation. The assessment of kidney stones relied largely on clinical history, which, considering the pain associated with this common disorder, was judged to be a reliable measure. In addition, if the AFHS had used plain films, the films would have not picked up passed stones and would have identified only roughly 85 percent of stones if they were present (i.e., approximately 15 percent are radiolucent).

In the dependent variable-covariate associations, the findings were in complete agreement with established clinical patterns regarding kidney stones and kidney function. With respect to kidney stones, there was an increase with age and greater prevalence in non-Blacks versus Blacks. Regarding kidney disease, there was an increase in prevalence with age, Blacks, and diabetics. This was reflected both in the parameters of GFR and in the incidence of proteinuria, albuminuria, and abnormal urine sediment. Age, race, and diabetic class were significantly associated with the majority of the renal parameters studied. The adjusted analysis took into account age, race, military occupation, and diabetic status. Analysis of albuminuria was also adjusted for the participants' use of various anti-hypertensive agents.

Several models were used in the 2002 AFHS evaluation to assess renal function in participants exposed to herbicides or dioxin. Model 1 evaluated Ranch Hands to a matched Comparison group, whereas the other models (Models 2, 3, and 4) assessed dose-response effects using three alternative measures of serum dioxin. Given the number of measurements and contrasts, it would be prudent to interpret with caution any significant finding not supported by other significant findings. To judge whether herbicide or dioxin exposure is linked to any one abnormality, it would be ideal to see the effect in all models in a dose-dependent fashion. That is, a story should emerge from data analysis with some internal consistency.

There was no difference in Ranch Hands and Comparisons in the adjusted analysis of kidney stones. In the models involving dioxin exposure, there was no evidence of increased risk with dioxin exposure; in fact, the models suggested a decreased risk with increasing dioxin exposure. No significant findings of

increased risk with herbicide or dioxin exposure existed in the analyses of kidney disease or blood urea nitrogen after adjusting for age, race, military occupation, and diabetic class.

Serum creatinine and creatinine clearance were the laboratory measures used to assess GFR. Mean values of serum creatinine were significantly lower in Ranch Hands relative to Comparisons and the adjusted analyses in the models using dioxin levels were not significant. These findings suggest a higher GFR in Ranch Hands. Serum creatinine, however, is affected not only by GFR, but also by muscle mass, meat intake, and the secretion of creatinine into urine (creatinine enters urine by glomerular filtration and secretion). An effect on GFR is also not supported by the creatinine clearance analysis, which shows that Ranch Hands and Comparisons were no different in the adjusted analyses. The models using categorized dioxin and 1987 levels of dioxin actually suggest a higher GFR in persons with the greatest exposures. These findings would not be expected if increasing levels of dioxin were doing harm to the renal system, as individuals with a low GFR are at higher risk of progressive loss of kidney function and complications due to kidney disease.

Ranch Hands had significantly lower albuminuria than Comparisons in the adjusted analyses. In Model 3, Ranch Hands in the low and high dioxin categories combined had significantly lower albuminuria than Comparisons. Models using initial dioxin exposure or 1987 dioxin levels did not support this dioxin association. Lower excretion of albumin in the urine is not a marker of any known kidney disease in clinical practice.

The prevalences of microhematuria, pyuria, and proteinuria were similar in Ranch Hands and Comparisons. There was no apparent association with herbicide or dioxin exposure on these urinalysis results.

17.4 SUMMARY

The renal assessment was based on questionnaire data, which was subsequently verified by a review of medical records, and laboratory data. Associations with herbicide exposure (i.e., group – Model 1), initial dioxin (Model 2), categorized dioxin (Model 3), and 1987 dioxin levels (Model 4) were examined for each variable in the renal assessment. The significant adjusted results are discussed in the sections below.

17.4.1 Model 1: Group Analysis

Adjusted group analyses revealed that Ranch Hands had a significantly lower mean serum creatinine level than Comparisons, as well as a lower mean urinary microalbumin to urinary creatinine ratio than Comparisons. Stratifying by military occupation revealed Ranch Hand officers had a significantly lower mean serum creatinine level than Comparison officers. In addition, among enlisted groundcrew, Ranch Hands had a significantly lower mean urinary microalbumin to urinary creatinine ratio than Comparisons. The results of all unadjusted and adjusted Model 1 analyses are summarized in Table 17-14.

Table 17-14. Summary of Group Analysis (Model 1) for Renal Variables (Ranch Hands vs. Comparisons)

The p-value was given if $p \leq 0.05$. The relative risk was given in parentheses for a significant result from the analysis of a discrete dependent variable. The slope was given in parentheses for a significant result from the analysis of a continuous dependent variable.

A capital “NS” denotes a nonsignificant positive association. A lowercase “ns” denotes a nonsignificant inverse association.

17.4.3 Model 3: Categorized Dioxin Analysis

The adjusted Model 3 analysis revealed significantly lower mean creatinine clearance values among Comparisons than among Ranch Hands in the low dioxin category. In addition, Comparisons displayed a significantly lower mean creatinine clearance value than the Ranch Hands in the combined low and high dioxin categories. The mean urinary microalbumin to urinary creatinine ratio was significantly lower for Ranch Hands in the low dioxin category than for Comparisons. The results of all unadjusted and adjusted Model 3 analyses are summarized in Table 17-16.

17.4.5 Summary of Significant Results

Table 17-18 summarizes the significant results ($p\leq 0.05$) for the adjusted analyses that were performed for the renal assessment. The dependent variable and its table reference are listed along with the model and the contrast or description of the model. The p-value is provided along with analysis statistics that correspond to the type of analysis that was performed (either continuous or discrete). A description of the analysis and the statistics that are presented is referenced under the “Note” column and is explained in footnotes.

Table 17-18. Summary of Results from Significant Adjusted Analyses in the Renal Assessment

Dependent Variable (Table Reference)	Model	Contrast or Description	p-Value	Analysis Statistics	Adjusted Mean or Percent Abnormal	Note
Serum Creatinine (17-6)	1	RH vs. C, All	0.031	-0.02	RH: 1.17 mg/dL C: 1.19 mg/dL	(a)
	1	RH vs. C, Officer	0.010	-0.04	RH: 1.16 mg/dL C: 1.20 mg/dL	(a)
Creatinine Clearance (17-7)	3	Low RH vs. C	0.015	2.92	RH: 85.27 C: 82.35	(b)
	3	Low plus High RH vs. C	0.014	2.26	RH: 84.61 C: 82.35	(b)
	4	All RH: 1987 Dioxin	<0.001	0.118 (0.025)	Low: 79.36 Medium: 85.48 High: 86.92	(c)
Urinary Microalbumin to Urinary Creatinine Ratio (17-8)	1	RH vs. C, All	0.037	-12.69	RH: 27.44 µg/mg C: 40.13 µg/mg	(a)
	1	RH vs. C, Enlisted Groundcrew	0.024	-19.06	RH: 23.85 µg/mg C: 42.91 µg/mg	(a)
	3	Low RH vs. C	0.033	-16.47	RH: 22.00 µg/mg C: 38.47 µg/mg	(b)

(a): Continuous variable: difference of adjusted means was presented; confidence interval was not presented because analysis was not performed on original scale; adjusted means were transformed to original scale and were presented for each exposure group in contrast.

(b): Continuous variable: difference of adjusted means was presented; confidence interval was not presented because analysis was not performed on original scale; adjusted means were transformed to original scale and were presented for each dioxin category in contrast.

(c): Continuous variable: slope and standard error were presented and were based on square root of dependent variable versus \log_2 (1987 dioxin); adjusted means were transformed to original scale and were presented for each of three 1987 dioxin categories.

Note: RH = Ranch Hand.

C = Comparison.

Model 3: Background (Ranch Hand): 1987 dioxin \leq 10 ppt.

Low (Ranch Hand): 1987 dioxin > 10 ppt, 10 ppt < initial dioxin \leq 118 ppt.

High (Ranch Hand): 1987 dioxin > 10 ppt, initial dioxin > 118 ppt.

Model 4: Low = \leq 7.8 ppt; Medium = >7.8–19.2 ppt; High = >19.2 ppt (Ranch Hands only).

17.5 CONCLUSION

One of the goals of the AFHS was to determine whether herbicide or dioxin exposure increases the risk of renal disease. Evaluating the presence or absence of kidney disease among participants was done through the study of clinical histories and laboratory parameters. The study applied screening parameters used today in clinical practice to determine the presence of disease.

Ranch Hands had a lower mean serum creatinine level, as well as a lower mean urinary microalbumin to urinary creatinine ratio. The mean urinary microalbumin to urinary creatinine ratio was higher for Comparisons than for Ranch Hands in the low dioxin category. Lower mean creatinine clearance values

were observed more often among Comparisons than among Ranch Hands in the low dioxin category. An increase in mean creatinine clearance values was observed as 1987 dioxin levels increased.

The results from the renal assessment indicated no association between any marker of kidney disease and either herbicides or dioxin. In particular, there was no evidence that exposure to herbicides or dioxin was associated with renal dysfunction, kidney stones, reduction in glomerular filtration rate, incidence of proteinuria or albuminuria, or cells in the urine.

18 ENDOCRINOLOGY ASSESSMENT

18.1 INTRODUCTION

18.1.1 Background

18.1.1.1 Organs/Diseases

Several sites of endocrine activity, including the thyroid gland, pancreas, and hypothalamic-pituitary-testis axis have been evaluated for dioxin toxicity in animal and human studies. Ranch Hands and Comparisons were evaluated for thyroid disease, diabetes, and testosterone and other sex hormone levels as part of the endocrinology assessment in the Air Force Health Study (AFHS).

The thyroid produces thyroxine (T_4) and triiodothyronine (T_3), hormones that are released in response to thyroid-stimulating hormone (TSH) secreted by the anterior pituitary gland. To maintain thyroid hormone homeostasis, the pituitary is stimulated to release more TSH when circulating T_3 and T_4 levels are low. Conversely, high levels of circulating T_3 and T_4 trigger the pituitary to reduce TSH production. Disruptions in this feedback loop can lead to diseases such as hypothyroidism and hyperthyroidism. A family history of thyroid disease and age are positively associated with both hypothyroidism and hyperthyroidism.

The two most important hormones secreted by the pancreas are insulin and glucagon. Insulin stimulates liver cells to take up glucose from the blood and convert it into glycogen. Glucagon stimulates the conversion of glycogen into glucose, which is then released into the blood. The production of insulin is regulated by blood glucose concentrations; high blood glucose concentrations combined with insulin deficiency results in diabetes. Type 1 diabetes is a condition caused by a genetically based autoimmune destruction of β -cells and the subsequent inability of the body to manufacture insulin (1). Type 2 diabetes, the diagnosis given to approximately 90 percent of all diabetes cases, describes a combination of insulin resistance, insulin deficiency, and glucose overproduction. Risk factors for Type 2 diabetes include older age and being overweight and physically inactive. Additional risk factors for diabetes include a family history of diabetes, ethnicity, abnormal blood lipid levels, and high blood pressure (2, 3).

The hypothalamic-pituitary-testis axis produces several hormones affecting gonadal function. The hypothalamus releases gonadotropin-releasing hormone that subsequently signals the pituitary to release luteinizing hormone (LH), the hormone that regulates growth and development of eggs and sperm. Within the testis, LH stimulates testosterone production in the Leydig cells. Testosterone from the testes, as well as follicle-stimulating hormone (FSH) released by the pituitary, stimulates production of sperm. Excess testosterone converts to estradiol by the aromatase enzyme. Male-mediated adverse reproductive effects can be due to any number of imbalances in gonadal hormones produced via the hypothalamic-pituitary-testis axis. Although not analyzed in this report, the AFHS examined outcomes such as sex of offspring, pre-term birth, intrauterine growth retardation, and infant deaths (4, 5), all of which are discussed further in this section.

18.1.1.2 Toxicology

Dioxin binds to the aryl hydrocarbon (Ah) receptor, which has similarities to the endocrine receptors that mediate function of the thyroid, adrenal, and gonadal hormones (6-9). Animal research documented that the thyroid is a target organ for dioxin toxicity, although the mechanism has not been defined clearly and

remains under investigation (10-17). Also, dioxin-induced changes in thyroid indices (T_4 , T_3 , and TSH) differ according to species and strain specificity (18, 19), as well as dose and duration of exposure (20, 21).

Studies of guinea pigs, rats, and mice that have been dosed with dioxin at levels between 0.03 – 1.0 μg per kg demonstrated reduced glucose transport activity in adipose, liver, and pancreas tissue (22-26). Glucose and insulin levels decreased in rats dosed with dioxin in excess of 100 mg per kg (27, 28). The mechanism by which dioxin alters glucose transport remains unknown.

Additional experiments explored the effects of dioxin on the pituitary and hypothalamus (29, 30). The use of microsurgical techniques in male rats revealed that removal of the pituitary gland aggravated dioxin toxicity, but the effect was attenuated upon administering either corticosterone or thyroid hormone (29). Another study defined a biochemical basis for the effect of dioxin on prolactin levels controlled by the adenohypophysis in male rats (31). Studies on the effects of dioxin on the pituitary-adrenal axis documented significant suppression of corticosterone production by the adrenal gland (32) and defined a biochemical basis for the apparent reduction in bioactivity of adrenocorticotrophic hormone secreted by the pituitary (33).

The finding in laboratory animals of physicochemical similarities between the dioxin-binding Ah and glucocorticoid receptors (9, 34) has prompted further investigation into the interaction of dioxin with other steroid hormones. Couture and colleagues (35) provided a comprehensive review of the research into the developmental toxicity and teratogenicity of dioxin in experimental animals.

Experimental studies documented numerous adverse male reproductive effects in laboratory animals exposed to dioxin, including reduced testicular weight, impaired spermatogenesis, decreased testicular testosterone secretion, and atrophy of the androgen-sensitive seminal vesicles and epididymis (36-43). Although dioxin administration is associated with diminished testosterone secretion in rats (39, 44, 45), the mechanism is unknown and may involve the hypothalamic-pituitary axis. In rats, dioxin inhibits the secretion of LH by the pituitary gland, an effect associated with androgen deficiency (46, 47). In other experiments, dioxin inhibited the response of the pituitary to gonadotropin-releasing hormone secreted by the hypothalamus (48).

18.1.1.3 Epidemiology: Thyroid Disease

Zober and colleagues (49) reported an increase in thyroid disease among workers exposed to 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD or dioxin) following a 1953 industrial accident in a trichlorophenol production unit in Germany. Thyroid disease and goiter occurred more frequently among dioxin-exposed workers, including those with an occupational history of chloracne as an indicator of high exposure, than among referents. Thyrotoxicosis, or hyperthyroidism, and hypothyroidism were reported among a small number of workers with dioxin concentrations of at least 1,000 parts per trillion (ppt) and a history of moderate to severe chloracne. In the analyses of laboratory measurements from the same exposed population, the researchers found positive associations between each of the exposure indices and selected tests of thyroid function: T_4 and thyroxine binding globulin (50).

Workers at two plants that manufactured 2,4,5-T or one of its derivatives had a statistically significantly higher adjusted mean free T_4 index than referents and a higher adjusted mean total T_4 (51). Although the adjusted mean total T_4 and T_4 index were higher for workers in each category of exposure compared to referents, a dose-response trend was not observed. Adjusted mean TSH did not differ between workers and referents.

After adjusting for age, race, and military occupation, Pavuk and colleagues (52) found that Ranch Hands in the low and high dioxin categories had significantly higher TSH than the Comparison population, with a significant increase in TSH with increased exposure. No changes in clinical thyroid disease were seen.

In 2002, the Institute of Medicine (IOM) (53) concluded that there is inadequate or insufficient evidence to determine if an association existed between Agent Orange and other herbicides used in Vietnam and altered thyroid function.

18.1.1.4 Epidemiology: Diabetes

The possibility that dioxin might affect glucose metabolism in humans was first raised in 1981 with the publication of an occupational study that reported an unusually high prevalence of abnormal glucose tolerance tests (40%) and a 20-percent incidence of diabetes in chemical production workers exposed to dioxin (54). Since then, several studies examined the association between occupational dioxin exposure and diabetes or related indicators, including those conducted by the National Institute of Occupational Safety and Health (NIOSH) (51, 55, 56), the International Agency for Research on Cancer (57), and BASF (49, 50). Other studies examined this association among Seveso, Italy, residents (58) and Vietnam veterans (59-62).

A NIOSH study (56) reported statistically significant associations between the prevalence of diabetes and elevated fasting blood sugar with increasing serum dioxin levels among workers employed more than 15 years earlier at one of two plants that produced trichlorophenol contaminated with dioxin. Another NIOSH study found that the 279 trichlorophenol production workers exposed to dioxin did not differ from 258 neighborhood referents with no occupational dioxin exposure on serum glucose overall (51). Workers with the highest half-life extrapolated serum dioxin concentrations, however, had increased adjusted mean serum glucose concentrations compared to referents. An increased risk of diabetes was also seen after adjusting for race, age, body mass index, family history of Type 2 diabetes, and current medications that increase serum glucose concentrations, based on 26 workers and 18 referents who met one of the NIOSH definitions for diabetes. Of the 10 workers with the highest serum dioxin concentrations (>1,500 pg/g lipid), 6 had diabetes mellitus. In contrast, no association was found between glucose intolerance and exposure to dioxins among BASF employees exposed to dioxin (49, 50).

A NIOSH mortality study of 5,172 dioxin-exposed workers at 12 plants showed a statistically significant trend between increased risk of diabetes mortality and decreased cumulative dioxin exposure (55). An international cohort study of 21,863 workers producing or spraying phenoxyacid herbicides and chlorophenols and employed in 36 cohorts from 12 countries found an increased risk of mortality from diabetes among workers with dioxin exposure (57). Mortality from diabetes was increased among residents—and significantly increased among women—who lived in the moderate and low contaminated zones in Seveso, Italy (58, 63).

A 2003 Korean veteran study of 1,224 Vietnam and 154 non-Vietnam veterans in Korea found a statistically significant increased risk of diabetes among Vietnam veterans relative to nonveterans; however, there was no clear trend in prevalence of diabetes across estimated levels of Agent Orange exposure among veterans (62).

Henriksen and colleagues (59) found that the risk of diabetes and glucose abnormalities increased with dioxin among Ranch Hands. The relative risk of diabetes was 1.5 (95% confidence interval: [1.2, 2.0]) among the high-exposed Ranch Hands, an effect that was later shown to be independent of serum triglyceride level (64). In nondiabetic Ranch Hands, insulin abnormalities increased with dioxin levels.

In the AFHS 1992 follow-up examination, Michalek and colleagues (60) studied the influence of dioxin levels on the relation between sex hormone-binding globulin (SHBG) and insulin-related metabolism using lab measures of Ranch Hand cohort and Air Force personnel who were in Southeast Asia (SEA) during the same period but not exposed to herbicides. Among diabetics, no significant correlations were seen between SHBG and either fasting glucose or insulin for any exposure category. Among nondiabetics, SHBG was negatively correlated with insulin for all exposure categories. The authors concluded that a compensatory metabolic relation exists between dioxin and insulin regulation and the negative correlation between SHBG levels and insulin levels suggests that the transported sex hormones are down-regulating insulin release. For nondiabetic veterans in the high exposure category, the geometric mean of insulin level was significantly increased as contrasted with the Comparison group. Fasting serum glucose level was significantly increased among diabetic veterans in the high exposure category; the prevalence of diabetes was similar between the Ranch Hands (12.7%) and the Comparison group (11.2%). Longnecker and Michalek (61) reported an association between serum dioxin levels and diabetes mellitus within a group of Air Force veterans chosen as a comparison cohort for Ranch Hand veterans. Adjusted odds ratios for Type 2 diabetes increased with serum dioxin level; adding serum triglyceride level to the model attenuated the associations.

One hypothesis examined is that dioxin elimination rates explain the relation between diabetes and dioxin concentrations seen in the Ranch Hand study (65). Under this hypothesis, individuals who have a longer dioxin half-life due to slow elimination rates are at an increased risk of diabetes, while individuals who eliminate dioxin more quickly (and have a shorter dioxin half-life) are at a decreased risk of diabetes. Because dioxin is stored in adipose tissue, heavier individuals have a slower elimination rate than lean individuals. The risk of diabetes increased with body fat in Ranch Hand veterans. Michalek and colleagues (65) reported that neither the occurrence of diabetes nor the time of onset to diabetes were related to dioxin elimination after adjustment for dioxin body burden, age, body mass index, family history of diabetes, and smoking history among 343 Ranch Hand veterans.

The epidemiologic studies suggest that any increased risk of Type 2 diabetes from herbicide or dioxin exposure is small when compared to the known predictors—family history, obesity, physical inactivity—for diabetes. Based on its comprehensive review of the literature, one IOM committee found limited or suggestive evidence of an association between exposure to herbicides, including 2,4,5-T and its contaminant dioxin, and Type 2 diabetes (66). This conclusion remained unchanged in the 2002 IOM update (53).

18.1.1.5 Epidemiology: Reproductive and Developmental Effects

Serum levels of three endocrine indices—testosterone, LH, and FSH—were examined in relation to current and calculated initial serum dioxin levels in 248 factory workers who experienced significant occupational exposure to dioxin in chemical production plants (67). NIOSH investigators found that current serum dioxin levels were positively and significantly related to both LH and FSH and inversely related to testosterone. In contrast to the NIOSH results, investigators for the AFHS population found no relation between the body burden of dioxin and reproductive or endocrine indices, including serum testosterone, FSH, LH, sperm counts and morphology, and anatomic abnormalities of the testes using categorical measures (68). In the NIOSH cohort, on average, dioxin concentrations were 10 times greater than in the Ranch Hand cohort. When testosterone, FSH, and LH were measured continuously, testosterone decreased with dioxin. After adjusting for military occupation, the investigators found that the relation between dioxin and testosterone was strongest among officers, who were the least exposed, and weakest among enlisted groundcrew, who were the most exposed (69).

Several studies examined sex ratio of children born to parents exposed to dioxin (4, 70-73) and reported conflicting results. An excess of daughters was seen among children born to parents in the Seveso cohort

(70, 72) and in an Austrian chloracne cohort (73). A nonsignificant excess of sons was seen among workers in the NIOSH cohort (71) and in the Ranch Hand cohort (4).

Other studies examined paternal dioxin exposure and reproductive outcomes such as preterm birth, intrauterine growth retardation and infant death (5), spontaneous abortion (71, 74, 75), and stillbirth and birth defects (74, 75). No association was found between dioxin exposure and these reproductive outcomes by any of the investigators.

In 1996, the IOM concluded that limited or suggestive evidence of an association between herbicides used in Vietnam and neural tube defects in the children of veterans (76) exists, a finding that remains unchanged in the 2002 IOM update (53). This conclusion was based in large part on an analysis of birth defects among the offspring of Ranch Hands who reported four neural tube defects among infants, including two cases of spina bifida in infants whose fathers were in the high dioxin exposure group (74). In contrast, no cases of neural tube defects were seen among the Comparison infants. Also in the 2002 update, the IOM concluded that the evidence was inadequate or insufficient to determine whether an association exists between exposure to herbicides used in Vietnam and the following reproductive and developmental outcomes: birth defects other than spina bifida; altered male reproductive hormone concentrations, semen quality, or infertility; spontaneous abortion; stillbirth, neonatal death, or infant death; low birth weight or preterm delivery; altered sex ratio; and childhood cancers (53).

18.1.2 Summary of Previous Analyses of the Air Force Health Study

18.1.2.1 1982 Baseline Examination Summary Results

A laboratory evaluation of the endocrine system was used for analysis in the baseline examination in 1982. Five measures of endocrine status were assessed: T₃ percent uptake, T₄, free thyroxine index (FTI), testosterone, and 2-hour postprandial glucose.

Results showed significant group differences for T₃ percent uptake (abnormally low), predominantly in Ranch Hands 40 years old or younger. The highest percentage of abnormalities was in participants with high body fat. No group difference was noted for elevated 2-hour postprandial glucose values and, as expected, the prevalence of abnormal values was associated with increased age and higher body fat. Lower testosterone values also were associated with increased age and higher body fat. Higher mean testosterone values were significantly more prevalent in the Ranch Hand group. Significant mean shifts were not noted for the T₃ percent uptake, T₄, and the FTI.

18.1.2.2 1985 Follow-up Examination Summary Results

Questionnaire and review-of-systems data for past thyroid disease were similar in both the Ranch Hand and Comparison groups. These historical data were confirmed by a medical records review. Physical examination findings were limited to data from palpation of the thyroid gland and testicles.

Evaluation of the endocrine system was conducted primarily by laboratory testing. The thyroid test battery consisted of T₃ percent uptake and TSH, as determined by radioimmunoassay techniques. Testosterone, initial cortisol, differential cortisol (the difference between the initial and 2-hour cortisol levels), and 2-hour postprandial glucose levels also were analyzed. The T₃ percent uptake data showed no group differences for either mean values or frequency of abnormally low or high values. TSH results revealed a significantly higher mean level in the Ranch Hand group, but this difference was not detected by the discrete analysis of abnormally high TSH results.

Two timed cortisol specimens showed no significant group differences in mean values or the percentage of participants with abnormalities. Differential cortisol showed no significant group differences for non-Blacks or Blacks born before 1942, but Black Ranch Hands born in or after 1942 had a lower mean differential cortisol level than did their Comparisons.

Group means of 2-hour postprandial glucose levels were not statistically different, but analysis of the discrete form of 2-hour postprandial glucose revealed that there was a significantly higher frequency of glucose-impaired Comparisons (at least 140 mg/dL, but less than 200 mg/dL) than Ranch Hands. A variable comprising known diabetics and individuals classified as diabetic by the glucose tolerance test showed no difference between the Ranch Hand and Comparison groups.

18.1.2.3 1987 Follow-up Examination Summary Results

The endocrinology assessment did not disclose any statistically significant differences between the Ranch Hand and Comparison groups. The percentage of participants who indicated problems with current thyroid disease was similar between groups, as were the percentages with thyroid and testicular abnormalities determined by palpation at the physical examination. Ranch Hand and Comparison mean levels were similar for T₃ percent uptake, TSH, FSH, testosterone, and 2-hour postprandial glucose. The percentage of Ranch Hands with abnormal values for these five laboratory variables was higher than the percentage of Comparisons with abnormal values; however, the difference in the percentage of abnormal values between Ranch Hands and Comparisons was not statistically significant for these five laboratory variables. In addition, analyses were performed on a composite diabetes indicator. A participant was considered diabetic for this indicator if he had a verified history of diabetes or had a 2-hour postprandial glucose level of at least 200 mg/dL. The difference in the percentage of Ranch Hands and Comparisons considered diabetic, as determined through this composite diabetes indicator, was not significant.

18.1.2.4 Serum Dioxin Analysis of 1987 Follow-up Examination Summary Results

The endocrinology assessment found a significant positive association between initial dioxin and diabetes prevalence and testes abnormalities. The analyses of dioxin levels in Ranch Hands and Comparisons indicated that the increased risk was apparent for Ranch Hands in the high dioxin category (>33.3 ppt). These Ranch Hands also had significantly higher mean levels of TSH, fasting glucose, and 2-hour postprandial glucose than background Comparisons, as well as lower mean levels of T₃ percent uptake and testosterone. The analyses of these variables in their discrete form found a significant increase in abnormally elevated fasting glucose levels and diabetic 2-hour postprandial glucose levels as both initial dioxin and 1987 dioxin increased. In addition, hemoglobin A1c levels increased as 1987 dioxin levels in Ranch Hands increased.

18.1.2.5 1992 Follow-up Examination Summary Results

The assessment of the endocrine system included an extensive evaluation of thyroid, pancreatic, and gonadal functions and their relation to dioxin. Analyses of thyroid functions did not identify significant differences between Ranch Hands and Comparisons. Similarly, the prevalence of diabetes in the two populations was not significantly different, although significant positive associations were found between time to the onset of diabetes and both lipid-adjusted and whole weight dioxin levels, as measured in 1987.

Significant glucose metabolism results were confined to the dioxin analyses. These results suggested a possible mechanism for dioxin effect on glucose metabolism and the development of diabetes. Diabetic Ranch Hands with high levels of dioxin had significantly higher fasting glucose levels than diabetic Ranch Hands with lower levels of dioxin. Nondiabetic Ranch Hands, on the other hand, exhibited an inverse association between fasting glucose and dioxin and a positive association between 2-hour

postprandial glucose and dioxin. Serum dioxin levels were significantly related to elevated insulin levels in nondiabetic, but not diabetic, Ranch Hands. This was suggestive of a dioxin effect on glucose metabolism with a heightened release of insulin in Ranch Hands with a fully responsive pancreas. When this pancreatic response is no longer effective, elevated glucose levels lead to the clinical diagnosis of diabetes and loss of the dose-response between dioxin and insulin.

Analyses of gonadal functions detected a significant inverse dose-response relation between dioxin and total serum testosterone in Ranch Hands. These results supported those described in the serum dioxin analysis of the 1987 follow-up examination report (77), but the clinical meaning was uncertain.

In conclusion, although the existence of endocrine disorders was comparable in Ranch Hands and Comparisons, the assessment of glucose metabolism showed the possibility of adverse effects from dioxin in relation to glucose intolerance and insulin production.

18.1.2.6 1997 Follow-up Examination Summary Results

The assessment of the endocrine system included an extensive evaluation of thyroid, pancreatic, and gonadal function and their relation to dioxin. A significantly greater percentage of abnormally high TSH values was found in Ranch Hand enlisted groundcrew.

A significant positive association between diabetes and initial and 1987 dioxin was observed. Consistent with previous reports, the prevalence of diabetes for Ranch Hands with high dioxin levels was significantly greater than for Comparisons. A greater percentage of Ranch Hands than Comparisons used insulin to control their Type 2 diabetes, primarily officers and enlisted groundcrew. As initial dioxin levels increased, the percentage of Ranch Hands who required insulin to control their diabetes also increased. A greater percentage of Ranch Hands in the high dioxin category required insulin to control their Type 2 diabetes than did Comparisons. The percentage of participants who treated their diabetes through diet and exercise and the percentage of participants who used oral hypoglycemics increased with 1987 dioxin level.

As initial and 1987 dioxin levels in Ranch Hands increased, both fasting glucose and hemoglobin A1c levels increased, and the time to diabetes onset decreased. The presence of fasting urinary glucose also increased with 1987 dioxin. Increased hemoglobin A1c levels were observed for Ranch Hands in the high dioxin category.

In summary, data from the 1997 AFHS follow-up examination revealed no relation between gonadal disorders and thyroid function and herbicide or dioxin; however, the 1997 follow-up examination results and past results indicated a consistent and potentially meaningful adverse relation between serum dioxin levels and diabetes. A significant dose-response relation was found, where Ranch Hands in the high dioxin category exhibited an increase in diabetes prevalence (relative risk=1.47, 95% confidence interval: [1.00, 2.17]). A dioxin-related increase in severity, a decrease in the time from exposure to first diagnosis, and an increase in fasting glucose and hemoglobin A1c supported this finding. Similar patterns were observed in diabetes and fasting glucose at the 1987 and 1992 follow-up examinations and hemoglobin A1c at the 1992 follow-up examination.

18.1.3 Parameters for the 2002 Endocrinology Assessment

18.1.3.1 Dependent Variables

Questionnaire, physical examination, and laboratory data collected at the AFHS 2002 follow-up examination were used in the endocrinology assessment. The self-reported information collected from the 2002 questionnaire was subsequently verified and analyses were based on the verified data.

18.1.3.1.1 Medical Records Variables

The 2002 questionnaire posed a general screening question on thyroid function and disease. Each participant was asked the following question during the in-person health interview: “Since the date of the last interview, has a doctor told you for the first time that you had thyroid problems?” Medical records review was accomplished to confirm reported problems with thyroid function and to identify any unreported thyroid conditions for each participant that attended the 2002 physical examination. These data from the 2002 physical examination were combined with data from the 1982 baseline examination and the 1985, 1987, 1992, and 1997 follow-up examinations to form a complete history of thyroid disease for each participant. Thyroid disease was classified according to International Classification of Diseases, 9th Revision, Clinical Modification (ICD-9-CM) diagnostic codes. The ICD-9-CM codes for thyroid disease encompassed 240.0-246.9. Based on the verified data, history of thyroid disease was classified as “yes” or “no.” Participants with a pre-SEA history of thyroid disease were excluded from the analysis of thyroid disease history. The analyses performed in this chapter were based on the 1,951 participants who attended the 2002 follow-up examination.

Similar information was asked of each participant regarding diabetes. This information also was verified and combined with previous information. The ICD-9-CM codes for diabetes included 250.00-250.93. Participants verified as diabetics are included in both of the definitions of diabetics below.

Diabetes was defined for the AFHS 2002 follow-up examination using guidelines set forth by the American Diabetes Association (ADA). Under the sponsorship of the ADA, the Expert Committee on the Diagnosis and Classification of Diabetes Mellitus (78) recommended that diabetics be defined as participants with a 2-hour postprandial glucose level of 200 mg/dL or greater on two separate occasions, or a fasting glucose level of 126 mg/dL or greater on two separate occasions, or one 2-hour postprandial glucose level of 200 mg/dL or greater and a fasting glucose level of 126 mg/dL or greater on separate occasions. Participants who met this criterion and participants with a verified history of diabetes were combined and designated as diabetic. This definition is termed “2002 AFHS diabetes definition” in subsequent analyses.

Analyses of the composite diabetes indicator, diabetic control, and time to diabetes onset were also carried out using the definition of diabetes used in previous AFHS examinations. Under this definition, participants with a verified history of diabetes were combined with those participants with a 2-hour postprandial glucose level of 200 mg/dL or greater at the 2002 physical examination and classified as “yes” for a composite diabetes indicator variable. Those participants without a verified history of diabetes and with a 2-hour postprandial glucose level of less than 200 mg/dL at the 2002 physical examination were classified as “no.” Participants classified as “yes” were designated as diabetics and participants classified as “no” were designated as nondiabetics. This definition is termed “pre-2002 AFHS diabetes definition” in subsequent analyses.

As part of the 2002 questionnaire, questions were asked of diabetics regarding the use of insulin, oral diabetes medication, and diet. This self-reported information was verified and a diabetic severity index was constructed and analyzed for all participants. This index was categorized as “requiring insulin,” “oral hypoglycemics,” “diet and exercise,” or “no treatment” for diabetics and “no diabetes” for nondiabetics.

The analysis of diabetic severity index was carried out twice, using both the pre-2002 AFHS diabetes definition and the 2002 AFHS diabetes definition.

A variable that was termed “time to diabetes onset” was analyzed. This variable combined both diabetics and nondiabetics. For diabetics, time to diabetes onset was the number of years between the date of diagnosis of diabetes and the end date of the last qualifying tour of duty in SEA. For nondiabetics, this variable was the number of years between the date of the 2002 follow-up physical examination and the end date of the last qualifying tour of duty in SEA. The “time to diabetes onset” variable was defined in this way to allow statistical analysis using the proportional hazards model, as described in Chapter 7. The analysis of time to diabetes onset was carried out twice, using both the pre-2002 AFHS diabetes definition and the 2002 AFHS diabetes definition.

Participants with a pre-SEA history of diabetes were excluded from the composite diabetes indicator, diabetic control, and time to diabetes onset analyses. Type 1 diabetics would also have been excluded, but all of the diabetics in the AFHS were verified as Type 2 diabetics.

18.1.3.1.2 Physical Examination Variable

The physical examination of endocrine function included manual palpation of the thyroid gland and testes. Thyroid abnormalities consisted of enlarged gland, tenderness, presence of nodules, or a thyroidectomy (ICD-9-CM procedure codes X06.2-X06.6). Testicular abnormalities consisted of atrophied or absent testes because of a post-SEA orchiectomy (orchiectomies were coded as ICD-9-CM procedure codes X62.3-X62.42). Participants with a pre-SEA history of thyroid disease and participants who were currently taking thyroid medication (ICD-9-CM medication codes 68:36.04 and 68:36.08) were excluded from the analysis of the thyroid gland. For the analysis of testicular abnormalities, participants with a pre-SEA orchiectomy or participants with a missing testicle because of an undescended testicle, a congenital absence, or as a result of injury (ICD diagnostic codes 752.51-752.8) were excluded.

18.1.3.1.3 Laboratory Variables

For the AFHS 2002 follow-up examination, 17 laboratory variables were analyzed statistically in the endocrinology assessment for all participants. In addition, diabetics were tested for the presence or absence of islet cell antibodies, but no participant had islet cell antibodies present and further statistical analysis was not conducted.

TSH ($\mu\text{IU/mL}$), T_4 (ng/dL), total testosterone (ng/dL), LH (mIU/mL), and FSH (mIU/mL) were measured using Bayer Centaur[®] equipment. Abbott AXSYM[®] equipment was used to measure estradiol (pg/mL). Anti-thyroid antibodies were analyzed using passive hemagglutination assay. Free testosterone (pg/mL) was conducted by radioimmunoassay.

Measurements for fasting and 2-hour postprandial glucose (mg/dL) were taken using Dade RxL[®] equipment. Analyses for 2-hour postprandial urinary glucose were conducted by dipstick methods using Bayer Atlas[®] equipment. DPC Immulite[®] equipment was used to measure serum insulin (fasting and 2-hour postprandial). The 100-gram glucose load for the postprandial assays was standardized by the use of Glucola[®] and was not given to participants with a verified history of diabetes unless requested by the participant.

Participants classified as “diabetic” under the 2002 AFHS diabetes definition, as described above, and participants who stated that they were diabetic at the time of the 2002 physical examination were tested for hemoglobin A1c (percent), C-peptide (ng/mL), proinsulin (pmol/L), and glutamic acid decarboxylase antibodies (GADA). Bio-Rad Variant[®] equipment was used to measure hemoglobin A1c (percent), and

C-peptide was measured by DPC Immulite[®] equipment. Presence or absence of GADA was determined by radioimmunoassay. Presence or absence of islet cell antibodies was determined by immunofluorescence antibodies. Proinsulin was determined by Associates Regional and University Pathology Lab in Salt Lake City using enzyme immunoassay methods.

All laboratory variables were analyzed in both discrete and continuous forms except for anti-thyroid antibodies, 2-hour postprandial urinary glucose, and GADA. These variables were analyzed as discrete variables only and were categorized as “present” or “absent.”

TSH and insulin (fasting and 2-hour postprandial) were categorized as “abnormally low,” “normal,” and “abnormally high,” based on Scripps laboratory cutpoints. The analysis of 2-hour postprandial glucose, which was performed for nondiabetics only, was coded as “normal” and “impaired.” Those participants without a verified history of diabetes, using the 2002 AFHS diabetes definition, and with a 2-hour postprandial glucose level of at least 140 mg/dL or a fasting glucose level of at least 110 mg/dL at the 2002 physical examination were classified as “impaired.” Those participants without a verified history of diabetes, a 2-hour postprandial glucose level less than 140 mg/dL, and a fasting glucose level of less than 110 mg/dL at the 2002 physical examination were classified as “normal.”

All other laboratory results were dichotomized as “normal” or “abnormal” (abnormally high for all variables, except for free T₄, total testosterone, and free testosterone, which were classified according to abnormally low values). A sparse number of abnormally high values for free T₄, total testosterone, and free testosterone existed.

Participants with a pre-SEA history of thyroid disease, a thyroidectomy, or who took thyroid medication were excluded from the analyses of TSH, free T₄, and anti-thyroid antibodies. For total and free testosterone, estradiol, LH, and FSH, participants with bilateral orchiectomies (pre-SEA or post-SEA) and participants currently taking testosterone medication (ICD-9-CM medication code 68:08) were excluded.

Participants with pre-SEA diabetes were excluded from the analysis of fasting glucose and fasting insulin. Participants who had a verified history of diabetes or participants who stated that they had diabetes at the time of the 2002 physical examination were not tested for 2-hour postprandial glucose, 2-hour postprandial urinary glucose, and 2-hour postprandial insulin, and consequently these participants were excluded from the statistical analyses of these variables. In addition, participants classified as “diabetic” under the ADA criteria described above were excluded from the analyses of 2-hour postprandial glucose, 2-hour postprandial urinary glucose, and 2-hour postprandial insulin. Nondiabetics were excluded from the analysis of hemoglobin A1c, C-peptide, proinsulin, and GADA.

18.1.3.2 Covariates

The endocrinology assessment included the effects of age, race, military occupation, and body mass index (kg/m²) in the adjusted analyses of all variables. Lifetime cigarette smoking history (pack-years), the ratio of the waist measurement to the hip measurement at the 2002 physical examination, and a covariate characterizing family history of diabetes also were included for the diabetes-related variables. The dependent variables included the composite diabetes indicator, diabetic control, time to diabetes onset, fasting and 2-hour postprandial glucose, 2-hour postprandial urinary glucose, fasting and 2-hour postprandial insulin, hemoglobin A1c, C-peptide, proinsulin, and GADA.

Age, race, and military occupation were determined from military records. Body mass index was calculated as weight/(height)², where the weight was measured in kilograms and the height was measured in meters at the physical examination (79). For purposes of covariate associations for discrete dependent variables, body mass index was dichotomized as “not obese” (≤30 kg/m²) and “obese” (>30 kg/m²).

Lifetime cigarette smoking history was based on questionnaire data. For lifetime cigarette smoking history, the respondent's average smoking was estimated over his lifetime based on his responses to the 2002 questionnaire, with 1 pack-year defined as 365 packs of cigarettes smoked during a single year.

A measurement of each participant's hips and waist (in cm) was taken at the 2002 physical examination. This information was used to construct a waist-to-hip ratio that was used as a covariate for diabetes-related dependent variables.

Each participant was asked in the 2002 questionnaire whether anyone in his immediate family ever had diabetes or sugar diabetes. A family history of diabetes covariate was constructed from the responses to this question and used in adjusted analyses of all diabetic-related dependent variables.

18.1.4 Statistical Methods

Table 18-1 summarizes the statistical analysis performed for the 2002 endocrinology assessment. The first part of this table lists the dependent variables analyzed, source of the data, form of the data, cutpoints, covariates, exclusions, and statistical methods. The second part of the table further describes the covariates. A covariate was used in its continuous form whenever possible for all adjusted analyses. If the covariate was inherently discrete (e.g., military occupation), or if a categorized form was needed to develop measures of association with the dependent variables, the covariate was categorized as shown in Table 18-1.

The analysis of time to diabetes onset was based on a proportional hazards model, in which time to onset was modeled as a linear combination of exposure variables and covariates. Instead of mean values, the summary statistic provided was the 10th percentile of the hazard function. Because approximately 20 percent of the participants at the 2002 follow-up examination were diabetic, the 10th percentile is being used to represent an estimate of the approximate median time to diabetes onset. This observed time represents an estimate of the number of years that have elapsed since the end of the last qualifying tour until 10 percent of participants in the cohort of interest were diagnosed as diabetic. Further details on the statistical procedures used for the analysis of time to onset are discussed in Chapter 7, Statistical Methods.

A large number of estradiol measurements below the machine sensitivity limit of 10 pg/mL were present. The measurements above the sensitivity limit exhibited a positively skewed distribution, so a logarithmic transformation was applied to the measurements above the sensitivity limit to achieve an approximate normal distribution. The logarithmic transformation, however, could not be applied to the nonquantified measurements below the sensitivity limit. Consequently, the continuous form of only the estradiol measurements above the sensitivity limit was analyzed. The discrete form of estradiol was analyzed using Scripps laboratory cutpoints, as shown in Table 18-1.

Four models were examined for each dependent variable given in Table 18-1. The analyses of these models are presented below. Further details on dioxin and the modeling strategy are found in Chapters 2 and 7, respectively. These analyses were performed both unadjusted and adjusted for covariates. These covariates are given in Table 18-1. Model 1 examined the relation between the dependent variable and group (i.e., Ranch Hand or Comparison). In this model, exposure was defined as “yes” for Ranch Hands and “no” for Comparisons without regard to the magnitude of the exposure. In an attempt to quantify exposure, three contrasts of Ranch Hands and Comparisons were performed along with the overall Ranch Hand versus Comparison contrast. These three contrasts compared Ranch Hands and Comparisons within each military occupational category (i.e., officers, enlisted flyers, and enlisted groundcrew). As described in previous reports and Table 2-4, the median level of exposure to dioxin was highest for enlisted groundcrew, followed by enlisted flyers, then officers.

During the 1987, 1992, 1997, and 2002 examinations, serum dioxin levels were measured by the CDC using high-resolution gas chromatography and high-resolution mass spectrometry and were reported in parts per trillion (ppt) on a lipid weight basis (80). These dioxin measurements are referred to as “lipid-adjusted.” All measures of dioxin used in this report were based on lipid-adjusted dioxin measurements.

Model 2 examined the relation between the dependent variable and an extrapolated initial dioxin measure for Ranch Hands who had a 1987 dioxin measurement greater than 10 ppt. The initial dioxin was calculated by extrapolating the 1987 dioxin level back in time to the end of the tour of duty that qualified a Ranch Hand veteran for inclusion in this study. If a Ranch Hand did not have a 1987 dioxin level, then the first dioxin measured, either at 1992, 1997, or 2002, was used to estimate the initial dioxin level. Regardless of when the dioxin was measured, Ranch Hand veterans with a level less than or equal to 10 ppt were excluded from statistical analyses based on Model 2. A statistical adjustment for body mass

index at the time of the participant's blood measurement of dioxin was included in this model to account for body mass index-related differences in elimination rate (81).

Model 3 divided the Ranch Hands examined in Model 2 into two categories based on their initial dioxin measures. These two categories were referred to as “low Ranch Hand” and “high Ranch Hand.” Two additional categories—Ranch Hands with serum dioxin levels at or below 10 ppt and Comparisons—were formed and included in the model. Ranch Hands with serum dioxin levels at or below 10 ppt were assigned to the “background Ranch Hand” category. If a Ranch Hand did not have a 1987 dioxin measurement, the first measured dioxin level was used. Another category was examined by combining the low and high Ranch Hand categories. This combination is referred to in the tables as the “low plus high Ranch Hand” category. These five categories—Comparisons, background Ranch Hands, low Ranch Hands, high Ranch Hands, and low plus high Ranch Hands—were used in Model 3 analyses. The relation between the dependent variable in each of the four Ranch Hand categories and the dependent variable in the Comparison category was examined. As in Model 2, a statistical adjustment for body mass index at the time of the participant's blood measurement of dioxin was included in this model for the unadjusted and adjusted analyses of all dependent variables. One Ranch Hand without a dioxin measure was excluded from statistical analyses based on Model 3.

Model 4 examined the relation between the dependent variable and 1987 dioxin levels in all Ranch Hands with a dioxin measurement. If a Ranch Hand did not have a 1987 dioxin measurement, the first dioxin level obtained, either in 1992, 1997, or 2002, was extrapolated to the date of the 1987 physical examination. If the first dioxin level was not obtained in 1987 and was less than or equal to 10 ppt, it was not extrapolated to 1987 level, but was used at the measured value. One Ranch Hand without a dioxin measurement was excluded from statistical analyses based on Model 4.

The term “unadjusted” was used in the text and tables as follows: Models 1 and 4 did not adjust for any covariates. Models 2 and 3 adjusted only for body mass index at the time of the blood measurement for dioxin. The term “adjusted” was used in the text and tables as follows: Models 1 and 4 adjusted for the covariates shown in Table 18-1 unless otherwise specified by a footnote to the table. Models 2 and 3 additionally adjusted only for body mass index at the time of the blood measurement for dioxin.

Table 18-2 provides a summary of the number of participants with missing dependent variable and covariate data. In addition, the number of participants that were excluded from analyses is given.

Table 18-2. Number of Participants Excluded or with Missing Data for the Endocrinology Assessment

Variable	Variable Use	Group ^a		Dioxin (Ranch Hands Only) ^b		Categorized Dioxin ^c

^a777 Ranch Hands and 1,174 Comparisons for group.

^b424 Ranch Hands for initial dioxin; 776 Ranch Hands for 1987 dioxin.

^c776 Ranch Hands and 1,174 Comparisons for categorized dioxin.

^dIncluded 2-hour postprandial glucose, 2-hour postprandial urinary glucose, and 2-hour postprandial insulin. Most participants who were excluded were diabetics.

^eOther components of diabetic assay panel (in addition to hemoglobin A1c) included C-peptide, proinsulin, and GADA. Most participants who were excluded were nondiabetics.

Note: DEP = Dependent variable.

COV = Covariate.

EXC = Exclusion.

18.2 RESULTS

18.2.1 Dependent Variable-covariate Associations

The endocrine dependent variables were tested for associations with each of the covariates used in the adjusted analyses. The complete results are presented in Appendix F, Table F-10. These associations were pairwise between the dependent variable and the covariate and were not adjusted for any other covariates. A brief summary of the pattern of significant ($p \leq 0.05$) dependent variable-covariate associations is described in the following paragraphs.

Older participants had a higher prevalence of diabetes, which necessitated an increase in all forms of treatment for their diabetes. The time to the onset of diabetes also was shorter for older participants. Age was significantly associated with the results of the testicular examination, TSH in its continuous form, and hemoglobin A1c in its continuous form. Older participants had a higher percentage of abnormal testicular examination results. TSH levels increased with age and hemoglobin A1c levels decreased with age. Fasting glucose, 2-hour postprandial glucose, LH, and FSH in both continuous and discrete forms increased with age. Fasting insulin, proinsulin, total testosterone, and free testosterone in their discrete and continuous forms each decreased with age.

A higher percentage of Black participants were classified as diabetic. Race also was significantly associated with diabetic control. Black participants controlled their diabetes with oral hypoglycemics twice as often as non-Black participants. Time to the onset of diabetes also was shorter for Black participants.

Race was associated with the continuous form of TSH, fasting glucose, 2-hour postprandial insulin, hemoglobin A1c, C-peptide, and estradiol. The mean fasting glucose, 2-hour postprandial insulin, hemoglobin A1c, and estradiol values were higher for Blacks than non-Blacks. Non-Black participants had a higher mean TSH and C-peptide value than Black participants. The discrete forms of 2-hour postprandial insulin and C-peptide were also significantly associated with race. Black participants were more likely to have abnormally high 2-hour postprandial insulin values than non-Black participants. Non-Black participants were more than three times as likely to have abnormally high C-peptide values as Black participants.

Officers had higher mean TSH and FSH values than enlisted flyers or enlisted groundcrew. Officers had lower mean fasting glucose, fasting insulin, 2-hour postprandial insulin, hemoglobin A1c, and free testosterone levels than enlisted flyers or enlisted groundcrew. Enlisted flyers had a higher mean 2-hour postprandial glucose value than officers or enlisted groundcrew.

More officers had abnormally low fasting insulin and 2-hour postprandial insulin than enlisted participants. In addition, officers had a greater percentage of high FSH values than enlisted participants. Fewer officers than enlisted flyers and enlisted groundcrew had abnormal results for 2-hour postprandial glucose, 2-hour postprandial urinary glucose, and hemoglobin A1c. Fewer officers were classified as diabetic based on the pre-2002 AFHS diabetes definition than enlisted participants. Enlisted flyers had a smaller percentage of abnormally low free testosterone levels than officers or enlisted groundcrew.

Obese participants had a higher prevalence of diabetes, which required more treatment, and a shorter time to onset more often than participants who were not obese. Body mass index was inversely associated with free T₄, total testosterone, and free testosterone in their continuous and discrete forms. Body mass index was also positively associated with fasting glucose, 2-hour postprandial glucose, fasting insulin, 2-hour postprandial insulin, C-peptide, and proinsulin in their continuous and discrete forms.

The heaviest lifetime cigarette smokers (in terms of pack-years) had the highest prevalence of diabetes and required an increase in all forms of treatment for their diabetes. The time to the onset of diabetes also was shorter for the heaviest lifetime cigarette smokers. Participants who were heavier smokers throughout their lives had the highest prevalence of abnormally high measurements for fasting glucose, 2-hour postprandial insulin, and C-peptide. Fasting glucose, fasting insulin, and C-peptide increased with lifetime cigarette smoking.

The waist-to-hip ratio was positively associated with all diabetic-related variables except hemoglobin A1c and GADA. Participants with larger waist-to-hip ratios had the higher prevalence of diabetes, which required more treatment, and developed diabetes sooner than participants with smaller waist-to-hip ratios. In addition, more participants with waist-to-hip ratios greater than one had abnormally high fasting insulin and 2-hour postprandial insulin levels than participants with waist-to-hip ratios less than or equal to one.

Participants who had a family history of diabetes had a higher prevalence of diabetes than participants who did not have a family history of diabetes. This higher prevalence of diabetes was associated with an increase in all forms of treatment for their diabetes. The time to the onset of diabetes also was shorter for participants who had a family history of diabetes.

Participants with a family history of diabetes had higher mean fasting glucose, 2-hour postprandial glucose, fasting insulin, and 2-hour postprandial insulin values than participants with no family history of diabetes. Higher percentages of abnormally high fasting glucose, fasting insulin, and 2-hour postprandial insulin values were seen among participants with a family history of diabetes than among participants with no family history of diabetes.

18.2.2 Exposure Analysis

The following section presents results of the statistical analyses of the dependent variables shown in Table 18-1. Dependent variables are grouped into three sections: (1) the medical records variables, derived from the questionnaire that was administered in the 2002 follow-up and previous AFHS examinations and verified by a review of medical records, (2) variables obtained during the 2002 physical examination, and (3) laboratory variables.

18.2.2.1 Medical Records Variables

18.2.2.1.1 Past Thyroid Disease

All unadjusted and adjusted analyses of past thyroid disease for Models 1 through 4 were nonsignificant (Table 18-3(a-h): $p > 0.06$ for all analyses).

Table 18-3. Analysis of Past Thyroid Disease

(a) MODEL 1: RANCH HANDS VS. COMPARISONS – UNADJUSTED					
Occupational Category	Group	n	Number (%) Yes	Unadjusted Relative Risk (95% C.I.)	p-Value

18.2.2.1.2 Composite Diabetes Indicator (2002 AFHS Diabetes Definition)

The unadjusted and adjusted Model 1, 2, and 3 analyses of the composite diabetes indicator using the 2002 AFHS diabetes definition did not show any significant results (Table 18-4(a-f): $p > 0.06$ for each analysis). A significant association between 1987 dioxin and the composite diabetes indicator was seen in both the unadjusted and adjusted Model 4 analyses (Table 18-4(g,h): Unadjusted Relative Risk [RR]=1.27, $p < 0.001$; Adjusted RR=1.29, $p = 0.001$). The percentage of diabetic participants in the low, medium, and high 1987 dioxin categories were 9.6, 20.2, and 24.9, respectively.

18.2.2.1.3 Composite Diabetes Indicator (Pre-2002 AFHS Diabetes Definition)

No group differences were seen in the unadjusted and adjusted Model 1 analysis of the composite diabetes indicator using the pre-2002 AFHS diabetes definition (Table 18-5(a,b): p>0.26 for each analysis).

The unadjusted Model 2 analysis revealed no significant association between the composite diabetes indicator and initial dioxin (Table 18-5(c): p=0.286). After adjusting for covariates the results became significant (Table 18-5(d): Adjusted RR=1.34, p=0.010). The percentages of diabetic participants in the low, medium, and high initial dioxin categories were 22.1, 27.5, and 27.0, respectively. Both the unadjusted and adjusted Model 3 analyses of the composite diabetes indicator revealed no significant contrasts (Table 18-5(e,f): p>0.12 for each analysis).

A significant association between 1987 dioxin and the composite diabetes indicator was seen in both the unadjusted and adjusted Model 4 analyses (Table 18-5(g,h): Unadjusted RR=1.24, p<0.001; Adjusted RR=1.27, p=0.001). The percentages of diabetic participants in the low, medium, and high 1987 dioxin categories were 12.3, 22.1, and 27.6, respectively.

18.2.2.1.4 Diabetic Control (2002 AFHS Diabetes Definition)

The unadjusted and adjusted Model 1 analyses of diabetic control, using the 2002 AFHS diabetes definition, were nonsignificant (Table 18-6(a,b): $p>0.16$ for each analysis).

Significant positive relations were seen between initial dioxin and Ranch Hands requiring insulin in both the unadjusted and adjusted Model 2 analyses (Table 18-6(c,d): Unadjusted RR=1.76, $p=0.004$; Adjusted RR=2.78, $p<0.001$). The percentages of Ranch Hands requiring insulin in the low, medium, and high initial dioxin categories were 0.7, 2.1, and 7.1, respectively. The remaining contrasts in the unadjusted and adjusted Model 2 analyses were nonsignificant (Table 18-6(c,d): $p>0.07$ for each contrast).

Among participants requiring insulin to control diabetes, a significant difference between the percentage of Ranch Hands in the high dioxin category and Comparisons was seen in both the unadjusted and adjusted Model 3 analyses (Table 18-6(e,f): Unadjusted RR=2.11, $p=0.037$; Adjusted RR=2.66, $p=0.016$). Ranch Hands in the high dioxin category had a higher percentage of participants requiring insulin than did the Comparisons (5.6 % and 2.5 %, respectively). All other contrasts in both the unadjusted and adjusted Model 3 analyses were nonsignificant (Table 18-6(e,f): $p\geq 0.07$ for each analysis).

The unadjusted and adjusted Model 4 analyses each revealed a significant positive association between 1987 dioxin and the percentage of diabetics who used oral hypoglycemics to treat diabetes (Table 18-6(g,h): Unadjusted RR=1.32, $p<0.001$; Adjusted RR=1.32, $p=0.006$). A positive association between 1987 dioxin and the percentage of diabetics requiring insulin also was observed in both the unadjusted and adjusted Model 4 analyses (Table 18-6(g,h): Unadjusted RR=1.43, $p=0.007$; Adjusted RR=1.53, $p=0.021$). The percentages of Ranch Hands taking oral hypoglycemics in the low, medium, and high 1987 dioxin categories were 3.9, 11.2, and 14.0, respectively. Among Ranch Hands requiring insulin to control diabetes, the percentages in the low, medium, and high 1987 dioxin categories were 1.9, 1.2, and 5.1, respectively. The remaining two contrasts in each of the unadjusted and adjusted Model 4 analyses were nonsignificant (Table 18-6(g,h): $p>0.15$ for each contrast).

18.2.2.1.5 Diabetic Control (Pre-2002 AFHS Diabetes Definition)

The unadjusted and adjusted Model 1 analyses of diabetic control, using the pre-2002 AFHS diabetes definition, revealed no overall group differences between Ranch Hands and Comparisons (Table 18-7(a,b): $p > 0.36$ for each contrast). After stratifying by occupation, however, each of the unadjusted and adjusted Model 1 analyses revealed a significant difference between the percentage of Ranch Hand and Comparison enlisted groundcrew who used no treatment for diabetes (Table 18-7(a,b): Unadjusted $RR = 0.51$, $p = 0.036$; Adjusted $RR = 0.51$, $p = 0.037$). Among Ranch Hand enlisted groundcrew, 4.2 percent used no treatment for diabetes versus 7.8 percent of Comparisons. The remaining contrasts were nonsignificant (Table 18-7(a,b): $p > 0.10$ for each unadjusted and adjusted contrast).

The unadjusted and adjusted Model 2 analyses each revealed a significant positive relation between initial dioxin and Ranch Hands who require insulin to control diabetes (Table 18-7(c,d): Unadjusted $RR = 1.79$, $p = 0.003$; Adjusted $RR = 2.90$, $p < 0.001$). The percentages of Ranch Hands requiring insulin in the low, medium, and high initial dioxin categories were 0.7, 2.1, and 7.1, respectively. All other unadjusted and adjusted Model 2 results were nonsignificant (Table 18-7(c,d): $p > 0.10$ for each contrast).

Among participants requiring insulin to control diabetes, a significant difference between the percentage of Ranch Hands in the high dioxin category and Comparisons was seen in both the unadjusted and adjusted Model 3 analyses (Table 18-7(e,f): Unadjusted $RR = 2.11$, $p = 0.038$; Adjusted $RR = 2.64$, $p = 0.017$). Ranch Hands in the high dioxin category had a higher percentage of participants requiring insulin than did the Comparisons (5.6% and 2.5%, respectively). All other contrasts in both the unadjusted and adjusted Model 3 analyses were nonsignificant (Table 18-7(e,f): $p > 0.16$ for each analysis).

The unadjusted and adjusted Model 4 analyses each revealed a significant positive association between 1987 dioxin and Ranch Hands taking oral hypoglycemics (Table 18-7(g,h): Unadjusted $RR = 1.32$, $p < 0.001$; Adjusted $RR = 1.32$, $p = 0.005$), as well as a significant positive association between 1987 dioxin and Ranch Hands requiring insulin to control diabetes (Table 18-7(g,h): Unadjusted $RR = 1.43$, $p = 0.007$; Adjusted $RR = 1.54$, $p = 0.019$). The percentages of Ranch Hands taking oral hypoglycemics in the low, medium, and high 1987 dioxin categories were 3.9, 11.2, and 14.0, respectively. The percentages of Ranch Hands requiring insulin in the low, medium, and high 1987 dioxin categories were 1.9, 1.2, and 5.1, respectively. The remaining contrasts in the unadjusted and adjusted Model 4 analyses were nonsignificant (Table 18-7(g,h): $p > 0.17$ for each contrast).

Note: Low = ≤7.8 ppt; Medium = >7.8–19.2 ppt; High = >19.2 ppt.

(h) MODEL 4: RANCH HANDS — 1987 DIOXIN — ADJUSTED			
Analysis Results for Log ₂ (1987 Dioxin)			
n	Contrast	Adjusted Relative Risk (95% C.I.) ^a	p-Value
766	No Treatment vs. Nondiabetic	1.17 (0.90,1.52)	0.238
	Diet and Exercise vs. Nondiabetic	0.97 (0.69,1.37)	0.867
	Oral Hypoglycemics vs. Nondiabetic	1.32 (1.09,1.61)	0.005**
	Requiring Insulin vs. Nondiabetic	1.54 (1.07,2.21)	0.019*

^aRelative risk for a twofold increase in 1987 dioxin.

* : Statistically significant (0.010<p-value≤0.050).

** : Statistically significant (p-value≤0.010).

Note: Results were not adjusted for race because of the sparse number of Black Ranch Hands requiring treatment for diabetes.

18.2.2.1.6 Time to Diabetes Onset (2002 AFHS Diabetes Definition)

The time to diabetes onset from time of duty in SEA, using the 2002 AFHS diabetes definition, did not differ significantly between Ranch Hands and Comparisons in the Model 1 unadjusted and adjusted analyses (Table 18-8(a,b): $p>0.26$ for all analyses).

The Model 2 unadjusted and adjusted analyses did not reveal a significant relation between initial dioxin and time to diabetes onset (Table 18-8(c,d): $p>0.05$ for all analyses).

The Model 3 unadjusted and adjusted analyses revealed a significant difference in time to diabetes onset between Ranch Hands in the background dioxin category and Comparisons (Table 18-8(e,f): Unadjusted Hazard Ratio=0.67, $p=0.017$; Adjusted Hazard Ratio=0.69, $p=0.030$, respectively). The time to diabetes onset was significantly longer for Ranch Hands in the background dioxin category than for Comparisons. The 10th percentile for time to diabetes onset was 33.17 years for Ranch Hands in the background category and 28.41 years for Comparisons.

The unadjusted and adjusted Model 4 analyses revealed a significant association between time to diabetes onset and 1987 dioxin (Table 18-8(g,h): Unadjusted Hazard Ratio=1.25, $p<0.001$; Adjusted Hazard Ratio=1.28, $p<0.001$, respectively). In each analysis, the time to diabetes onset was shorter for Ranch Hands with higher 1987 dioxin levels. The 10th percentile of Ranch Hands in the low 1987 dioxin category was 34.42 years compared to 26.75 years for Ranch Hands in the medium dioxin category and 23.67 years for Ranch Hands in the high dioxin category.

18.2.2.1.7 Time to Diabetes Onset (Pre-2002 AFHS Diabetes Definition)

The analyses based on the pre-2002 AFHS diabetes definition yielded very similar results to those attained when using the 2002 AFHS diabetes definition. No significant findings were revealed in both the unadjusted and adjusted analyses of Model 1 (Table 18-9(a,b): $p > 0.12$ for all analyses).

Similarly, the unadjusted analysis of Model 2 did not reveal significant findings in the time to diabetes onset (Table 18-9(c): $p = 0.54$). When adjusted for covariates, a significant relation between initial dioxin and time to diabetes onset was revealed (Table 18-9(d): Adjusted Hazard Ratio=1.21, $p = 0.033$). The time to diabetes onset was significantly shorter for Ranch Hands with higher initial dioxin levels. Ten percent of Ranch Hands in the low initial dioxin category had developed diabetes by 25.75 years after the last qualifying tour of duty compared to 25.91 years for Ranch Hands in the medium dioxin category and 21.58 years for Ranch Hands in the high dioxin category.

Both unadjusted and adjusted analyses of Model 3 revealed significant differences in time to diabetes onset between Ranch Hands in the background dioxin category and Comparisons (Table 18-9(e,f): Unadjusted Hazard Ratio=0.69, $p = 0.016$; Adjusted Hazard Ratio=0.71, $p = 0.030$, respectively). Thus, the time to diabetes onset was significantly longer for Ranch Hands in the background dioxin category (10th percentile of time to diabetes onset: 33.08 years) than for Comparisons (10th percentile of time to diabetes onset: 28.41 years). No other comparisons were significant (Table 18-9(e,f): $p > 0.59$ for all analyses).

The unadjusted and adjusted Model 4 analyses each revealed significant associations between time to diabetes onset and 1987 dioxin (Table 18-9(g,h): Unadjusted Hazard Ratio=1.23, $p < 0.001$; Adjusted Hazard Ratio=1.26, $p < 0.001$, respectively). In both analyses, the time to diabetes onset was shorter for Ranch Hands with higher 1987 dioxin levels. The 10th percentile of Ranch Hands in the low 1987 dioxin category was 33.50 years compared to 26.75 years for Ranch Hands in the medium dioxin category and 23.67 years for Ranch Hands in the high dioxin category.

18.2.2.2 Physical Examination Variables

18.2.2.2.1 Thyroid Gland

The unadjusted and adjusted Model 1 and Model 2 analyses of thyroid gland showed no significant results (Table 18-10(a-d): p>0.06 for each analysis).

The unadjusted Model 3 analysis of the thyroid gland revealed a significant difference between Comparisons and Ranch Hands in the low and high categories combined (Table 18-10(e): p=0.044). Two Ranch Hands (0.5%) in the low and high dioxin categories combined and 24 (2.2%) Comparisons had an abnormal thyroid gland. After adjusting for covariates, no significant results were seen (Table 18-10(f): p>0.30 for each contrast).

The Model 4 unadjusted and adjusted analyses revealed no significant relation between 1987 dioxin and thyroid gland abnormalities (Table 18-10(g,h): p>0.16 for each analysis).

18.2.2.3 Laboratory Variables

18.2.2.3.1 TSH (Continuous)

Both the unadjusted and adjusted Model 1 analyses of TSH in its continuous form showed significant overall group differences (Table 18-12(a,b): difference of means=0.108 μ IU/mL, $p=0.023$; difference of adjusted means=0.096 μ IU/mL, $p=0.024$). The overall adjusted mean TSH values were 1.653 μ IU/mL for Ranch Hands and 1.557 μ IU/mL for Comparisons. After stratifying by military occupation, unadjusted and adjusted analyses revealed group differences within the officer stratum (Table 18-12(a,b): difference of means=0.211 μ IU/mL, $p=0.010$; difference of adjusted means=0.189 μ IU/mL, $p=0.009$). Among officers, Ranch Hands had a higher adjusted mean TSH value than Comparisons (1.778 μ IU/mL and 1.589 μ IU/mL, respectively).

The unadjusted and adjusted Model 2 analyses revealed no significant relation between TSH and initial dioxin (Table 18-12(c,d): $p>0.54$ for each analysis).

Model 3 unadjusted and adjusted analyses each revealed a significant difference in mean TSH levels between Ranch Hands in the background dioxin category and Comparisons (Table 18-12(e,f): difference of means=0.174 μ IU/mL, $p=0.007$, for the unadjusted analysis; difference of adjusted means=0.122 μ IU/mL, $p=0.036$, for adjusted analysis). The adjusted mean TSH level for Ranch Hands in the background dioxin category was 1.682 μ IU/mL versus 1.560 μ IU/mL for the Comparisons.

No significant relation was seen between TSH in its continuous form and 1987 dioxin in either the unadjusted or adjusted Model 4 analyses (Table 18-12(g,h): $p>0.40$ for each analysis).

18.2.2.3.2 TSH (Discrete)

All unadjusted and adjusted analyses of TSH in its discrete form for Models 1 through 4 were nonsignificant (Table 18-13(a-h): $p>0.09$ for each analysis).

(h) MODEL 4: RANCH HANDS – 1987 DIOXIN – ADJUSTED				
Analysis Results for Log ₂ (1987 Dioxin)				
n	Abnormal Low vs. Normal		Abnormal High vs. Normal	
	Adjusted Relative Risk (95% C.I.) ^a	p-Value	Adjusted Relative Risk (95% C.I.) ^a	p-Value
731	2.13 (0.72,6.30)	0.171	0.93 (0.70,1.24)	0.633

^aRelative risk for a twofold increase in 1987 dioxin.

Note: Results were not adjusted for race and military occupation because of the sparse number of Ranch Hands with abnormally low TSH.

18.2.2.3.3 Free T₄ (Continuous)

The Model 1 unadjusted analysis of free T₄ in its continuous form revealed a significant mean difference between Ranch Hands and Comparisons over all military occupations, as well as within the enlisted flyer stratum (Table 18-14(a): difference of means=0.016 ng/dL, p=0.047, overall; difference of means=0.062 ng/dL, p=0.001, for enlisted flyer stratum). The adjusted Model 1 analysis of free T₄ showed no significant overall group differences (Table 18-14(b): p=0.056). After stratifying the adjusted analysis by military occupation, a significant difference between Ranch Hands and Comparisons was seen among enlisted flyers (Table 18-14(b): difference of adjusted means=0.061 ng/dL, p=0.002). A higher adjusted mean free T₄ level was seen among Ranch Hand enlisted flyers (1.115 ng/dL) than among Comparison enlisted flyers (1.054 ng/dL).

All unadjusted and adjusted analyses for free T₄ in Models 2, 3, and 4 were nonsignificant (Table 18-14(c-h): p≥0.09 for each analysis).

18.2.2.3.4 Free T_4 (Discrete)

The unadjusted and adjusted Model 1 analyses of free T_4 in its discrete form revealed no overall group difference (Table 18-15 (a,b): $p>0.37$ for both analyses). After stratifying by military occupation, however, a significant decrease in the percentage of free T_4 abnormalities was seen between Ranch Hands and Comparisons in the enlisted flyer stratum (Table 18-15(a,b): Unadjusted RR=0.37, $p=0.025$; Adjusted RR=0.37, $p=0.026$). Among enlisted flyers, Comparisons had a higher percentage of low free T_4 values than Ranch Hands (13.8 and 5.6, respectively).

No significant associations were seen in the unadjusted and adjusted analyses of free T_4 in Models 2 through 4 (Table 18-15(c-h): $p>0.21$ for each analysis).

18.2.2.3.7 Fasting Glucose (Discrete)

No significant associations were revealed in the unadjusted and adjusted Model 1 through 3 analyses of fasting glucose in its discrete form (Table 18-18(a-f): p>0.16 for each analysis).

The unadjusted Model 4 analysis showed a significant positive relation between fasting glucose in its discrete form and 1987 dioxin (Table 18-18(g): Unadjusted RR=1.12, p=0.032). After covariate adjustment the results became nonsignificant (Table 18-18(h): p=0.729).

18.2.2.3.8 2-hour Postprandial Glucose (Nondiabetics Only) (Continuous)

No overall group differences were revealed in the unadjusted and adjusted Model 1 analyses of 2-hour postprandial glucose in its continuous form for nondiabetic participants (Table 18-19(a,b): $p > 0.45$ for each analysis). After stratifying by military occupation, a significant group difference was revealed among enlisted groundcrew in the unadjusted and adjusted analyses (Table 18-19(a,b): difference of means = -6.7 mg/dL, $p = 0.013$; difference of adjusted means = -7.4 mg/dL, $p = 0.006$). Among the enlisted groundcrew, Ranch Hands had a mean 2-hour postprandial glucose value of 107.4 mg/dL versus 114.8 mg/dL for Comparisons.

All unadjusted and adjusted analyses of 2-hour postprandial glucose in its continuous form were nonsignificant for Models 2 through 4 (Table 18-19(c-h): $p \geq 0.10$ for each analysis).

18.2.2.3.9 2-hour Postprandial Glucose (Nondiabetics Only) (Discrete)

The unadjusted and adjusted Model 1 analyses of 2-hour postprandial glucose in its discrete form on nondiabetic participants revealed no significant group differences (Table 18-20(a,b): $p>0.17$ for each analysis).

A significant association between 2-hour postprandial glucose and initial dioxin was revealed in the unadjusted Model 2 analysis (Table 18-20(c): Unadjusted RR=0.79, $p=0.037$). After adjusting for covariates, however, the results were nonsignificant (Table 18-20(d): $p=0.094$).

No significant associations were seen in the Model 3 and 4 unadjusted and adjusted analyses of 2-hour postprandial glucose (Table 18-20(e-h): $p>0.09$ for each analysis).

18.2.2.3.10 2-hour Postprandial Urinary Glucose (Nondiabetics Only)

The unadjusted Model 1 analysis of 2-hour postprandial urinary glucose on nondiabetic participants showed no group differences (Table 18-21(a): $p \geq 0.07$ for each analysis). Adjusting for covariates in Model 1 showed no overall group differences (Table 18-21(b): $p=0.583$). Stratifying by military occupation, however, revealed a significant difference between Ranch Hands and Comparisons among officers (Table 18-21(b): Adjusted RR=1.48, $p=0.050$). Among officers, Ranch Hands had a higher prevalence of 2-hour postprandial urinary glucose than Comparisons did (23.6% versus 17.7%).

All results for the unadjusted and adjusted analyses of 2-hour postprandial urinary glucose for Models 2 and 3 were nonsignificant (Table 18-21(c-f): $p > 0.50$ for each analysis).

No significant relation was seen between 1987 dioxin and 2-hour postprandial urinary glucose in the unadjusted Model 4 analysis (Table 18-21(g): $p=0.660$). After adjusting for covariates, however, the results became significant (Table 18-21(h): Adjusted RR=0.87, $p=0.040$). The percentages of Ranch Hands with 2-hour postprandial urinary glucose present were 27.9, 25.5, and 28.3 for the low, medium, and high 1987 dioxin categories, respectively.

18.2.2.3.11 Fasting Insulin (Continuous)

The unadjusted and adjusted Model 1 analyses of fasting insulin in its continuous form were nonsignificant (Table 18-22(a,b): $p \geq 0.16$ for each analysis).

Both the unadjusted and adjusted Model 2 analyses revealed significant positive relations between initial dioxin and fasting insulin (Table 18-22(c,d): Slope=0.047, $p=0.030$; Adjusted Slope=0.056, $p=0.014$). The adjusted mean fasting insulin levels in the low, medium, and high initial dioxin categories were 11.84 $\mu\text{IU/mL}$, 11.86 $\mu\text{IU/mL}$, and 13.01 $\mu\text{IU/mL}$, respectively.

The Model 3 unadjusted analysis revealed two significant contrasts: Ranch Hands in the high dioxin category versus Comparisons and Ranch Hands in the low and high dioxin categories combined versus Comparisons (Table 18-22(e): difference of means=1.21 $\mu\text{IU/mL}$, $p=0.009$; difference of means=0.96 $\mu\text{IU/mL}$, $p=0.006$, respectively). After covariate adjustment, all contrasts were nonsignificant (Table 18-22(f): $p > 0.23$ for each contrast).

The unadjusted Model 4 analysis revealed a significant relation between 1987 dioxin and fasting insulin in its continuous form (Table 18-22(g): Slope=0.077, $p < 0.001$). After adjusting for covariates, the results became nonsignificant (Table 18-22(h): $p=0.349$).

18.2.2.3.12 Fasting Insulin (Discrete)

A significant difference in the percentage of participants with abnormally high fasting insulin levels was observed between Ranch Hands and Comparisons in the unadjusted Model 1 analysis (Table 18-23(a): Unadjusted RR=1.45, p=0.046). After adjusting for covariates, the results became nonsignificant (Table 18-23(b): p=0.072). No significant associations were seen in the unadjusted and adjusted analyses after stratifying by military occupation (Table 18-23(a,b): p>0.05 for each analysis).

Both the unadjusted and adjusted Model 2 analysis revealed a significant positive association between initial dioxin and abnormally high fasting insulin levels (Table 18-23(c,d): Unadjusted RR=1.31, p=0.019; Adjusted RR=1.54, p=0.006). The percentages of Ranch Hands with abnormally high fasting insulin levels in the low, medium, and high initial dioxin categories were 6.4, 9.9, and 13.5, respectively.

Two significant contrasts were revealed in the Model 3 unadjusted analysis of abnormally high fasting insulin (Table 18-23(e): Unadjusted RR=1.96, p=0.009 for Ranch Hands in the high dioxin category versus Comparisons; Unadjusted RR=1.67, p=0.018 for Ranch Hands in the low and high dioxin categories combined versus Comparisons). After adjusting for covariates, the results became nonsignificant (Table 18-23(f): p>0.07 for each contrast).

The unadjusted Model 4 analysis revealed a significant inverse association between 1987 dioxin and abnormally low fasting insulin levels, as well as a significant positive association between 1987 dioxin and abnormally high fasting insulin levels (Table 18-23(g): Unadjusted RR=0.76, $p=0.002$; Unadjusted RR=1.34, $p<0.001$, respectively). After covariate adjustment, however, these relations became nonsignificant (Table 18-23(h): $p>0.09$ for each analysis).

18.2.2.3.13 2-hour Postprandial Insulin (Nondiabetics Only) (Continuous)

The unadjusted Model 1 analysis of 2-hour postprandial insulin in its continuous form for nondiabetic participants did not show a significant group difference overall or after stratifying by military occupation (Table 18-24(a): $p\geq 0.09$ for each analysis). After adjusting for covariates, the difference in mean 2-hour postprandial insulin levels between all Ranch Hands and Comparisons was not significant, and no significant difference was seen between Ranch Hands and Comparisons in the officer or enlisted flyer strata (Table 18-24(b): $p>0.34$ for each analysis). A significant difference in mean 2-hour postprandial insulin level was seen, however, between Ranch Hands and Comparisons within the enlisted groundcrew stratum (Table 18-24(b): difference of adjusted means=-7.64 $\mu\text{IU/mL}$, $p=0.033$). Among the enlisted groundcrew, Ranch Hands had a mean 2-hour postprandial insulin level of 61.83 $\mu\text{IU/mL}$ versus 69.47 $\mu\text{IU/mL}$ for Comparisons.

The Model 2 and 3 unadjusted and adjusted analyses of 2-hour postprandial insulin revealed no significant results (Table 18-24(c-f): $p>0.16$ for each analysis).

A significant positive association was revealed between 1987 dioxin and the 2-hour postprandial insulin in the unadjusted Model 4 analysis (Table 18-24(g): Slope=0.058, $p=0.004$). After adjusting for covariates, however, the results became nonsignificant (Table 18-24(h): $p=0.937$).

18.2.2.3.14 2-hour Postprandial Insulin (Nondiabetics Only) (Discrete)

No significant results were revealed in the unadjusted Model 1 analysis of 2-hour postprandial insulin in its discrete form for nondiabetic participants (Table 18-25(a): $p > 0.10$ for each contrast). After covariate adjustment, a significant difference in the percentage of abnormally high 2-hour postprandial insulin levels was seen between Ranch Hands and Comparisons within the enlisted groundcrew stratum (Table 18-25(b): Adjusted RR=0.70, $p=0.043$). Among enlisted groundcrew, the percentage of participants with abnormally high 2-hour postprandial insulin levels was 49.1 percent for Ranch Hands versus 56.2 percent for Comparisons. All other contrasts were nonsignificant in the adjusted analysis (Table 18-25(b): $p > 0.32$ for each contrast).

All results of the unadjusted and adjusted Model 2 and 3 analyses of 2-hour postprandial insulin in its discrete form were nonsignificant (Table 18-25(c-f): $p > 0.11$ for each analysis).

A significant positive relation was seen between 1987 dioxin and abnormally high 2-hour postprandial insulin in the unadjusted Model 4 analysis (Table 18-25(g): Unadjusted RR=1.15, $p=0.009$). After covariate adjustment, however, all contrasts were nonsignificant (Table 18-25(h): $p > 0.66$ for each contrast).

18.2.2.3.15 Hemoglobin A1c (Diabetics Only) (Continuous)

No significant differences in mean hemoglobin A1c values in diabetic participants were seen between exposure groups in Model 1 unadjusted and adjusted analyses (Table 18-26(a,b): $p > 0.45$ for each analysis).

The unadjusted Model 2 analysis revealed a significant positive association between initial dioxin and hemoglobin A1c in its continuous form (Table 18-26(c): Slope=0.032, $p=0.014$). After adjusting for covariates, the results were no longer significant (Table 18-26(d): $p=0.358$). The unadjusted and adjusted Model 3 analyses revealed no significant contrasts (Table 18-26(e,f): $p > 0.23$ for each analysis).

A significant positive relation was seen between 1987 dioxin and hemoglobin A1c in the unadjusted Model 4 analysis (Table 18-26(g): Slope=0.023, $p=0.023$). After adjusting for covariates, however, the results became nonsignificant (Table 18-26(h): $p=0.095$).

18.2.2.3.16 Hemoglobin A1c (Diabetics Only) (Discrete)

Both the unadjusted and adjusted Model 1 analyses of hemoglobin A1c in its discrete form showed no significant group differences for diabetic participants (Table 18-27(a,b): p>0.50 for each analysis).

A significant positive association was seen between initial dioxin and hemoglobin A1c in the unadjusted Model 2 analysis (Table 18-27(c): Unadjusted RR=1.51, p=0.017). After adjusting for covariates, the results were no longer significant (Table 18-27(d): p=0.060).

No significant associations between hemoglobin A1c and categorized dioxin were revealed in the unadjusted and adjusted Model 3 analyses (Table 18-27(e,f): p>0.12 for each contrast).

The unadjusted and adjusted Model 4 analyses each showed a significant positive relation between 1987 dioxin and hemoglobin A1c in its discrete form (Table 18-27(g): Unadjusted RR=1.38, p=0.005; Adjusted RR=1.35, p=0.031). The percentages of participants with abnormally high hemoglobin A1c values in the low, medium, and high 1987 dioxin categories were 48.0, 62.0, and 73.4, respectively.

18.2.2.3.25 Free Testosterone (Discrete)

No significant overall group difference was seen in the unadjusted and adjusted Model 1 analyses of categorized free testosterone (Table 18-36(a,b): $p > 0.43$ for each analysis). After stratifying by military occupation, however, a significant difference between Ranch Hands and Comparisons was seen among officers in both the unadjusted and adjusted analyses (Table 18-36(a,b): Unadjusted RR=1.92, $p=0.025$; Adjusted RR=1.87, $p=0.039$). Among officers, Ranch Hands had a higher percentage of abnormally low free testosterone values (9.2%) versus Comparisons (5.0%).

No significant relations were seen in the unadjusted and adjusted Model 2 through 4 analyses of free testosterone in its discrete form (Table 18-36(c-h): $p > 0.09$ for each analysis).

Table 18-36. Analysis of Free Testosterone (Discrete)

^aRelative risk for a twofold increase in 1987 dioxin.

18.2.2.3.28 LH (Continuous)

The unadjusted and adjusted Model 1 analyses of LH in its continuous form showed no group differences among all participants (Table 18-39(a,b): $p > 0.11$ for each analysis). After stratifying by military occupation, however, a significant difference between Ranch Hands and Comparisons was seen among officers in both the unadjusted and adjusted analyses (Table 18-39(a,b): difference of means=0.46 mIU/mL, $p=0.034$; difference of adjusted means=0.40 mIU/mL, $p=0.040$). Ranch Hand officers had a higher adjusted mean LH value (4.49 mIU/mL) than Comparison officers (4.09 mIU/mL).

A significant inverse association was revealed between initial dioxin and LH in the unadjusted Model 2 analysis (Table 18-39(c): Slope=-0.051, $p=0.020$). After covariate adjustment, the results were no longer significant (Table 18-39(d): $p=0.217$).

Both the unadjusted and adjusted Model 3 analyses revealed a significant difference in mean LH levels between Ranch Hands in the low dioxin category and Comparisons (Table 18-39(e,f): difference of means=0.61 mIU/mL, $p=0.006$, for unadjusted analysis; difference of adjusted means=0.51 mIU/mL, $p=0.015$, for adjusted analysis). Ranch Hands in the low dioxin category had an adjusted mean LH value of 4.81 mIU/mL versus 4.30 mIU/mL for Comparisons.

The unadjusted and adjusted Model 4 analyses showed no significant associations between 1987 dioxin and LH in its continuous form (Table 18-39(g,h): $p > 0.05$ for each analysis).

Table 18-39. Analysis of LH (mIU/mL) (Continuous)

18.2.2.3.30 FSH (Continuous)

The unadjusted Model 1 analysis of FSH in its continuous form showed no significant group differences (Table 18-41(a): p=0.562). After stratifying by occupation, a significant difference between Ranch Hands and Comparisons was seen among officers (Table 18-41(a): difference of means=0.63 mIU/mL, p=0.043). In the adjusted Model 1 analyses of FSH, however, no significant group differences were noted among all participants or within each military occupation (Table 18-41(b): p>0.05 for each analysis).

A significant inverse association between initial dioxin and FSH in its continuous form was seen in the unadjusted Model 2 analysis (Table 18-41(c): Slope=-0.061, p=0.011). After covariate adjustment, the results were no longer significant (Table 18-41(d): p=0.267).

The unadjusted Model 3 analysis revealed a significant difference in mean FSH levels between Ranch Hands in the low dioxin category and Comparisons (Table 18-41(e): difference of means=0.72 mIU/mL, p=0.019). After adjusting for covariates, the results were nonsignificant (Table 18-41(f): p>0.06 for each contrast).

No significant associations between 1987 dioxin and FSH in its continuous form were revealed in the unadjusted and adjusted Model 4 analyses (Table 18-41(g,h): p>0.30 for each analysis).

18.3 DISCUSSION

As part of the endocrinology assessment, Ranch Hands and Comparisons were evaluated for thyroid disease, diabetes, and testosterone and other sex hormone levels. Particular attention was given to the possible effects that herbicides and dioxin could have had on the pituitary, gonadal, and thyroid glands, as well as the possible relation between herbicide exposure or dioxin levels and diabetes and insulin resistance.

Using standard diabetes definitions employed in this study (82) and based on estimates from the CDC, the prevalence of diabetes mellitus in U.S. adults aged 45 to 64 increased from approximately 6 percent to 9 percent between 1997 and 2002 (83). The most likely factor driving this increase is the steadily rising prevalence of obesity. According to the CDC, the percentage of overweight Americans rose from 51 percent to 64 percent during the same time span (83). Because both gonadal functions and diabetes are strikingly affected by obesity, as well as aging, it is important to correct for possible effects of increasing body weight and aging when trying to isolate the potential effects herbicides and dioxin has on the human body.

A review of the dependent variable-covariate associations showed findings that were consistent with existing literature on Type 2 diabetes. Mokdad and colleagues conducted a study in 2001 and concluded that there was a correlation of increasing diabetes risk and severity with increasing age, adiposity, a family history of diabetes, and non-Caucasian race (83). Likewise, the significant decline in total testosterone with increasing age is consistent with the current literature. A decline in total testosterone is usually not accompanied by an increase in LH, and no association was present between total testosterone and LH in these data. No unusual patterns were seen as compared to age-matched populations already studied (84).

For a statistically significant finding to be physiologically or clinically significant, the finding should be consistent with physiology, have some consistency with known data regarding clinically significant findings and, ideally, be reproducible in more than one statistical model. Only the diabetes data seem to fulfill each of these criteria. The known associations of Type 2 diabetes with obesity and insulin resistance fit the model analysis and were consistent across two or more model assessments, with a dose-response effect evident regarding prevalence and severity of diabetes. For the thyroid and gonadal findings, generally only one model was significant and no positive dose-response relation was seen. These considerations and the small differences in means in the thyroid and gonadal measures make a clinically significant finding very unlikely.

As indicated in the 1997 follow-up examination and again in the 2002 examination, significant associations exist between dioxin levels and diabetes. A greater prevalence of diabetes, diabetes of greater severity (as evidenced by the need for more medication and higher hemoglobin A1c levels), and a shorter time to onset of diabetes were seen more often in Ranch Hands as 1987 dioxin levels increased. The association between 1987 dioxin and diabetes was similar regardless of whether the participant was obese. The mechanism for the increase in diabetes is not clear. In animals exposed to 100 mg/kg of dioxin, a reduction in insulin levels relative to glucose was seen (25), suggesting a possible direct pancreatic effect. In the 2002 follow-up examination, however, a statistically higher fasting insulin level that was more consistent with increased insulin resistance was seen in Ranch Hand participants. Insulin resistance is a near universal finding in Type 2 diabetes mellitus, but it is also found in about 25 percent of the U.S. population and about 45 percent in subjects aged 60 and higher based on clinical criteria (85). No difference was seen in the prevalence of GADA, a marker of Type 1 diabetes. These results are most compatible with an “unmasking” or acceleration of Type 2 diabetes, possibly by worsening insulin resistance. This could be explained by a direct effect of dioxin or by a slightly accelerating rate of weight gain in this group of individuals. Some effect on insulin release cannot be excluded based on these data.

As for a dioxin effect related to thyroid disease, the 2002 examination data did not support such a relation. No differences of the thyroid or in anti-thyroid antibodies were observed during the 2002 physical examination. Although statistically significant, the difference in adjusted mean TSH (mean of 1.653 μ IU/mL in Ranch Hands versus 1.557 μ IU/mL in Comparisons) was not considered clinically significant. The same was true for the free T₄ values in enlisted flyers (mean of 1.115 ng/dL in Ranch Hands versus 1.054 ng/dL in Comparisons). If a primary thyroid effect were present, one would expect the TSH to

move in the opposite direction of the free T_4 , which was not seen in these data. There may be, however, other mechanisms of action.

A similar conclusion may be drawn regarding reproductive hormones. SHBG is known to rise with increasing age and adiposity. In the Massachusetts Male Aging Study of healthy men aged 40 to 70, total testosterone was seen to fall at a rate of 0.8 percent per year and free testosterone at 2 percent per year (84). The difference in adjusted free testosterone means in Ranch Hands versus Comparisons was 10.95 versus 10.47, respectively. The LH means for Ranch Hand and Comparison officers were 4.49 mIU/mL versus 4.09 mIU/mL, respectively. Both were well within one standard deviation of normal-age matched populations. No evidence of a dose-response effect was seen based on categorized dioxin or 1987 dioxin levels.

In summary, the association noted at previous AFHS examinations between Type 2 diabetes mellitus and dioxin persisted. A higher prevalence of diabetes, as well as severity, as dioxin increased was evident, even after adjustment for such factors as age and body mass index. In contrast, the association of dioxin with thyroid or gonadal abnormalities appeared weak at best and unlikely to be clinically significant.

18.4 SUMMARY

The endocrinology assessment was based on questionnaire, physical examination, and laboratory data. Associations with herbicide exposure (i.e., group – Model 1), initial dioxin (Model 2), categorized dioxin (Model 3), and 1987 dioxin levels (Model 4) were examined for each variable in the endocrinology assessment. The significant adjusted results are discussed in the sections below.

18.4.1 Model 1: Group Analysis

Ranch Hands had a significantly higher mean TSH value than Comparisons when examined across all participants and within officers. A significant difference between Ranch Hands and Comparisons was seen among officers in the analysis of LH in its continuous form, as well as in the analyses of 2-hour postprandial urinary glucose and free testosterone in their discrete form. In each case, Ranch Hand officers had a higher mean value or percent abnormal than Comparison officers.

Comparison enlisted flyers had a lower mean free T_4 value and a greater percentage of abnormally low values than Ranch Hand enlisted flyers. When diabetes was classified using the pre-2002 AFHS definition, a significantly higher percentage of Comparison enlisted groundcrew used nothing to treat their diabetes compared to Ranch Hand enlisted groundcrew. Among enlisted groundcrew, Ranch Hands had significantly lower mean 2-hour postprandial glucose and 2-hour postprandial insulin levels than Comparisons. Ranch Hand enlisted groundcrew also had fewer abnormally high 2-hour postprandial insulin values than Comparison enlisted groundcrew.

The results of the group analysis are shown in Table 18-43.

^aA hazard ratio was used. A hazard ratio greater than 1.0 implied a shorter time to the onset of diabetes for Ranch Hands than for Comparisons. A hazard ratio less than 1.0 implied a longer time to the onset of diabetes for Ranch Hands than for Comparisons.

^bA negative difference in means (Ranch Hand mean less than Comparison mean) was considered adverse for this variable.

Note: NS or ns: Not significant ($p>0.05$).

C: Continuous form of dependent variable.

D: Discrete form of dependent variable.

The p-value was given if $p\leq 0.05$. The relative risk was given in parentheses for a significant result from the analysis of a discrete dependent variable. The difference in means was given in parentheses for a significant result from the analysis of a continuous dependent variable.

A capital “NS” denotes a nonsignificant positive association. A lowercase “ns” denotes a nonsignificant inverse association.

^bA negative difference in means (Ranch Hand mean less than Comparison mean) was considered adverse for this variable.

--: Analysis was not performed because of the sparse number of participants with an abnormality.

Note: NS or ns: Not significant (p>0.05).

C: Continuous form of dependent variable.

D: Discrete form of dependent variable.

The p-value was given if p≤0.05. The relative risk was given in parentheses for a significant result from the analysis of a discrete dependent variable. The difference in means was given in parentheses for a significant result from the analysis of a continuous dependent variable.

A capital “NS” denotes a nonsignificant positive association. A lowercase “ns” denotes a nonsignificant inverse association.

18.4.2 Model 2: Initial Dioxin Analysis

The adjusted Model 2 analyses revealed a significant positive association between diabetes and initial dioxin when using the pre-2002 AFHS definition. In addition, time to diabetes onset decreased as the initial dioxin level increased when using the pre-2002 AFHS definition. Significant positive relations were seen between initial dioxin and Ranch Hands requiring insulin to control diabetes. A significant positive association was seen between initial dioxin and fasting insulin in both its continuous and discrete form. A significant inverse association was seen between C-peptide in its continuous form and initial dioxin. The results of all unadjusted and adjusted Model 2 analyses are summarized in Table 18-44.

^aA hazard ratio was used. A hazard ratio greater than 1.0 implies that onset of diabetes becomes shorter as initial dioxin increases. A hazard ratio less than 1.0 implies that onset of diabetes becomes longer as initial dioxin increases.

^bA negative slope was considered adverse for this variable.

Note: NS or ns: Not significant ($p > 0.05$).

C: Continuous form of dependent variable.

D: Discrete form of dependent variable.

The p-value was given if $p \leq 0.05$. The relative risk was given in parentheses for a significant result from the analysis of a discrete dependent variable. The slope was given in parentheses for a significant result from the analysis of a continuous dependent variable.

A capital “NS” denotes a nonsignificant positive association. A lowercase “ns” denotes a nonsignificant inverse association.

18.4.3 Model 3: Categorized Dioxin Analysis

The adjusted Model 3 analysis revealed significantly higher mean TSH values and a longer time to develop diabetes among Ranch Hands in the background dioxin category than among Comparisons. Ranch Hands in the low dioxin category displayed a significantly higher mean LH value than Comparisons. More Ranch Hands in the high dioxin category required insulin to control diabetes than Comparisons. The results of all unadjusted and adjusted Model 3 analyses are summarized in Table 18-45.

^bA negative difference in means (Ranch Hand mean less than Comparison mean) was considered adverse for this variable.

--: Analysis was not performed because of the sparse number of participants with an abnormality.

Note: NS or ns: Not significant ($p > 0.05$).

C: Continuous form of dependent variable.

D: Discrete form of dependent variable.

The p-value was given if $p \leq 0.05$. The relative risk was given in parentheses for a significant result from the analysis of a discrete dependent variable. The difference in means was given in parentheses for a significant result from the analysis of a continuous dependent variable.

A capital "NS" denotes a nonsignificant positive association. A lowercase "ns" denotes a nonsignificant inverse association.

18.4.4 Model 4: 1987 Dioxin Level Analysis

The Model 4 analyses showed a significant positive association between 1987 dioxin and diabetes. A significant positive association between 1987 dioxin and the percentage of Ranch Hands taking oral hypoglycemics was seen, as was a significant positive association between 1987 dioxin and the percentage of Ranch Hands requiring insulin to control diabetes. Time to diabetes onset decreased as 1987 dioxin level increased. The prevalence of 2-hour postprandial urinary glucose decreased as the 1987 dioxin level increased. The percentage of abnormally high hemoglobin A1c values increased as the 1987 dioxin level increased. All results for Model 4 unadjusted and adjusted analyses are summarized in Table 18-46.

^aA hazard ratio was used. A hazard ratio greater than 1.0 implies that onset of diabetes becomes shorter as 1987 dioxin increases. A hazard ratio less than 1.0 implies that onset of diabetes becomes longer as 1987 dioxin increases.

^bA negative slope was considered adverse for this variable.

Note: NS or ns: Not significant (p>0.05).

C: Continuous form of dependent variable.

D: Discrete form of dependent variable.

The p-value was given if p≤0.05. The relative risk was given in parentheses for a significant result from the analysis of a discrete dependent variable. The slope was given in parentheses for a significant result from the analysis of a continuous dependent variable.

A capital “NS” denotes a nonsignificant positive association. A lowercase “ns” denotes a nonsignificant inverse association.

18.4.5 Summary of Significant Results

Table 18-47 summarizes the significant results ($p \leq 0.05$) for the adjusted analyses that were performed for the endocrinology assessment. The dependent variable and its table reference are listed along with the model and the contrast or description of the model. The p-value is provided along with analysis statistics that correspond to the type of analysis that was performed (either continuous or discrete). A description of the analysis and the statistics that are presented is referenced under the “Note” column and is explained in footnotes.

Table 18-47. Summary of Results from Significant Adjusted Analyses in the Endocrinology Assessment

Dependent Variable (Table Reference)	Model	Contrast or Description	p-Value	Analysis Statistics	Adjusted Mean or Percent Abnormal	Note

- (a): Discrete variable: adjusted relative risk and 95% confidence interval were presented for a twofold increase in 1987 dioxin; percent abnormal was presented for each of three 1987 dioxin categories.
- (b): Discrete variable: adjusted relative risk and 95% confidence interval were presented for a twofold increase in initial dioxin; percent abnormal was presented for each of three initial dioxin categories.
- (c): Discrete variable: adjusted relative risk and 95% confidence interval were presented; percent abnormal was presented for each dioxin category in contrast.
- (d): Discrete variable: adjusted relative risk and 95% confidence interval were presented; percent abnormal was presented for each exposure group in contrast.
- (e): Continuous variable: adjusted hazard ratio and 95% confidence interval were presented; 10th percentile of distribution of time to onset of diabetes was presented for each dioxin category in contrast.
- (f): Continuous variable: adjusted hazard ratio and 95% confidence interval were presented for a twofold increase in 1987 dioxin; 10th percentile of distribution of time to onset of diabetes was presented for each of three 1987 dioxin categories.
- (g): Continuous variable: adjusted hazard ratio and 95% confidence interval were presented for a twofold increase in initial dioxin; 10th percentile of distribution of time to onset of diabetes was presented for each of three initial dioxin categories.

Table 18-47. Summary of Results from Significant Adjusted Analyses in the Endocrinology Assessment (Continued)

- (h): Continuous variable: difference of adjusted means was presented; confidence interval was not presented because analysis was not performed on original scale; adjusted means were presented for each exposure group in contrast.
- (i): Continuous variable: difference of adjusted means was presented; confidence interval was not presented because analysis was not performed on original scale; adjusted means were presented for each dioxin category in contrast.
- (j): Continuous variable: slope and standard error were presented and were based on natural logarithm of dependent variable versus \log_2 (initial dioxin); adjusted means were presented for each of three initial dioxin categories.

^aA smaller group mean or decreasing mean time to onset values as dioxin increased was considered adverse for this variable.

^bA positive difference in means (Comparison mean less than Ranch Hand mean) was considered adverse to Comparisons for this variable.

Note: RH = Ranch Hand.
C = Comparison.

Model 2: Low = 32–79 ppt; Medium = >79–199 ppt; High = >199 ppt (Ranch Hands who had a 1987 dioxin measurement greater than 10 ppt).

Model 3: Background (Ranch Hand): 1987 dioxin \leq 10 ppt.
Low (Ranch Hand): 1987 dioxin > 10 ppt, 10 ppt < initial dioxin \leq 118 ppt.
High (Ranch Hand): 1987 dioxin > 10 ppt, initial dioxin > 118 ppt.

Model 4: Low = \leq 7.8 ppt; Medium = >7.8–19.2 ppt; High = >19.2 ppt (Ranch Hands only).

18.5 CONCLUSION

A number of significant adverse associations were found between dioxin levels and diabetes, glucose, insulin, gonadotropins, and thyroid hormones. These were not specific to a particular statistical model or to the form of the outcome variable (continuous or discrete) and are summarized below by statistical model.

With regard to group contrasts, Ranch Hands had a significantly higher mean TSH than Comparisons, primarily due to a significantly increased mean among Ranch Hand officers. Ranch Hand officers also exhibited a significantly increased mean LH, a significantly increased risk of abnormal 2-hour postprandial urinary glucose, and abnormal free testosterone.

Analyses using the extrapolated initial dioxin level found that mean fasting insulin and the risk of diabetes requiring insulin control increased significantly with initial dioxin. C-peptide and time to diabetes onset decreased as initial dioxin increased.

Analyses based on dioxin category found that the risk of diabetes requiring insulin control was significantly increased in the high dioxin category.

Analyses based on the 1987 dioxin level revealed an increase in the risk of diabetes requiring oral hypoglycemic or insulin control as 1987 dioxin levels increased. Time to diabetes onset decreased as 1987 dioxin levels increased. The risk of an abnormally high hemoglobin A1c increased with 1987 dioxin levels.

Some findings appeared to conflict with these, such as a decrease in the risk of 2-hour postprandial urinary glucose abnormalities with 1987 dioxin levels.

In summary, these findings appear consistent with the previously noted association between Type 2 diabetes and dioxin in Ranch Hand veterans. Increased risks of diabetes requiring insulin control were found with initial dioxin, in the high dioxin category, and with 1987 dioxin levels. In contrast, associations between dioxin levels and thyroid or gonadal hormone abnormalities were unlikely to be clinically important.

19 IMMUNOLOGY ASSESSMENT

19.1 INTRODUCTION

19.1.1 Background

19.1.1.1 Organs/Disease

The immune system includes major organs and tissues such as the thymus, spleen, skin, lymphatic system, and bone marrow, as well as cellular components such as white blood cells (WBCs), antibodies, the complement system, and hormone-like substances called cytokines. All WBCs are leukocytes, which arise from the stem cells of the bone marrow. Leukocytes are further subdivided into granulocytes, lymphocytes, and monocytes. Lymphocytes that mature in bone marrow are called B cells, while lymphocytes that mature in the thymus are called T cells. When stimulated, B cells mature into plasma cells, the cells that produce antibodies. Antibodies, or immunoglobulins, fall into one of five classes: IgA, IgD, IgE, IgG, and IgM. Complement refers to serum proteins that are released sequentially in response to infection (the “complement cascade”). Finally, cytokines include lymphokines, interleukins, interferon, and tumor necrosis factor.

T cells are divided into various sets and subsets, defined by cell surface markers that react with monoclonal antibodies that are grouped according to clusters of differentiation (CD) (1). To some extent, CD groupings describe cell function as well. For example, T cells that express CD3 and CD4 surface molecules describe helper T cells, while T cells that express CD3 and CD8 surface molecules are suppressor T cells (1).

There are two types of adaptive immunity responses: humoral immunity, or the production of circulating antibodies in response to an antigen and mediated by B lymphocytes, and cell-mediated immunity, the production of cytotoxic T cells, activated macrophages, activated natural killer cells, and cytokines in response to an antigen.

Ranch Hand and Comparison veterans were evaluated for immunologic function using cell surface marker studies, absolute lymphocytes, quantitative immunoglobulins, and a lupus panel. The lupus panel detects autoantibodies for various autoimmune disorders, such as systemic lupus erythematosus, rheumatoid arthritis, autoimmune thyroiditis, and autoimmune liver diseases, including chronic active hepatitis and primary biliary cirrhosis.

19.1.1.2 Toxicology

Since the early 1970s, when 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD or dioxin) was shown to cause marked involution of the thymus gland in experimental animals, the immune system has been recognized as a sensitive target of dioxin exposure (2-5). Numerous animal studies have demonstrated that exposure to dioxin increases host susceptibility to a broad range of bacterial (6-11), parasitic (12), and viral (13-16) infectious agents. The extensive body of literature pertinent to dioxin-induced immunotoxicity has been summarized in several review articles (17-23).

Toxic effects of dioxin exposure in laboratory animals have been demonstrated on all components of the immune system, including direct thymotoxic effects, particularly on the epithelial cells (19, 24-27); compromised cell mediated (2, 26, 28-31) and humoral (2, 6, 30, 32-36) immune function; impaired

myeloproliferative (7, 37-40) and lymphoproliferative (26, 38-40) responses; and suppressed complement activity (8, 41-43).

The role of the aryl hydrocarbon (Ah) receptor as a mediator in dioxin toxicity has been long recognized (44, 45) and summarized in several literature reviews (23, 46-48). Much of the basic research in laboratory animals has focused on the role of the Ah receptor in dioxin-induced immunotoxicity, including suppressed humoral (32, 34, 49-55) and cellular (55-58) responses and impaired complement activity in mice (59), but not guinea pigs (60). Other studies demonstrated that dioxin exposure can cause immune system responses independent of the Ah receptor (50, 51, 53, 61-63). Primate experiments of the effects of dioxin on peripheral lymphocyte subpopulations in marmoset (63-67) and rhesus (68) monkeys found the ratios of selected lymphocyte subsets varied inconsistently in response to the dose (high versus low) and duration (acute versus chronic) of exposure. In none of the *in vivo* studies did the animals demonstrate any overt illness. The Ah receptor has been identified in several human tissues (46, 69-71), and research continues regarding the relevance of these observations to dioxin toxicity in humans.

The demonstration that human tonsils contain the Ah receptor (70) and the development of a tonsillar lymphocyte culture model have established a scientifically valid basis for comparison of the effects of dioxin on experimental animals and humans at the cellular level. In published results from two series of experiments, dioxin had identical effects on both human and murine B lymphocytes with dose-dependent suppression of cellular proliferation and a significant reduction in the secretion of immunoglobulins IgM and IgG (72, 73). Although the mechanism of action is unknown, these experiments provide evidence that the human lymphocyte is sensitive to dioxin, and are consistent with results from another laboratory investigating the effect of dioxin on human lymphocytes isolated from peripheral blood (74). These experimental models have been applied to human populations exposed to dioxin (75, 76).

19.1.1.3 Epidemiology

Indicators of immune function have been included in epidemiologic studies of populations exposed to dioxin as a result of environmental contamination (77-86), industrial accidents (87-96), occupational exposure (75, 76, 97-105), and military service in Vietnam (106-113).

Several studies have been conducted that included immunological measures of Missouri residents exposed to dioxin, although there was no evidence for clinical illness among those exposed. Reports of Quail Run, Missouri, residents of a mobile home park with dioxin levels up to 2,200 parts per billion in the soil documented abnormalities in several indices of immune function, including reduced delayed-type hypersensitivity to skin test antigens; significantly lower percentages of CD3, CD4, and CD2 cells; and nonsignificantly decreased CD4 to CD8 ratios in dioxin-exposed persons (77-79). Follow-up examinations found no significant differences in response to delayed-type hypersensitivity skin tests between the exposed and control cohorts, but the mean CD4 to CD8 ratios remained lower in the exposed group (80). No dioxin measurements were made in the exposed populations.

Webb and colleagues conducted a pilot study of health effects associated with dioxin among residents living in the Times Beach, Missouri, area and found no significant differences between high risk and low risk groups in delayed hypersensitivity skin test response, lymphocyte proliferation response, or in a comparison of T-cell subsets (84). A nonsignificant decrease in CD4 to CD8 ratios was seen among high-risk individuals. Follow-up studies measured dioxin levels in adipose tissue among a subset of the high risk group and found significant increases in several immunological indicators associated with dioxin levels in adipose tissue, as well as nonsignificant increases in serum IgA (84, 85).

In a 2002 study of residents of Seveso, Italy, who were exposed to high levels of dioxin from an industrial accident, plasma IgG levels decreased significantly with increasing dioxin plasma concentration (94). No consistent association was seen between dioxin levels and IgM, IgA, and C3 and C4 complement plasma levels. Reports published after the 1976 chemical explosion found no immune system abnormalities in exposed children (87, 88) or cleanup workers (90). Other investigators documented abnormal immune indices in children with chloracne (89, 91) that resolved with time and were not associated with any clinical immune deficiency illness (92, 93). The antinuclear antibody (ANA), immune complexes, and the number of natural killer cells (monoclonal antibody Leu-7) were significantly increased in a cohort of chemical workers exposed to dioxin in an industrial accident in England in 1968 (96); however, these abnormalities were not associated with any clinical illness (95, 96).

Epidemiologic studies have reported results of clinical examinations of workers who experienced significant occupational exposure to dioxin during employment at chemical factories in Germany (75, 76, 97-103) and the United States (104). The studies incorporated immune system parameters in the examination protocols and included serum dioxin data in the analyses, except for one study using insurance claims data that showed an increase in infectious and parasitic diseases among a subgroup of employees with severe chloracne (97). Ott and colleagues reported positive associations between dioxin and increases in IgA and IgG concentrations, marginal increases in complement, and slight decreases in the percentage of lymphocytes (99). Halperin and colleagues found decreased circulating activated T cells and decreased spontaneous proliferation of cultured lymphocytes with higher levels of dioxin (104). None of these studies of occupationally exposed workers showed any evidence of clinical illness associated with immune system disorders among the exposed or any gross abnormalities in the laboratory indices in relation to the body burden of dioxin. In addition, a study of 96 municipal solid waste incinerator workers in Japan did not find an association between serum dioxin levels and immunological function tests (105).

Finally, multiple immunologic indices were examined in relation to serum dioxin levels among members of Operation Ranch Hand veterans (109-112). Michalek and colleagues found no significant associations between dioxin category and mean serum IgA, IgG, or IgM levels, and the percentage of veterans who had an abnormal skin test response was increased in the background and low dioxin category but decreased in the high category (112). Mean absolute total lymphocyte counts and mean absolute lymphocyte subset counts were higher among veterans in the background dioxin category than those in the Comparison category, but no clear patterns were seen between veterans in the low and high dioxin categories. No consistent relations were seen between dioxin exposure and prevalence of the ANA, smooth muscle autoantibodies, mitochondrial autoantibodies, parietal cell autoantibodies, rheumatoid factor, and monoclonal immunoglobulins (112). In a study of 51 Korean Vietnam veterans and 36 nonveterans, total serum IgG levels were significantly decreased and Interleukin 4 (IL-4) levels were significantly increased in veterans exposed to Agent Orange (113).

In 2002, the Institute of Medicine found that the evidence determining whether an association exists between Agent Orange and other herbicides used in Vietnam and immune suppression or autoimmunity was inadequate or insufficient (114).

19.1.2 Summary of Previous Analyses of the Air Force Health Study

19.1.2.1 1982 Baseline Examination Summary Results

Immunologic function and phenotypic marker studies were performed on 592 participants (297 Ranch Hands, 295 Comparisons) randomly selected by the last digit of their participant study identification

number. Because of laboratory problems (e.g., fluctuating quality control and lack of simultaneous differential counts on the peripheral mononuclear cells), data could be analyzed on a group basis only.

Analyses of the cell surface markers (CD2+ or T₁₁ [T cells], CD3+ or T₃ [T cells], CD4+ or T₄ [helper T cells], CD8+ or T₈ [suppressor T cells], CD20+ [B cells], the CD4–CD8 [or T₄–T₈] ratio) and the total lymphocyte count (TLC) showed no significant group differences.

Functional studies of T and B cells via reaction to antigenic (tetanus toxoid) or mitogen (phytohemagglutinin [PHA], concanavalin A, and pokeweed) stimulation showed no group differences. Similarly, adjusted mean values of the four assays were not significantly different between groups.

In summary, neither immunologic function nor cell marker studies showed significant impairment in the Ranch Hand group, nor did they show patterns supportive of a herbicide effect.

19.1.2.2 1985 Follow-up Examination Summary Results

The 1985 AFHS physical examination placed more emphasis on the immunology assessment than did the 1982 baseline examination profile. Immunologic competence was measured by cell surface marker (phenotypic) studies and cell stimulation studies on 47 percent of the study population, and by a series of four skin test antigens in 76 percent of the participants to assess the delayed hypersensitivity response.

Surface marker studies were conducted for CD2+ cells (T cells), CD4+ cells (T cells), CD8+ cells (suppressor T cells), CD20+ (B cells), CD14+ cells (monocytes), and human leukocyte antigen-DR (HLA-DR) cells. The ratio of CD4 to CD8 cells also was included in the analysis. Because of inherent significant day-to-day and batch-to-batch variation, all results (including functional stimulation studies) were adjusted for blood-draw day. Statistical testing of the seven phenotypic cell markers did not reveal any significant group differences after adjusting for the covariates of age, race, occupation, current smoking, lifetime smoking history, current alcohol use, or lifetime alcohol use. Similarly, none of the adjusted analyses of the functional stimulation studies (for PHA, pokeweed mitogen, or mixed lymphocyte culture [MLC]) showed any statistically significant group differences. Overall, no pattern was identified to suggest an adverse health effect in any subgroup of either the Ranch Hands or Comparisons.

The delayed hypersensitivity response was assessed by the skin test antigens of mumps, *Candida albicans*, Trichophyton, and staphage lysate. The 48-hour measurements of skin induration and erythema for the four tests showed marked inter-reader variation. Consequently, all skin test data were declared invalid and were not used in the assessment of group differences. The skin test reading problems led to the use of additional clinical quality control procedures for the 1987 follow-up examination.

In conclusion, no significant group differences were found for the comprehensive cell surface marker or functional stimulation studies.

19.1.2.3 1987 Follow-up Examination Summary Results

For the assessment of the 1987 immunologic examination data, results from a composite skin reaction test were evaluated. Various laboratory examination measurements from cell surface marker studies, three groups of functional stimulation tests, and quantitative immunoglobulins also were analyzed. Ranch Hands had a higher frequency of individuals with possibly abnormal reactions on skin testing than Comparisons. For the adjusted analyses of the natural killer assay measurements with and without

Interleukin 2 (IL-2), significant interactions between group and race were present. The clinical meaning of these findings was not apparent and did not point to any known clinical endpoints.

19.1.2.4 Serum Dioxin Analysis of 1987 Follow-up Examination Summary Results

In general, the composite skin test diagnosis results were not associated with serum dioxin levels. The Ranch Hand analyses using initial dioxin and the analyses using dioxin and time since duty in Southeast Asia (SEA) generally displayed nonsignificant decreased risks. For the analyses contrasting Ranch Hands with unknown (termed as “background” in subsequent reports), low, and high dioxin to Comparisons with background dioxin levels, the risks were increased but nonsignificant.

For the most part, the cell surface marker variables and TLC did not display significant associations with serum dioxin. The longitudinal analyses of the CD4-CD8 ratio did not consistently show significant differences in the 1987 ratio relative to the 1985 measurement of the ratio.

For the analyses of PHA net responses, significant positive associations with initial dioxin were found. For the analyses involving dioxin and time since duty in SEA, the maximum PHA net response also displayed some significant positive associations. Depressed immune function would be expected to demonstrate lower PHA net response.

For unstimulated MLC and MLC net response, the three statistical analysis approaches generally displayed nonsignificant associations with serum dioxin. For the analysis involving Ranch Hands in the high dioxin category and Comparisons in the background dioxin category, Ranch Hands had a significantly higher unstimulated MLC mean. The analyses of the natural killer cell variables generally were nonsignificant.

Significant positive associations generally were found between IgA and initial dioxin. The analyses for IgA, IgG, and IgM using dioxin and time since duty in SEA were, for the most part, nonsignificant. For the three immunoglobulins, the overall contrasts of Ranch Hands in the unknown, low, and high dioxin categories versus Comparisons in the background dioxin category generally were significant. For IgA and IgG, the contrasts of Ranch Hands in the unknown dioxin category versus Comparisons in the background dioxin category were significant with Ranch Hands having lower immunoglobulin averages. Ranch Hands in the high dioxin category were not significantly different from Comparisons.

The indices of immune responses analyzed in the 1987 examination provided a comprehensive reflection of in vivo and in vitro immune function in the study population. No clinically meaningful indicators reflecting a relation between the body burden of dioxin or the extrapolated initial exposure and immune function were found. Increased IgA levels may have represented a chronic inflammatory response to dioxin exposure. Elevated erythrocyte sedimentation rates and increased WBC and platelet counts were other examples of indicators that may have represented a chronic inflammatory response to dioxin exposure.

19.1.2.5 1992 Follow-up Examination Summary Results

In general, the composite skin test diagnosis results did not differ significantly between Ranch Hands and Comparisons and were not positively associated with initial or 1987 dioxin levels. For the most part, the cell surface marker variables and total lymphocyte count did not display significant associations with serum dioxin. The longitudinal analyses of the CD4-CD8 ratio did not show significant differences between the 1992 ratio relative to the 1985 measurement of the ratio.

The prevalence of some lupus panel antibodies, such as the mouse stomach kidney (MSK) anti-smooth muscle antibody and the rheumatoid factor, decreased as dioxin exposure increased. This finding was inconsistent with a harmful effect from dioxin. The presence of lupus panel antibodies generally was considered abnormal. A smaller prevalence of the lupus panel antibodies was found in this study than would be expected in the general population. The presence of a smaller prevalence of abnormalities than expected also may have been regarded as an abnormal finding, suggesting a possible early immune alteration.

19.1.2.6 1997 Follow-up Examination Summary Results

The immunology assessment was based on laboratory data on six lymphocyte cell surface markers, absolute lymphocyte counts, three quantitative immunoglobulins, and six measurements from an autoantibody panel. The six cell marker measurements were carried out on a random sample of approximately 40 percent of the participants because of the complexity of the assay and the expense of the tests.

Group analyses revealed significant findings for the adjusted analyses of CD16+56+ cell (natural killer cell) count and for the MSK anti-smooth muscle antibody test in enlisted flyers. Among enlisted flyers, the mean CD16+56+ cell count was greater for Comparisons than for Ranch Hands, and a greater percentage of Comparisons than Ranch Hands had the anti-smooth muscle antibody present. For these analyses the magnitude of the mean differences was small; therefore, the clinical importance of these findings is unknown.

Consistent with the previous two physical examinations, the mean serum concentration of IgA increased significantly with initial dioxin, but was not significantly increased in enlisted groundcrew or the high dioxin category; IgA did not increase significantly with 1987 dioxin. The IgA results, although significant, were small in magnitude and their clinical significance is unknown.

When comparing categorized dioxin levels between Ranch Hands and Comparisons, a significantly higher CD16+56+ cell count mean was observed among Comparisons than among Ranch Hands in the high dioxin category. Analyses revealed significant associations between 1987 dioxin levels and CD3+ cell (T cell) count, CD4+ cell (helper T cell) count, and CD3+CD4+ cell (helper T cell) count. The cell counts increased as 1987 dioxin increased.

In summary, these findings do not provide evidence of a biologically meaningful relation between body burden of dioxin and parameters of immunology assessment.

19.1.3 Parameters for the 2002 Immunology Assessment

19.1.3.1 Dependent Variables

Table 19-1 presents the immunologic measurements that were evaluated and describes their medical importance. The absolute lymphocyte, immunoglobulin studies, and lupus panel tests were conducted on all participants, whereas the cell surface marker studies were carried out on a random sample of approximately 40 percent of the participants because of the complexity of the assay and the expense of the tests.

Table 19-1. Medical Significance of the Immunologic Data

Immunologic Measurements	Rationale of the Measurement	Disease/Syndrome/Condition Endpoint
<u>Cell Surface Marker Studies</u>		
CD3+	Pan-T cell marker (similar to CD2 in previous AFHS examinations). Measures all mature T cells (includes CD4, CD8, etc.). Generally 70 percent or more of peripheral blood lymphocytes are CD3 positive.	Decrease in absolute number of T cells indicates immunodeficiency. May occur because of direct effects of malignancy (e.g., lymphoma), acquired immune deficiency syndrome (AIDS), or chemotherapy. Increase may occur in lymphoproliferative disorders or in some infections.
CD4+	Measures T cells that exhibit helper or inducer phenotype. CD4+ cells initiate an immune response to processed antigens.	Markedly decreased in people with AIDS because of human immunodeficiency virus (HIV) infection of CD4+ cells; increased in autoimmune diseases.
CD8+	Measures T cells that exhibit suppressor and cytotoxic functions. Responsible for appropriate down regulation of an immune response after antigen has been cleared.	Variable in autoimmune diseases; increased in some viral illnesses and immunodeficiencies.
CD20+ (B1)	Measures peripheral blood B cells; no reaction with T cells, granulocytes, or monocytes.	Decreased result in humoral immune deficiency with impaired production of antibodies; increased in lymphoproliferative disorders.
<u>Double-Labeled Cells (cells that express both markers)</u>		
CD3+CD4+	Helper T cells and excludes monocytes but more specific than CD4+.	Same as CD4+.
CD16+56+ (CD3-)	Normally these markers do not occur on the same cells. Measures natural killer cells that can lyse foreign cells independent of antibody or prior contact with the target. CD16+ is an IgG receptor that appears on natural killer cells and neutrophils; CD56+ is more restricted to natural killer cells; joint use of CD16+ and CD56+ enhances enumeration of natural killer cells.	Natural killer cells are thought to attack neoplasms and naturally prevent growth of cancers.
<u>Absolute Lymphocytes</u>		
	Measures absolute number of total lymphocytes circulating in peripheral blood. Major immune mechanism against fungi and viruses.	Decreased in immunodeficiency; increased in lymphoproliferative disorders.

Table 19-1. Medical Significance of the Immunologic Data (Continued)

Immunologic Measurements	Rationale of the Measurement	Disease/Syndrome/Condition Endpoint
<u>Immunoglobulins</u>		
IgG IgA IgM	Each measures ability of specific B cell subgroup to secrete specific antibody class of molecules. Antibodies normally rise in response to infections or immunizations with bacteria, fungi, and viruses. Major immune mechanism against bacteria.	Increased in hyperglobulinemia or myeloma (monoclonal). Decreased in selective or total B cell immunodeficiency. Polyclonal increases in chronic inflammation and liver disease (cirrhosis).
<u>Lupus Panel</u>		
	The test composition of this profile was chosen to include the most frequently encountered autoantibodies. Presence of autoantibodies may indicate specific autoimmune diseases, especially if multiple autoantibodies are present. The individually named autoantibodies (excluding ANA and B cell clones) are associated with specific diseases. Any of these tests may also turn positive as a participant's immune system ages or otherwise is dysregulated.	
ANA Test	Screening assay (performed with monolayers of HEp-2) for many clinically meaningful autoantibodies that occur in systemic rheumatologic diseases.	Positive result suggests possible rheumatologic disease; likelihood increases with number of different positive autoantibodies.
Thyroid Microsomal Antibody	Measures autoantibodies against thyroid microsomal antigen.	Present in autoimmune thyroiditis.
MSK Anti-smooth Muscle Antibody	MSK indicates the tissues used in the assay (mouse stomach kidney); measures autoantibodies against actin in smooth muscle.	Present in autoimmune liver diseases, especially chronic active hepatitis.
MSK Anti-mitochondrial Antibody	Measures autoantibodies against mitochondrial antigens.	Present in autoimmune liver diseases, especially primary biliary cirrhosis.
MSK Anti-parietal Cell Antibody	Measures autoantibodies against parietal cells of the stomach that make intrinsic factor for the absorption of vitamin B ₁₂ .	Present in pernicious anemia (failure to absorb vitamin B ₁₂).
Rheumatoid Factor	Autoantibodies reactive with a person's own antibodies.	Present in rheumatoid arthritis; also in some infections, chronic pulmonary diseases, and other inflammatory or autoimmune diseases.

19.1.3.1.1 Laboratory Variables

The results of cell surface marker studies, absolute lymphocytes, quantitative immunoglobulins, and a lupus panel were analyzed. Participants who were taking anti-inflammatory medication (except aspirin and nonsteroidal) or immunosuppressive medication at the time of the 2002 physical examination were excluded from analysis. Participants who had received x-ray treatment or chemotherapy for cancer within 6 months of the 2002 physical examination and participants who tested positive for HIV also were excluded from analysis.

19.1.3.1.1.1 Cell Surface Marker (Phenotypic) Studies

Quantification of the different cell populations was carried out with the use of reagent mouse monoclonal antibodies using Becton Dickson FACScan equipment. Cell surface markers were analyzed in the statistical evaluation of the immunologic system. The unit of measurement was cells/mm³.

19.1.3.1.1.2 Absolute Lymphocytes

Absolute lymphocytes indicate the density of lymphocytes in the blood. Lymphocytes recognize and destroy bacteria, fungi, viruses, and other foreign bodies. Statistical analyses were performed on absolute lymphocytes, measured in cells/mm³ using Becton Dickson FACScan equipment. Absolute lymphocytes also were analyzed in the hematology assessment (see Chapter 16).

19.1.3.1.1.3 Immunoglobulins

Immunoglobulins measure the ability of a specific B-cell subgroup to secrete a specific antibody class of molecules. The antibodies typically rise in response to infections or immunizations with bacteria, fungi, and viruses. Statistical analyses were performed on the immunoglobulins IgA, IgG, and IgM, measured in mg/dL using the Beckman Coulter IMMAGE[®] system.

19.1.3.1.1.4 Lupus Panel

This group of laboratory tests detected the most frequent autoantibodies found in both patients and asymptomatic individuals. Autoantibodies are markers for autoimmune diseases, and the lupus panel is considered a screening assay for a wide spectrum of autoimmune disorders (e.g., rheumatoid arthritis, systemic lupus erythematosus). Occasionally, autoantibodies are detected in asymptomatic persons; this is alternatively explained as evidence for incipient autoimmune disease or a finding of unknown meaning. In any instance, the finding of an autoantibody is not normal and should be interpreted as an aberration of the immune system. The lupus panel comprises the following individual tests on serum, using a manual indirect fluorescent antibody method:

- ANA performed on HEp-2 cells
- Thyroid microsomal antibody
- MSK section stain for the following specific autoantibodies:
 - Anti-smooth muscle
 - Anti-mitochondrial
 - Anti-parietal cell
- Rheumatoid factor.

All the autoantibodies derive from abnormalities of the B-cell portion, the part of the immune system that produces immunoglobulins.

Statistical analyses were performed on the ANA, thyroid microsomal antibody, MSK anti-smooth muscle antibody, MSK anti-mitochondrial antibody, MSK anti-parietal cell antibody, and rheumatoid factor, with the responses to these tests scored as present or absent.

19.1.3.2 Covariates

Covariates used in the immunologic evaluation for adjusted statistical analyses included age, race, military occupation, body mass index (kg/m^2), current cigarette smoking (cigarettes/day), lifetime cigarette smoking history (pack-years), current alcohol use (drinks/day), lifetime alcohol history (drink-years), and a physical activity index (an index combining both duration and intensity of exercise).

Age, race, and military occupation were determined from military records. Body mass index was calculated as $\text{weight}/(\text{height})^2$, where the weight was measured in kilograms and the height was measured in meters at the physical examination (115). For purposes of covariate associations for discrete dependent variables, the body mass index was dichotomized as “not obese” ($\leq 30 \text{ kg/m}^2$) and “obese” ($> 30 \text{ kg/m}^2$).

Current cigarette smoking and lifetime cigarette smoking history were based on questionnaire data. For lifetime cigarette smoking history, the respondent’s average smoking was estimated over his lifetime based on his responses to the 2002 questionnaire, with 1 pack-year defined as 365 packs of cigarettes smoked during a single year.

Lifetime alcohol history was based on information from the 2002 questionnaire and combined with similar information gathered at the 1987, 1992, and 1997 follow-up examinations. Each participant was asked about his drinking patterns throughout his lifetime. When a participant’s drinking pattern changed, he was asked to describe how his alcohol consumption differed and the duration of time that the drinking pattern lasted. The participant’s average daily alcohol consumption was determined for each of the reported drinking pattern periods throughout his lifetime, and an estimate of the corresponding total number of drink-years was derived. One drink-year was the equivalent of drinking 1.5 ounces of an 80-proof alcoholic beverage, one 12-ounce beer, or one 5-ounce glass of wine per day for 1 year. Current alcohol use was defined as the average number of drinks per day during the 2 weeks prior to completing the physical examination.

A series of questions concerning exercise patterns in the 2 weeks prior to the physical examination were included as part of the 2002 questionnaire. The participants were asked questions on frequency, average duration per frequency, and increase of heart rate or breathing for more than 20 different activities. The answers to these questions were used and combined to determine an index of physical activity incorporating duration and intensity (116, 117); this covariate was used in adjusted statistical analyses. A participant was classified as active, moderately active, or sedentary based on his responses to the series of questions regarding exercise patterns.

19.1.4 Statistical Methods

Table 19-2 summarizes the statistical analysis performed for the 2002 immunology assessment. The first part of this table lists the dependent variables analyzed, source of the data, form of the data, cutpoints, covariates, exclusions, and statistical methods. The second part of the table further describes the covariates. A covariate was used in its continuous form whenever possible for all adjusted analyses. If the covariate was inherently discrete (e.g., military occupation), or if a categorized form was needed to develop measures of association with the dependent variables, the covariate was categorized as shown in Table 19-2.

Table 19-2. Statistical Analysis for the Immunology Assessment

Four models were examined for each dependent variable given in Table 19-2. The analyses of these models are presented below. Further details on dioxin and the modeling strategy are found in Chapters 2 and 7, respectively. These analyses were performed both unadjusted and adjusted for covariates. These covariates are given in Table 19-2. Model 1 examined the relation between the dependent variable and group (i.e., Ranch Hand or Comparison). In this model, exposure was defined as “yes” for Ranch Hands and “no” for Comparisons without regard to the magnitude of the exposure. In an attempt to quantify exposure, three contrasts of Ranch Hands and Comparisons were performed along with the overall Ranch Hand versus Comparison contrast. These three contrasts compared Ranch Hands and Comparisons within each military occupational category (i.e., officers, enlisted flyers, and enlisted groundcrew). As described in previous reports and Table 2-4, the median level of exposure to dioxin was highest for enlisted groundcrew, followed by enlisted flyers, then officers.

During the 1987, 1992, 1997, and 2002 examinations, serum dioxin levels were measured by the Centers for Disease Control and Prevention (CDC) using high-resolution gas chromatography and high-resolution mass spectrometry and were reported in parts per trillion (ppt) on a lipid weight basis (118). These dioxin measurements are referred to as “lipid-adjusted.” All measures of dioxin used in this report were based on lipid-adjusted dioxin measurements.

Model 2 examined the relation between the dependent variable and an extrapolated initial dioxin measure for Ranch Hands who had a 1987 dioxin measurement greater than 10 ppt. The initial dioxin was calculated by extrapolating the 1987 dioxin level back in time to the end of the tour of duty that qualified a Ranch Hand veteran for inclusion in this study. If a Ranch Hand did not have a 1987 dioxin level, then the first dioxin measured, either at 1992, 1997, or 2002, was used to estimate the initial dioxin level. Regardless of when the dioxin was measured, Ranch Hand veterans with a level less than or equal to 10 ppt were excluded from statistical analyses based on Model 2. A statistical adjustment for body mass index at the time of the participant’s blood measurement of dioxin was included in this model to account for body mass index-related differences in elimination rate (119).

Model 3 divided the Ranch Hands examined in Model 2 into two categories based on their initial dioxin measures. These two categories were referred to as “low Ranch Hand” and “high Ranch Hand.” Two

additional categories—Ranch Hands with serum dioxin levels at or below 10 ppt and Comparisons—were formed and included in the model. Ranch Hands with serum dioxin levels at or below 10 ppt were assigned to the “background Ranch Hand” category. If a Ranch Hand did not have a 1987 dioxin measurement, the first measured dioxin level was used. Another category was examined by combining the low and high Ranch Hand categories. This combination is referred to in the tables as the “low plus high Ranch Hand” category. These five categories—Comparisons, background Ranch Hands, low Ranch Hands, high Ranch Hands, and low plus high Ranch Hands—were used in Model 3 analyses. The relation between the dependent variable in each of the four Ranch Hand categories and the dependent variable in the Comparison category was examined. As in Model 2, a statistical adjustment for body mass index at the time of the participant's blood measurement of dioxin was included in this model for the unadjusted and adjusted analyses of all dependent variables. One Ranch Hand without a dioxin measure was excluded from statistical analyses based on Model 3.

Model 4 examined the relation between the dependent variable and 1987 dioxin levels in all Ranch Hands with a dioxin measurement. If a Ranch Hand did not have a 1987 dioxin measurement, the first dioxin level obtained, either in 1992, 1997, or 2002, was extrapolated to the date of the 1987 physical examination. If the first dioxin level was not obtained in 1987 and was less than or equal to 10 ppt, it was not extrapolated to 1987 level, but was used at the measured value. One Ranch Hand without a dioxin measurement was excluded from statistical analyses based on Model 4.

The term “unadjusted” was used in the text and tables as follows: Models 1 and 4 did not adjust for any covariates. Models 2 and 3 adjusted only for body mass index at the time of the blood measurement for dioxin. The term “adjusted” was used in the text and tables as follows: Models 1 and 4 adjusted for the covariates shown in Table 19-2 unless otherwise specified by a footnote to the table. Models 2 and 3 additionally adjusted only for body mass index at the time of the blood measurement for dioxin.

Table 19-3 provides a summary of the number of participants with missing dependent variable and covariate data. In addition, the number of participants that were excluded from analyses is given.

Table 19-3. Number of Participants Excluded or with Missing Data for the Immunology Assessment

^b424 Ranch Hands for initial dioxin; 776 Ranch Hands for 1987 dioxin.

^c776 Ranch Hands and 1,174 Comparisons for categorized dioxin.

Note: COV = Covariate.

DEP = Dependent variable.

EXC = Exclusion.

19.2 RESULTS

19.2.1 Dependent Variable-covariate Associations

The complete results of covariate associations with each immunologic dependent variable are documented in Appendix F, Table F-11. These associations were pairwise between the dependent variable and the covariate and were not adjusted for any other covariates. The following paragraphs summarize the pattern of significant ($p \leq 0.05$) dependent variable-covariate associations.

Age was significantly associated with absolute lymphocyte count, IgM, ANA, and all cell surface markers except CD8+ cells. CD3+ cells, CD4+ cells, CD20+ cells, CD3+CD4+ cells, absolute lymphocytes, and IgM decreased with increasing age. Natural killer cells (CD16+56+ cells) increased with increasing age. Older participants were more likely to have the ANA present than younger participants.

Blacks had significantly higher CD4+, CD20+, and CD3+CD4+ cell counts than non-Blacks. All three immunoglobulin measures were significantly associated with race. Blacks had higher IgA and IgG levels and lower IgM levels than non-Blacks. Blacks were more likely to have anti-smooth muscle antibodies and less likely to have the ANA present than non-Blacks.

Military occupation was significantly associated with rheumatoid factor, absolute lymphocyte count, IgA, IgG, and all cell surface markers except CD16+56+ cells. Officers had the lowest cell counts (cell surface marker and absolute lymphocyte) and immunoglobulin levels. Except for CD8+ cells, enlisted groundcrew had the highest cell counts and enlisted flyers had the second highest cell counts. For CD8+ cells, enlisted flyers had slightly higher counts than enlisted groundcrew. Rheumatoid factor was more prevalent in enlisted flyers than in enlisted groundcrew or officers.

Body mass index was positively correlated with CD20+ cell and absolute lymphocyte counts. Body mass index was also significantly associated with rheumatoid factor in that obese participants were more likely to have rheumatoid factor present than participants who were not obese.

Current cigarette smoking was significantly associated with the six cell surface markers, absolute lymphocytes, IgG, and rheumatoid factor. As current cigarette smoking increased, all cell surface markers except CD16+56+ cells increased. CD16+56+ cells and IgG levels decreased with increased current smoking. Rheumatoid factor was more prevalent in current smokers than in former smokers or nonsmokers.

Significant increases in CD3+ cells, CD4+ cells, CD8+ cells, CD3+CD4+ cells, and absolute lymphocytes were seen as lifetime cigarette smoking increased. Heavy smokers (more than 10 pack-years) and nonsmokers had the ANA present more often than moderate smokers (less than 10 pack-years). The prevalence of rheumatoid factor increased with increased lifetime cigarette smoking.

Current alcohol use was significantly associated with CD20+ cells, IgG levels, and rheumatoid factor. As current alcohol use increased, CD20+ cell counts and IgG levels decreased. Rheumatoid factor was more prevalent in participants currently drinking more than one drink per day than in participants who drank less.

Significant associations were seen between lifetime alcohol use and CD20+ cells and IgA. CD20+ cell counts decreased with increasing alcohol use and IgA levels increased with increasing alcohol use.

Significant associations were seen between the physical activity index and CD3+ cells, absolute lymphocytes, IgA levels, and thyroid microsomal antibodies. Mean CD3+ cell counts, absolute lymphocyte counts, and IgA levels were higher in sedentary participants than moderately active or very active participants. Thyroid microsomal antibodies were more prevalent in sedentary participants, followed by moderately active participants and very active participants.

19.2.2 Exposure Analysis

The following section presents results of the statistical analyses of the dependent variables shown in Table 19-2. All dependent variables were obtained from the laboratory measurements during the 2002 physical examination.

19.2.2.1 Laboratory Variables

19.2.2.1.1 CD3+ Cells (T Cells)

All unadjusted and adjusted analyses of CD3+ cells for Model 1 and Model 2 were nonsignificant (Table 19-4(a-d): $p > 0.21$ for all analyses). The Model 3 unadjusted analyses of CD3+ cells revealed that Ranch Hands in the high dioxin category had a significantly higher mean CD3+ cell count than Comparisons (Table 19-4(e): $p = 0.036$, difference of adjusted means = 130.6 cells/mm³). This contrast was nonsignificant in the Model 3 adjusted analysis (Table 19-4(f): $p = 0.167$). Results from the unadjusted and adjusted analyses of Model 4 were nonsignificant (Table 19-4(g-h): $p > 0.06$ for all analyses).

Table 19-4. Analysis of CD3+ Cells (T Cells) (cells/mm³)

(a) MODEL 1: RANCH HANDS VS. COMPARISONS – UNADJUSTED					
Occupational Category	Group	n	Unadjusted Mean^a	Difference of Unadjusted Means^b	p-Value^c
<i>All</i>	<i>Ranch Hand</i>	<i>272</i>	<i>1,234.5</i>	<i>31.5</i>	<i>0.402</i>
	<i>Comparison</i>	<i>422</i>	<i>1,203.0</i>

19.2.2.1.2 CD4+ Cells (Helper T Cells)

The unadjusted and adjusted analyses of CD4+ cells for Model 1 and Model 2 were nonsignificant (Table 19-5(a–d): $p > 0.25$ for all analyses). The unadjusted analyses of Model 3 revealed a significantly higher mean CD4+ cell count for Ranch Hands in the high dioxin category than Comparisons (Table 19-5(e): $p = 0.036$, difference of adjusted means = 90.4 cells/mm³). This contrast was nonsignificant in the Model 3 adjusted analysis (Table 19-5(f): $p = 0.133$). Results from the Model 4 unadjusted analysis and adjusted analyses of CD4+ cells were nonsignificant (Table 19-5(g–h): $p > 0.06$ for all analyses).

19.2.2.1.5 CD20+ Cells (B Cells)

All unadjusted and adjusted Model 1 results from the analyses of CD20+ cell count were nonsignificant (Table 19-8(a,b): $p > 0.37$ for all analyses). The Model 2 unadjusted and adjusted analyses revealed a significant positive association between initial dioxin and CD20+ cell count (Table 19-8(c,d): $p = 0.001$, Slope=0.119, unadjusted; $p = 0.016$, Slope=0.102, adjusted). The adjusted means for the low, medium, and high initial dioxin categories were 187.2, 263.8, and 257.7 cells/mm³, respectively.

The unadjusted analyses of Model 3 revealed that Ranch Hands in the low dioxin category had a significantly lower mean CD20+ cell count than Comparisons (Table 19-8(e): $p = 0.016$, difference of adjusted means=-34.1 cells/mm³). Ranch Hands in the high dioxin category, however, were found to have a higher mean CD20+ cell count than Comparisons (Table 19-8(e): $p = 0.047$, difference of adjusted means=32.7 cells/mm³). The Model 3 adjusted analyses did not reveal significant differences (Table 19-8(f): $p \geq 0.09$ for all analyses).

The Model 4 unadjusted analysis revealed a positive association between initial dioxin level and CD20+ cell count (Table 19-8(g): $p = 0.042$, Slope=0.046). The association was nonsignificant, however, in the adjusted analysis (Table 19-8(h): $p = 0.601$).

19.2.2.1.7 Absolute Lymphocytes

All unadjusted and adjusted analyses results from Model 1 for absolute lymphocytes were nonsignificant (Table 19-10(a,b): $p>0.29$ for all analyses). The unadjusted analyses for Models 2 and 4 were significant, revealing positive associations between initial dioxin and absolute lymphocytes (Table 19-10(c): $p=0.029$, Slope=0.031; and Table 19-10(g): $p=0.029$, Slope=0.021). The adjusted analyses for Models 2 and 4 were nonsignificant (Table 19-10(d,h): $p>0.22$ for all adjusted Model 2 and 4 analyses).

The unadjusted analyses of absolute lymphocytes in Model 3 revealed a significantly higher mean absolute lymphocyte count for Ranch Hands in the high dioxin category than Comparisons (Table 19-10(e): $p=0.017$, difference of adjusted means=129.6 cells/mm³). The adjusted analyses of Model 3 were nonsignificant (Table 19-10(f): $p>0.44$ for all analyses).

19.2.2.1.9 IgG

All unadjusted and adjusted analyses of IgG from Models 1, 2 and 4 were nonsignificant (Table 19-11(a-d,g,h): $p \geq 0.13$ for all analyses). The unadjusted Model 3 analyses revealed a significantly lower mean IgG level for Ranch Hands in the background dioxin category versus Comparisons (Table 19-12(e): $p=0.045$, difference of adjusted means=-34.6 cells/mm³). In the adjusted analyses of Model 3, there were no significant differences (Table 19-12(f): $p>0.20$ for all analyses).

19.2.2.1.11 Lupus Panel: ANA Test

All unadjusted and adjusted analyses results from Models 1, 3, and 4 for the ANA were nonsignificant (Table 19--14(a,b,e-h): $p>0.05$). A significant positive association was found between initial dioxin and the presence of the ANA in both the unadjusted and adjusted analyses of Model 2 (Table 19-14(c,d): Unadjusted Relative Risk [RR]=1.22, $p=0.037$; Adjusted RR=1.28, $p=0.035$, respectively). The percentages of Ranch Hands with the ANA present were 19.5, 11.7, and 27.8 percent in the low, medium, and high initial dioxin categories, respectively.

Analysis Results for Log₂ (1987 Dioxin)		
n	Adjusted Relative Risk (95% C.I.)^a	p-Value
691	1.01 (0.75,1.37)	0.944

^aRelative risk for a twofold increase in 1987 dioxin.

Note: Results were not adjusted for race because of the sparse number of Ranch Hands with a thyroid microsomal antibody present.

19.2.2.1.13 Lupus Panel: MSK Anti-smooth Muscle Antibody

Because of the sparse number of participants with the MSK anti-smooth muscle antibody present (9 Ranch Hands and 8 Comparisons), analysis was limited. The Model 1 unadjusted analysis did not reveal significant findings (Table 19-16(a): $p > 0.06$ for all analyses). The adjusted analysis of Model 1, however, revealed a significant difference in the presence of the MSK anti-smooth muscle antibody between Ranch Hands and Comparisons in the officer stratum (Table 19-16(b): $p = 0.045$, Adjusted RR=5.27). For officers, six Ranch Hands (2.2%) and two Comparisons (0.5%) had the MSK anti-smooth muscle antibody present. All other adjusted Model 1 contrasts were nonsignificant (Table 19-16(a,b): $p > 0.19$). Both adjusted and unadjusted analyses of Model 2 were nonsignificant (Table 19-16(c,d): $p > 0.15$ for both analyses).

The unadjusted analysis of Model 3 uncovered a significant difference in the presence of the MSK anti-smooth muscle antibody between Ranch Hands in the background dioxin category (1.9%) and Comparisons (0.7%) (Table 19-16(e): $p = 0.035$, Unadjusted RR=3.22). After adjustment for covariates, the association remained significant (Table 19-16(f): $p = 0.021$, Adjusted RR=3.91). All other Model 3 contrasts were nonsignificant in both the unadjusted and adjusted analyses (Table 19-16(e,f): $p > 0.30$ for all other contrasts).

The Model 4 unadjusted analysis revealed a significant association between 1987 dioxin levels and the presence of the MSK anti-smooth muscle antibody (Table 19-16(g): $p = 0.029$, Unadjusted RR=0.62). After adjustment for covariates, the association remained significant (Table 19-16(h): $p = 0.013$, Adjusted RR=0.47). The percentages of Ranch Hands with the MSK anti-smooth muscle antibody were 2.5%, 0.4%, and 0.9% for the low, medium, and high 1987 dioxin categories, respectively.

Table 19-16. Analysis of Lupus Panel: MSK Anti-smooth Muscle Antibody

19.2.2.1.16 Lupus Panel: Rheumatoid Factor

The analyses of Model 1 revealed a significant difference in the percentage of participants with a positive rheumatoid factor between Ranch Hands (22.5%) and Comparisons (16.1%) in the officer stratum. The analyses were significant both unadjusted and adjusted for covariates (Table 19-19(a,b): $p=0.035$, Unadjusted RR=1.51; $p=0.028$, Adjusted RR=1.55, respectively).

A significant inverse association was found between initial dioxin and the presence of a positive rheumatoid factor in both the unadjusted and adjusted Model 2 analyses (Table 19-19(c,d): $p<0.001$, Unadjusted RR=0.68; $p<0.001$, Adjusted RR=0.61, respectively). The percentage of Ranch Hands with the rheumatoid factor present were 30.9, 28.1, and 15.1 percent in the low, medium, and high initial dioxin categories, respectively.

The Model 3 unadjusted analysis revealed a significant difference in the percentage of participants with a positive rheumatoid factor between Ranch Hands in the low dioxin category (32.1%) and Comparisons (20.2%) (Table 19-19(e): $p<0.001$, Unadjusted RR=1.86). After adjustment for covariates, the difference remained significant (Table 19-19(f): $p=0.001$, Adjusted RR=1.81).

The Model 4 unadjusted analysis of the rheumatoid factor was not significant (Table 19-19(g): $p=0.118$, Unadjusted RR=0.92). After adjustment for covariates, however, the association became significant (Table 19-19(h): $p=0.042$, Adjusted RR=0.87). The percentages of Ranch Hands with the rheumatoid factor present were 21.9, 28.1, and 21.9 percent in the low, medium, and high 1987 dioxin categories, respectively.

19.3 DISCUSSION

The human immune system comprises the immune-surveillance system, which fights invading organisms such as bacteria, viruses, and fungi. With the ability to distinguish foreign from self, the system detects and destroys aberrant cells, including cancer cells.

The two functions of the immune system are innate immunity and adaptive immunity. Innate immunity, similar in all humans, is the body's first response to an invading organism. When the body experiences a foreign organism, the immune system adapts and develops a specific response to that organism.

The adaptive immune system can be further broken down into cellular and humoral immunity. The cellular immune system comprises granulocytes and lymphocytes, whereas the humoral immune system comprises immunoglobulins and complement proteins. Granulocyte abnormalities are discussed in the assessment of the hematologic system (Chapter 16). The two major classes of lymphocytes, a type of WBC, are T cells and B cells. These cells and the interactions that take place between them are an integral part of the body's ability to recognize and destroy invading organisms or tumor cells. B cells eventually mature into plasma cells, which produce the immunoglobulins in the humoral immune system. The T cells, which comprise both helper and suppressor cell subtypes, help maintain a balance in the immune response. Another type of lymphocyte—the natural killer cell—is responsible for the surveillance and destruction of tumors. Natural killer cells have the ability to target foreign cells without assistance from other parts of the immune system (thus a “natural killer” cell).

When the body's immune response is altered, it is because of an immune deficiency or an exaggerated response to the system. Immune deficiencies can be inherited or acquired. Acquired deficiencies in the

immune system are most commonly associated with a decrease in immunoglobulins and, therefore, the humoral immune system. Increased activity in the humoral immune system is manifested by autoantibodies directed against various normal human cells, which can result in disorders such as rheumatoid arthritis and systemic lupus erythematosus. Deficiencies in the T-cell function in the cellular immune system, often seen in HIV patients or in patients undergoing chemotherapy, result in opportunistic organisms such as *Pneumocystis carinii* or fungal infections.

During the 2002 AFHS follow-up examination, numerous immunologic parameters were assessed. The dependent variables included the absolute lymphocyte count, cell surface marker studies for CD3+ cells (total T cells), CD4+ cells (helper T cells), CD8+ cells (suppressor T cells), CD20+ cells (B-cells), CD3+CD4+ helper T cells, and CD16+56+ natural killer cells. The humoral immune system was measured by examining the immunoglobulin levels for IgG, IgA, and IgM; increased activity in the immune system was measured by investigating a lupus panel, which included rheumatoid factor, the ANA test, the thyroid microsomal antibody test, the MSK anti-smooth muscle antibody, the MSK anti-mitochondrial antibodies, and the MSK anti-parietal cell antibodies.

A number of covariates were also examined, including age, race, military occupation, body mass index, current cigarette smoking, lifetime cigarette smoking, current alcohol use, lifetime alcohol use, and a physical activity index. Results of dependent variable and covariate associations were as expected and as found in other studies, such as CD3 cell counts increasing with age, cigarette smoking, and sedentary activity.

The immunologic evaluation performed on AFHS participants went far beyond the usual medical examinations used for routine general health assessments. As a test panel battery, this assessment provided an indepth and broad review of immunologic parameters designed to detect abnormalities or variances that may or may not be of clinical importance. Isolated significant differences were present, but none in a meaningful, clinically consistent manner that would indicate overt disease.

Analyses revealed a significant positive correlation between initial dioxin exposure and CD20+ cell counts. The adjusted means were similar for the medium and high initial dioxin categories, and both were greater than the low initial dioxin category.

Ranch Hands had a significantly decreased mean IgM level among enlisted flyers. While the difference was statistically significant, the clinical relevance is unknown.

In the lupus panel, a significant positive association was found between initial dioxin level and the presence of the ANA. The percentages of Ranch Hands with the ANA present, however, were 19.5, 11.7, and 27.8 percent in the low, medium, and high initial dioxin categories, respectively. There did not appear to be a dose-response effect.

Analyses of the rheumatoid factor and the anti-smooth muscle antibody revealed several significant differences, but the prevalence of abnormalities decreased as dioxin increased and the results were not supportive of a positive dose-response relation.

In conclusion, while there were some isolated significant differences in some categories of immune system measurements, none appeared to be consistent or of clinical significance. There was an increasing prevalence of a positive ANA with increasing initial dioxin levels. When looking at the individual autoantibodies, however, there were no consistent findings to support the presence of the ANA.

19.4 SUMMARY

The immunology assessment was based only on laboratory data. Associations with herbicide exposure (i.e., group – Model 1), initial dioxin (Model 2), categorized dioxin (Model 3), and 1987 dioxin levels (Model 4) were examined for each variable in the immunology assessment. The significant adjusted results are discussed in the sections below.

19.4.1 Model 1: Group Analysis

The Model 1 adjusted analysis revealed significant findings for the analysis of certain military occupations for IgM, the MSK anti-smooth muscle antibody, and the rheumatoid factor. The mean IgM level was greater for Comparisons enlisted flyers than for Ranch Hand enlisted flyers. The significant results in the MSK anti-smooth muscle antibody test and in the rheumatoid factor test both occurred for officers. The MSK anti-smooth muscle analysis indicated that a greater percentage of Ranch Hand officers had the anti-smooth muscle antibody present than Comparison officers. Likewise, a greater percentage of Ranch Hand officers exhibited presence of a positive rheumatoid factor than Comparison officers. The results of the group analysis are provided in Table 19-20.

--: Analysis was not performed because of the sparse number of participants with an abnormality.

Table 19-20. Summary of Group Analysis (Model 1) for Immunology Variables (Ranch Hands vs. Comparisons) (Continued)

Note: NS or ns: Not significant ($p > 0.05$).

C: Continuous dependent variable.

D: Discrete dependent variable.

The p-value was given if $p \leq 0.05$. The relative risk was given in parentheses for a significant result from the analysis of a discrete dependent variable. The difference in means was given in parentheses for a significant result from the analysis of a continuous dependent variable.

A capital “NS” denotes a nonsignificant positive association. A lowercase “ns” denotes a nonsignificant inverse association.

--: Analysis was not performed because of the sparse number of participants with an abnormality.

Note: NS or ns: Not significant ($p > 0.05$).

C: Continuous dependent variable.

D: Discrete dependent variable.

The p-value was given if $p \leq 0.05$. The relative risk was given in parentheses for a significant result from the analysis of a discrete dependent variable. The difference in means was given in parentheses for a significant result from the analysis of a continuous dependent variable.

A capital “NS” denotes a nonsignificant positive association. A lowercase “ns” denotes a nonsignificant inverse association.

19.4.2 Model 2: Initial Dioxin Analysis

The Model 2 adjusted analysis revealed a significant association between CD20+ cell (B cell) counts and initial dioxin. The CD20+ cell count increased as initial dioxin increased. The associations between initial dioxin and both the overall ANA test and the rheumatoid factor were significant. For the ANA test, the percentage of Ranch Hands with the ANA present increased as initial dioxin increased. As initial dioxin increased, however, the percentage of Ranch Hands with a positive rheumatoid factor decreased. The results of the initial dioxin analysis are shown in Table 19-21.

C: Continuous dependent variable.

D: Discrete dependent variable.

The p-value was given if $p\leq 0.05$. The relative risk was given in parentheses for a significant result from the analysis of a discrete dependent variable. The slope was given in parentheses for a significant result from the analysis of a continuous dependent variable.

A capital "NS" denotes a nonsignificant positive association. A lowercase "ns" denotes a nonsignificant inverse association.

19.4.3 Model 3: Categorized Dioxin Analysis

Results for the Model 3 adjusted analysis revealed the presence of the MSK anti-smooth muscle antibody in a significantly higher percentage of Ranch Hands in the background dioxin category than Comparisons. In addition, the adjusted analysis indicated presence of a positive rheumatoid factor in a significantly higher percentage of Ranch Hands in the low dioxin category than Comparisons. The results of the categorized dioxin analysis are presented in Table 19-22.

A capital "NS" denotes a nonsignificant positive association. A lowercase "ns" denotes a nonsignificant inverse association.

19.4.4 Model 4: 1987 Dioxin Level Analysis

The Model 4 adjusted analysis uncovered significant associations between 1987 dioxin levels and the MSK anti-smooth muscle antibody and the rheumatoid factor. Both the percentage of Ranch Hands with presence of the MSK anti-smooth muscle antibody and the percentage of Ranch Hands with presence of a positive rheumatoid factor decreased as the 1987 dioxin levels increased. The results of the 1987 dioxin analysis are displayed in Table 19-23.

A capital “NS” denotes a nonsignificant positive association. A lowercase “ns” denotes a nonsignificant inverse association.

19.4.5 Summary of Significant Results

Table 19-24 summarizes the significant results ($p\leq 0.05$) for the adjusted analyses that were performed for the immunology assessment. The dependent variable and its table reference are listed along with the model and the contrast or description of the model. The p-value is provided along with analysis statistics that correspond to the type of analysis that was performed (either continuous or discrete). A description of the analysis and the statistics that are presented is referenced under the “Note” column and is explained in footnotes.

Table 19-24. Summary of Results from Significant Adjusted Analyses in the Immunology Assessment

Dependent Variable (Table Reference)	Model	Contrast or Description	p-Value	Analysis Statistics	Adjusted Mean or Percent Abnormal	Note
CD20+ Cells (B Cells) (19-8)	2	RH (1987 dioxin >10 ppt): Initial Dioxin	0.016	0.102 (0.042)	Low: 187.2 cells/mm ³ Medium: 263.8 cells/mm ³ High: 257.7 cells/mm ³	(a)
IgM (19-13)	1	RH vs. C: Enlisted Flyer	0.031	-13.82	RH: 80.01 mg/dL C: 93.83 mg/dL	(b)
Lupus Panel: ANA Test (19-14)	2	RH (1987 dioxin >10 ppt): Initial Dioxin	0.035	1.28 (1.02,1.61)	Low: 19.5% Medium: 11.7% High: 27.8%	(c)
Lupus Panel: MSK Smooth Muscle Antibody (19-16)	1	RH vs. C, Officer	0.045	5.27 (1.04,26.8)	RH: 2.2% C: 0.5%	(d)

	2	RH (1987 dioxin >10 ppt): Initial Dioxin	<0.001	0.61 (0.47,0.78)	Low: 30.9% Medium: 28.1% High: 15.1%	(c)
	3	Low RH vs. C	0.001	1.81 (1.28,2.57)	RH: 32.1% C: 20.2%	(e)
	4	All RH: 1987 Dioxin	0.042	0.87 (0.77,1.00)	Low: 21.9% Medium: 28.1% High: 21.9%	(f)

- (a): Continuous variable: slope and standard error were presented and were based on natural logarithm of dependent variable versus log₂ (initial dioxin); adjusted means were presented for each of three initial dioxin categories.
- (b): Continuous variable: difference of adjusted means was presented; confidence interval was not presented because analysis was not performed on original scale; adjusted means were presented for each exposure group in contrast.
- (c): Discrete variable: adjusted relative risk and 95% confidence interval were presented for a twofold increase in initial dioxin; percent abnormal was presented for each of three initial dioxin categories.
- (d): Discrete variable: adjusted relative risk and 95% confidence interval were presented; percent abnormal was presented for each exposure group in contrast.
- (e): Discrete variable: adjusted relative risk and 95% confidence interval were presented; percent abnormal was presented for each dioxin category in contrast.
- (f): Discrete variable: adjusted relative risk and 95% confidence interval were presented for a twofold increase in 1987 dioxin; percent abnormal was presented for each of three 1987 dioxin categories.

Table 19-24. Summary of Results from Significant Adjusted Analyses in the Immunology Assessment (Continued)

Note: RH = Ranch Hand.
C = Comparison.

- Model 2: Low = 32–79 ppt; Medium = >79–199 ppt; High = >199 ppt. (Ranch Hands who had a 1987 dioxin measurement greater than 10 ppt)
- Model 3: Background (Ranch Hand): 1987 dioxin \leq 10 ppt.
Low (Ranch Hand): 1987 dioxin > 10 ppt, 10 ppt < initial dioxin \leq 118 ppt.
High (Ranch Hand): 1987 dioxin > 10 ppt, initial dioxin > 118 ppt.
- Model 4: Low = \leq 7.8 ppt; Medium = >7.8–19.2 ppt; High = >19.2 ppt. (Ranch Hands only)
-

19.5 CONCLUSION

The immunologic evaluation performed on AFHS participants provided an indepth and broad review of immunologic parameters designed to detect abnormalities or variances that may or may not carry clinical importance. Analyses revealed a significant positive correlation between initial dioxin exposure and CD20+ cell counts and a significantly lower mean IgM level for Ranch Hand enlisted flyers.

In the lupus panel, a significant positive association was found between initial dioxin level and the presence of the ANA, but the association did not appear to support a dose-response relation. Analyses of the rheumatoid factor and the anti-smooth muscle antibody revealed several significant differences, but the prevalence of abnormalities decreased as dioxin increased.

There was an increasing prevalence of a positive ANA in Ranch Hands with increasing initial dioxin levels. When looking at the individual autoantibodies, however, there were no consistent findings to support the presence of the ANA. While there were some isolated significant differences in some categories of immune system measurements, there was nothing that appeared to be consistent or of clinical significance.

20 PULMONARY ASSESSMENT

20.1 INTRODUCTION

20.1.1 Background

20.1.1.1 Organs/Diseases

The Air Force Health Study (AFHS) included clinical assessments and questionnaire ascertainment of several nonmalignant respiratory outcomes, including asthma, bronchitis, pneumonia, and thorax and lung abnormality based on the presence of asymmetrical expansion, hyperresonance, dullness, wheezes, rales, or chronic obstructive pulmonary disease (COPD). The analyses of these outcomes in previous AFHS reports have adjusted for current and lifetime smoking. Mortality and morbidity studies evaluated the relation between dioxin exposure and these diverse nonmalignant acute and chronic respiratory diseases. Morbidity studies used the following clinical measures as study endpoints: lung or thorax abnormalities found on clinical examination; pulmonary function tests, such as forced expiratory volume at one second (FEV₁), which measures airflow obstruction, and forced vital capacity (FVC), which measures restriction; and abnormalities found on chest x-ray films.

Cigarette smoking is a strong risk factor for many respiratory diseases; consequently, smoking could easily obscure weaker associations between disease and other exposures, such as dioxin. Smoking history was often not available or considered in most studies that evaluated nonmalignant respiratory disease among dioxin exposed individuals, even though U.S. veterans reportedly smoked more heavily than nonveterans (1).

20.1.1.2 Toxicology

The toxic effects of dioxin most likely occur as a result of dioxin binding to a protein, the aryl hydrocarbon (Ah) receptor, which initiates a sequence of events at the cellular level, including the induction of enzymes capable of metabolizing chemicals to reactive intermediates (2, 3). Several studies have demonstrated that dioxin enhances the activity of cytochrome P-450 and Ah hydroxylase in respiratory tract epithelium. Research into the pulmonary toxicity of dioxin in laboratory animals has focused on the physiochemical properties of the Ah receptor and the carcinogenic potential of the cytochrome P-450 enzyme system in mice (4), rats (5, 6), and rabbits (7-12). A recent study found that gestational and lactational dioxin exposure to rats resulted in the induction of the cytochrome P-450 1A1 and 1A2 enzymes in the lungs of offspring that was long-lasting and gender-dependent (13). Both cytochrome P-450 enzymes have been found in human lung biopsy specimens (14).

In mice, the induction of cytochrome P-450 enzymes by dioxin in the lung was found similar to that in the liver (15). In rats (16, 17), the intratracheal administration of dioxin was associated with significant dose-related increases in hepatic enzymes as well, establishing the transpulmonary absorption of dioxin and the potential for pneumotoxicity. The most recent update of the Institute of Medicine's (IOM) *Veterans and Agent Orange* report states that it is biologically plausible that exposure to dioxin could be related to acute and chronic lung disease (18). Given that smoking is a major risk factor for these disorders and that the cytochrome P-450 enzymes also play a role in the activation of chemicals found in cigarette smoke, it is possible that dioxin may synergize the adverse effects of other chemicals (18).

20.1.1.3 Epidemiology

Early case reports of chemical workers exposed to dioxin-contaminated herbicides through industrial accidents have described acute respiratory effects, including irritation (19) and tracheo-bronchitis (20). The well-studied cohort that includes Seveso, Italy, residents exposed to substantial amounts of relatively pure dioxin following an industrial accident in 1976 is one of a few nonoccupationally exposed populations. The mortality experience of the cohort through 1991 (up to 15 years) (21, 22) was compared to a large population from the surrounding noncontaminated territory. Findings revealed that male residents closest to the plant at the time of the accident experienced a twofold increase in mortality from all respiratory diseases and a threefold increase for COPD mortality. The most recent update by Bertazzi and colleagues (23), which extended the follow-up to 20 years, reported results similar to earlier reports.

Studies of occupationally exposed workers revealed both nonmalignant respiratory morbidity and mortality. In one such study, workers exposed to dioxin had similar chest x-ray film findings when compared to unexposed referents. Although significant reductions were reported in FEV₁ and FVC among cigarette smokers only, pulmonary measures remained significantly reduced in the dioxin-exposed cohort relative to controls (24). Zober and colleagues (25) found that dioxin-exposed workers with severe chloracne had significantly more episodes of respiratory diseases overall, and specifically more upper respiratory tract infections and COPD than referents. In contrast, another occupational cohort did not exhibit increases in chronic bronchitis, COPD, or abnormal pulmonary function parameters, such as FEV₁ and FVC (26, 27).

Occupational mortality studies have generally demonstrated lower mortality rates for respiratory disease than expected (28-34). The largest of these, a multinational historical cohort study of 21,863 workers (32, 33), reported a statistically significant reduced rate (18%) of respiratory disease mortality for males based on 252 observed deaths. Few studies included dose of dioxin from biomonitoring data or estimated dose from job histories (31-34), and none adjusted their statistical analyses for the confounding effect of smoking.

No differences in chest x-ray film findings (35, 36) or pulmonary function tests have been found in studies of Vietnam veterans compared to non-Vietnam veterans (35). The frequency of self-reported physician-diagnosed chronic bronchitis was not significantly different between veterans who served in Southeast Asia (SEA) and veterans who served elsewhere (37). Furthermore, among those with service in SEA, the frequency of chronic bronchitis among herbicide handlers did not differ significantly from nonhandlers (37). Reports of other chronic respiratory conditions, including colds, hay fever, bronchitis, and emphysema, were higher among Australian Army Vietnam veterans compared to the general Australian population (38). Although results were not adjusted for smoking, the authors reported that the proportion of Vietnam veterans who had ever smoked was significantly higher than the proportion in the general population.

Similar to occupational studies, studies of the Air Force Ranch Hand cohort (39) reported that Vietnam veterans exhibited fewer deaths than the referent group for nonmalignant respiratory diseases, including one report of fewer than expected deaths from COPD, specifically (40). The mortality described by Dalager and Kang (41) of Army Chemical Corps veterans found a statistically nonsignificant excess of respiratory system diseases among Corps veterans who served in Vietnam compared to non-Vietnam veterans. Chemical Corps veterans were responsible for the storage, preparation, and applications of a variety of herbicides, including Agent Orange.

Overall, with the exception of the recent Seveso reports (21-23), mortality studies have failed to find any excess of respiratory disease mortality, and more often reported fewer deaths than expected. Many studies are hampered by one or more methodological limitations, including relatively few observed deaths, the absence of data on confounders such as smoking, and the reliance on death certificates for cause of death information. Furthermore, though a few of these studies assessed COPD mortality

separately, most grouped the wide range of respiratory disorders and assessed mortality for “all nonmalignant respiratory diseases” collectively.

In the 1987 and 1992 AFHS examinations, Ranch Hand participants were more likely than the Comparison group to have an abnormality of the thorax and lungs (42, 43); this finding was not seen in the 1997 examination (44). Ranch Hands and Comparisons did not differ on any respiratory measures in 1987, 1992, or 1997. In the analysis of the 1987 and 1992 follow-up examinations, a reduction in FVC, and as a consequence, an increase in the FEV₁ to FVC ratio, was noted in association with increasing serum dioxin levels. The 1997 examination also showed that Ranch Hands were more likely to have a history of bronchitis and asthma than the Comparison group. Ranch Hand officers exhibited a significantly higher prevalence of mild obstructive abnormality than the Comparison officers, which persisted after adjustment for smoking (44).

The IOM *Veterans and Agent Orange* reports, including the most recent 2002 update, consistently concluded that there is “inadequate or insufficient” evidence to determine the existence of an association between exposure to certain herbicides used in Vietnam and nonmalignant respiratory disorders (18).

20.1.2 Summary of Previous Analyses of the Air Force Health Study

20.1.2.1 1982 Baseline Examination Summary Results

The 1982 baseline examination explored a history of pulmonary disease by questionnaire and active pulmonary function by standardized spirometric techniques. These areas were of significant interest because of reported operational inhalation of Agent Orange by some Ranch Hand enlisted flyers and enlisted groundcrew.

The questionnaire revealed no group differences for historical diagnoses of tuberculosis and fungal infections, pneumonia, cancer, or chronic sinusitis and upper respiratory disease. At the physical examination, the Ranch Hand and Comparison unadjusted means for FEV₁ (percent predicted), FVC, and the ratio of FEV₁ to FVC were similar. Adjusted mean values were not calculated because of significant interactions (group-by-age for FEV₁ and FVC, group-by-smoking for the ratio of FEV₁ to FVC).

Exposure analyses showed two significant associations in the enlisted flyer and enlisted groundcrew strata, but neither was indicative of a linear dose-response relation. Overall, there were no pulmonary diseases, pulmonary function data, or associations of concern.

20.1.2.2 1985 Follow-up Examination Summary Results

Because of the lack of significant results from the pulmonary analyses from the baseline examination, pulmonary function (spirometric) studies were not performed during the 1985 follow-up examination. Collection of pulmonary data was limited to a questionnaire history of respiratory disease, physical examination of the thorax and lungs, and pulmonary abnormalities detected on a routine chest x-ray film. Mortality because of respiratory disease also was evaluated.

There were no significant group differences found for reported history of asthma, bronchitis, pleurisy, or tuberculosis based on the analyses adjusted for age and lifetime smoking, although there was a significant group-by-lifetime smoking interaction for pleurisy and tuberculosis. Ranch Hands who were moderate lifetime smokers (up to 10 pack-years) had a significantly increased prevalence of pleurisy and tuberculosis than did Comparisons who were moderate lifetime smokers.

Similarly, there were no significant group differences in the adjusted analyses for the radiological and clinical respiratory findings of thorax and lungs, asymmetrical expansion, hyperresonance, dullness, wheezes, rales, and the interpretation of the chest x-ray film. Also, the exposure index analyses revealed no consistent dose-response pattern.

20.1.2.3 1987 Follow-up Examination Summary Results

The pulmonary assessment was based on five self-reported respiratory illnesses, seven clinical observations, and eight laboratory measurements. The self-reported illnesses were based on participant-reported responses to the personal history form and the health history questionnaire and confirmed by medical records review. No evidence of a herbicide effect was detected in the assessment of the reported respiratory illnesses. No significant group differences were detected in the adjusted analyses when comparing all Ranch Hands with all Comparisons. Exploration of interactions did not reveal a consistent pattern indicating a herbicide effect. The adverse effects of smoking on pulmonary status were evident in all analyses.

20.1.2.4 Serum Dioxin Analysis of 1987 Follow-up Examination Summary Results

In general, there was no association between initial dioxin levels and the self-reported respiratory illnesses and clinical observations. For the majority of the laboratory measurements, there appeared to be an inverse association with initial dioxin. In the categorized dioxin analyses, the percentage of abnormalities did not differ significantly among the four dioxin categories for any of the questionnaire and physical examination variables, except under the analysis of an abnormality of the thorax and lung. In this case, Ranch Hands in the high dioxin category had a higher percentage of abnormalities than did Comparisons; but Ranch Hands in the low dioxin category had a lower percentage of abnormalities than did Comparisons. For the continuous variables, the means differed among the dioxin categories. For FVC, FEV₁, and forced expiratory flow maximum (FEF_{max}), the mean for the Ranch Hands in the unknown (termed as “background” in subsequent reports) category tended to be greater than the mean for the Comparisons in the background category, but the means for the low and high categories were less than the mean for the background category. In the analysis of the ratio of observed FEV₁ to observed FVC, this trend was reversed.

In the longitudinal analysis of the ratio of observed FEV₁ to observed FVC, there was a significant positive association with 1987 dioxin and a significant difference among the dioxin categories, with the mean increase from 1982 to 1987 in the high dioxin category greater than the mean increase from 1982 to 1987 in Comparisons.

In summary, the historical, physical examination, and most laboratory data analyzed from the 1987 follow-up examination for associations with serum dioxin revealed no evidence for an increased occurrence of pulmonary disease in the Ranch Hand cohort in relation to the body burden of dioxin. Analysis of two laboratory variables, FVC and the ratio of observed FEV₁ to observed FVC, yielded results that were consistent with subtle dose-response effects related to the body burden of dioxin in Ranch Hands.

20.1.2.5 1992 Follow-up Examination Summary Results

For the medical records and physical examination pulmonary variables, the group analysis revealed significant associations for bronchitis and thorax and lung abnormality. For enlisted flyers, significantly more Ranch Hands than Comparisons had bronchitis and a thorax and lung abnormality. The initial dioxin, categorized dioxin, and 1987 dioxin analyses for these variables did not confirm a dioxin dose-response relation.

For the laboratory variables, a statistically significant inverse relation was revealed between percent of predicted FVC and initial and 1987 dioxin for Ranch Hands. When Ranch Hands were contrasted with Comparisons, no significant differences were detected. Also, the analysis of the ratio of observed FEV₁ to observed FVC within Ranch Hands revealed a significant relation with initial dioxin indicating that the ratio increases (becomes closer to 1) for increasing levels of initial dioxin, which may have been due to the diminishing magnitude of FVC in the denominator of the ratio.

In the longitudinal analysis of the ratio of observed FEV₁ to observed FVC, there was a significant group difference for the enlisted flyers. The Ranch Hand enlisted flyers had a larger decrease in the ratio between 1982 and 1992 than did the Comparison enlisted flyers.

In summary, the historical, physical examination, and laboratory data analyzed for this assessment revealed no consistent evidence of an increased prevalence of pulmonary disease in the Ranch Hand cohort in relation to body burden of dioxin.

20.1.2.6 1997 Follow-up Examination Summary Results

To assess the pulmonary status for the 1997 AFHS follow-up examination, verified histories of asthma, bronchitis, and pneumonia were studied. A composite measure of thorax and lung abnormality, as determined from the presence of asymmetrical expansion, hyperresonance, dullness, wheezes, rales, COPD, or the physician's assessment of abnormality, also was analyzed. A routine chest x-ray film and five measures of pulmonary function using standard spirometric techniques were analyzed.

Few significant increases in adverse pulmonary conditions were observed for Ranch Hands, and isolated and inconsistent associations between the pulmonary endpoints and increased dioxin were seen. No consistent pattern or dose-response relation was evident. Ranch Hands in the background dioxin category exhibited a significantly higher percentage of abnormalities on the chest x-ray film than did Comparisons. Ranch Hand officers had a significantly higher prevalence of mild obstructive abnormality than did Comparison officers; the corresponding contrast was not significant in 1992, and officers were not analyzed as a separate stratum in 1982, 1985, or 1987. The meaning of this finding was unclear because the risk was not significantly increased in Ranch Hand enlisted groundcrew—the military occupation with the highest median dioxin level.

20.1.3 Parameters for the 2002 Pulmonary Assessment

20.1.3.1 Dependent Variables

The pulmonary assessment was based on questionnaire, physical examination, and laboratory data collected at the 2002 follow-up examination.

20.1.3.1.1 Medical Records Variables

In the self-administered family and personal history section, each study participant was asked whether he had ever experienced asthma, bronchitis, or pneumonia. The following International Classification of Diseases, 9th Revision, Clinical Modification (ICD-9-CM) codes were used: asthma: 493.0–493.92; bronchitis: 466.0–466.19, 490.0–491.9, and 494.0–494.1; and pneumonia: 480.0–486 and 487.0. Medical records review was accomplished to confirm reported pulmonary conditions and to identify any unreported conditions for each participant that attended the 2002 physical examination. These data from the 2002 physical examination were combined with data from the 1982 baseline examination and the 1985, 1987, 1992, and 1997 follow-up examinations to form a complete history of asthma, bronchitis, and pneumonia for each participant. These three variables were individually analyzed as measures of the pulmonary health status of each participant. The analyses performed in this chapter were based on the 1,951 participants who attended the 2002 follow-up examination. Participants with occurrences of asthma, bronchitis, or pneumonia before duty in SEA were excluded from the analyses of the respective variables.

20.1.3.1.2 Physical Examination Variable

Part of the pulmonary assessment was based on the results of the physical examination of the thorax and lungs. A composite variable—thorax and lung abnormality—was constructed based on the presence or

absence of asymmetrical expansion, hyperresonance, dullness, wheezes, rales, or COPD, as well as the physician's assessment of abnormality. This variable was coded as "abnormal" if any of these conditions was present and "normal" if none of these conditions was present. No participants were excluded for medical reasons from the analysis of this variable.

20.1.3.1.3 Laboratory Variables

The assessment of the laboratory examination data included the interpretation of pulmonary abnormalities detected on a routine chest x-ray film. This variable was coded as "normal" or "abnormal." The assessment also included the analysis of pulmonary physiologic data collected during the physical examination employing standard spirometry techniques. Numerous indices were derived, including FVC—a measurement of the amount of air in liters expelled from maximum inspiration to full expiration—and FEV₁ in liters, an index derived from the FVC that quantifies the amount of air expelled at 1 second. The values used for these variables were the percentages of predicted values rather than the actual volume or flow rate. The calculations of the predicted values included an adjustment for age and height, as prescribed by the American Thoracic Society (ATS). The laboratory used the same predictive values regardless of race. For these indices, lower values indicated greater compromise in the lung function. These two variables were analyzed as continuous and discrete variables. In addition, the ratio of observed FEV₁ to observed FVC was calculated as an index reflective of obstructive airway disease. Lower values of this ratio also indicated greater compromise in the lung function.

As a guideline for determining normal and abnormal categories for percent of predicted FVC and FEV₁, the following ATS classifications for lung impairment were used (45):

- Normal function: >80%
- Mild impairment: 60–80%
- Moderate impairment: 50–59%
- Severe impairment: ≤49%.

Participants with mild, moderate, or severe impairment (≤80%) were classified as abnormal, and participants with normal lung function (>80%) were classified as normal. The FVC and the FEV₁ were based on the percent of predicted values, and the predicted values were adjusted for age and height.

Loss of vital capacity and obstructive abnormality were classified by the examiner as none, mild, moderate, or severe and analyzed as part of the pulmonary assessment. Due to the low frequencies in the moderate and severe categories, these two categories were combined in the analysis of loss of vital capacity.

Participants judged by the Scripps Clinic pulmonologist to have inadequate technical quality were excluded from the analysis of FVC, FEV₁, the ratio of observed FEV₁ to observed FVC, loss of vital capacity, and obstructive abnormality. A spirometry test was considered to be of inadequate technical quality if any of the following criteria applied:

- There was extreme variability between the trials (extreme was defined as greater than 10%).
- The participant could not or did not exhale for at least 6 seconds.
- The "peak flow" was disproportionately low when compared to the other tests (requiring visual inspection of the graph).

20.1.3.2 Covariates

The effects of age, race, military occupation, current cigarette smoking (cigarettes /day), lifetime cigarette smoking history (pack-years), body mass index (kg/m²), and exposure to industrial chemicals (yes, no) were used in adjusted statistical analyses evaluating the pulmonary dependent variables.

Age, race, and military occupation were determined from military records. Body mass index was calculated as weight/(height)², where the weight was measured in kilograms and the height was measured in meters at the physical examination (46). For purposes of covariate associations for discrete dependent variables, body mass index was dichotomized as “not obese” (≤ 30 kg/m²) and “obese” (>30 kg/m²).

Current cigarette smoking and lifetime cigarette smoking history were based on questionnaire data. For lifetime cigarette smoking history, the respondent’s average smoking was estimated over his lifetime based on his responses to the 2002 questionnaire, with 1 pack-year defined as 365 packs of cigarettes smoked during a single year. The participant’s lifetime exposure through 1997 to industrial chemicals was updated with information reported in the 2002 questionnaire.

Current cigarette smoking was used as a covariate for the physical examination and laboratory variables only. Lifetime cigarette smoking history was used to investigate the cumulative effects of cigarette smoking.

20.1.4 Statistical Methods

Table 20-1 summarizes the statistical analysis performed for the 2002 pulmonary assessment. The first part of this table lists the dependent variables analyzed, source of the data, form of the data, cutpoints, covariates, exclusions, and statistical methods. The second part of the table further describes the covariates. A covariate was used in its continuous form whenever possible for all adjusted analyses. If the covariate was inherently discrete (e.g., military occupation), or if a categorized form was needed to develop measures of association with the dependent variables, the covariate was categorized as shown in Table 20-1.

Table 20-1. Statistical Analysis for the Pulmonary Assessment

Statistical Analysis:	U: Unadjusted analysis A: Adjusted analysis
Statistical Methods:	CS: Chi-square contingency table analysis (continuity-adjusted for 2x2 tables) GLM: General linear models analysis LR: Logistic regression analysis PR: Polytomous logistic regression analysis TT: Two-sample t-test

Four models were examined for each dependent variable given in Table 20-1. The analyses of these models are presented below. Further details on dioxin and the modeling strategy are found in Chapters 2 and 7, respectively. These analyses were performed both unadjusted and adjusted for covariates. These covariates are given in Table 20-1. Model 1 examined the relation between the dependent variable and group (i.e., Ranch Hand or Comparison). In this model, exposure was defined as “yes” for Ranch Hands and “no” for Comparisons without regard to the magnitude of the exposure. In an attempt to quantify exposure, three contrasts of Ranch Hands and Comparisons were performed along with the overall Ranch Hand versus Comparison contrast. These three contrasts compared Ranch Hands and Comparisons within each military occupational category (i.e., officers, enlisted flyers, and enlisted groundcrew). As described in previous reports and Table 2-4, the median level of exposure to dioxin was highest for enlisted groundcrew, followed by enlisted flyers, then officers.

During the 1987, 1992, 1997, and 2002 examinations, serum dioxin levels were measured by the Centers for Disease Control and Prevention (CDC) using high-resolution gas chromatography and high-resolution mass spectrometry and were reported in parts per trillion (ppt) on a lipid weight basis (47). These dioxin measurements are referred to as “lipid-adjusted.” All measures of dioxin used in this report were based on lipid-adjusted dioxin measurements.

Model 2 examined the relation between the dependent variable and an extrapolated initial dioxin measure for Ranch Hands who had a 1987 dioxin measurement greater than 10 ppt. The initial dioxin was calculated by extrapolating the 1987 dioxin level back in time to the end of the tour of duty that qualified a Ranch Hand veteran for inclusion in this study. If a Ranch Hand did not have a 1987 dioxin level, then the first dioxin measured, either at 1992, 1997, or 2002, was used to estimate the initial dioxin level. Regardless of when the dioxin was measured, Ranch Hand veterans with a level less than or equal to 10 ppt were excluded from statistical analyses based on Model 2. A statistical adjustment for body mass index at the time of the participant’s blood measurement of dioxin was included in this model to account for body mass index-related differences in elimination rate (48).

Model 3 divided the Ranch Hands examined in Model 2 into two categories based on their initial dioxin measures. These two categories were referred to as “low Ranch Hand” and “high Ranch Hand.” Two additional categories—Ranch Hands with serum dioxin levels at or below 10 ppt and Comparisons—were formed and included in the model. Ranch Hands with serum dioxin levels at or below 10 ppt were assigned to the “background Ranch Hand” category. If a Ranch Hand did not have a 1987 dioxin measurement, the first measured dioxin level was used. Another category was examined by combining the low and high Ranch Hand categories. This combination is referred to in the tables as the “low plus high Ranch Hand” category. These five categories—Comparisons, background Ranch Hands, low Ranch Hands, high Ranch Hands, and low plus high Ranch Hands—were used in Model 3 analyses. The relation between the dependent variable in each of the four Ranch Hand categories and the dependent variable in the Comparison category was examined. As in Model 2, a statistical adjustment for body mass index at the time of the participant's blood measurement of dioxin was included in this model for the

unadjusted and adjusted analyses of all dependent variables. One Ranch Hand without a dioxin measure was excluded from statistical analyses based on Model 3.

Model 4 examined the relation between the dependent variable and 1987 dioxin levels in all Ranch Hands with a dioxin measurement. If a Ranch Hand did not have a 1987 dioxin measurement, the first dioxin level obtained, either in 1992, 1997, or 2002, was extrapolated to the date of the 1987 physical examination. If the first dioxin level was not obtained in 1987 and was less than or equal to 10 ppt, it was not extrapolated to 1987 level, but was used at the measured value. One Ranch Hand without a dioxin measurement was excluded from statistical analyses based on Model 4.

The term “unadjusted” was used in the text and tables as follows: Models 1 and 4 did not adjust for any covariates. Models 2 and 3 adjusted only for body mass index at the time of the blood measurement for dioxin. The term “adjusted” was used in the text and tables as follows: Models 1 and 4 adjusted for the covariates shown in Table 20-1 unless otherwise specified by a footnote to the table. Models 2 and 3 additionally adjusted only for body mass index at the time of the blood measurement for dioxin.

Table 20-2 provides a summary of the number of participants with missing dependent variable and covariate data. In addition, the number of participants that were excluded from analyses is given.

Table 20-2. Number of Participants Excluded or with Missing Data for the Pulmonary Assessment

Variable	Variable Use	Group ^a		Dioxin (Ranch Hands Only) ^b		Categorized Dioxin ^c	
		Ranch Hand	Comparison	Initial Dioxin	1987 Dioxin	Ranch Hand	Comparison

^a777 Ranch Hands and 1,174 Comparisons for group.

^b424 Ranch Hands for initial dioxin; 776 Ranch Hands for 1987 dioxin.

^c776 Ranch Hands and 1,174 Comparisons for categorized dioxin.

Note: DEP = Dependent variable.

COV = Covariate.

EXC = Exclusion.

20.2 RESULTS

20.2.1 Dependent Variable-covariate Associations

The pulmonary dependent variables were tested for associations with each of the covariates used in the adjusted analyses. The complete results are presented in Appendix F, Table F-12. These associations were pairwise between the dependent variable and the covariate and were not adjusted for any other covariates. A brief summary of the pattern of significant ($p \leq 0.05$) dependent variable-covariate associations is described in the following paragraphs. In the discussion of the results below, low levels were considered adverse for FVC and FEV₁.

As age increased, the number of abnormalities for asthma, bronchitis, pneumonia, thorax and lungs, x-ray interpretation, and FEV₁ increased. As age increased, FEV₁ and the ratio of observed FEV₁ to observed FVC decreased. More obstructive abnormality and moderate or severe loss of vital capacity were observed in the older participants, but more mild loss of vital capacity was seen in the younger participants.

As expected, a lower mean FVC and FEV₁ were seen in Blacks, as well as an increased number of abnormally low measurements. The ratio of observed FEV₁ to observed FVC was lower in non-Blacks because the difference between Blacks and non-Blacks in FVC was larger than the difference in FEV₁ between Blacks and non-Blacks. Loss of vital capacity was higher among Black participants, but the presence of an obstructive abnormality was more prevalent among non-Black participants.

Thorax and lung abnormalities were more prevalent among enlisted flyers. Mean FVC levels were lower for enlisted personnel than for officers, and the percentage of abnormally low FVC measurements was higher for enlisted personnel than officers. Mean FEV₁ levels were lowest for enlisted flyers, and the percentage of abnormally low FEV₁ measurements was highest for enlisted flyers. The ratio of observed FEV₁ to observed FVC was lower for officers and enlisted flyers than for enlisted groundcrew. Mild loss of vital capacity was more prevalent among enlisted personnel than officers. Obstructive abnormalities were also more prevalent among enlisted flyers, followed by officers, then enlisted groundcrew.

The percentage of thorax and lung abnormalities and abnormal x-ray interpretations increased as the number of cigarettes per day currently smoked increased. Former and moderate current cigarette smokers (no more than one pack a day, on average) exhibited the higher percentages of FVC abnormalities and loss of vital capacity. FEV₁ and the ratio of observed FEV₁ to FVC decreased as current cigarette smoking increased. The percentage of abnormally low FEV₁ also increased as current cigarette smoking increased. A higher prevalence of and more severe obstructive abnormalities were seen as current cigarette smoking increased.

Bronchitis, thorax and lung abnormalities, and abnormal x-ray interpretations were more prevalent in the heaviest smokers. FVC and FEV₁ decreased as lifetime cigarette smoking history increased, as did the ratio of observed FEV₁ to observed FVC. The prevalence of abnormally low FVC and FEV₁ values increased as lifetime cigarette smoking history increased. A higher prevalence of and more severe loss of vital capacity and obstructive abnormality were seen as lifetime cigarette smoking history increased.

As body mass index increased, FVC and FEV₁ decreased. An increased number of abnormally low measurements was seen for FVC and FEV₁ in obese participants. As body mass index decreased, the ratio of observed FEV₁ to observed FVC decreased because the association between body mass index and FVC was stronger than the association between body mass index and FEV₁. Mild, moderate, or severe loss of vital capacity was observed more often in obese participants. Mild and severe obstructive abnormalities were less prevalent in obese participants, but moderate obstructive abnormalities were more prevalent in obese participants.

More thorax and lung abnormalities and low FVC measurements were observed in participants who had been exposed to industrial chemicals than in those who had not been exposed to industrial chemicals.

20.2.2 Exposure Analysis

The following section presents results of the statistical analyses of the dependent variables shown in Table 20-1. Dependent variables are grouped into three sections: (1) medical records variables, derived from the questionnaire that was administered in the 2002 follow-up and previous AFHS examinations and verified by a review of medical records, (2) variables obtained during the 2002 physical examination, and (3) pulmonary laboratory variables.

20.2.2.1 Medical Records Variables

20.2.2.1.1 Asthma

All unadjusted and adjusted results from the analyses of a history of asthma were nonsignificant for Models 1 through 4 (Table 20-3(a-h): $p > 0.11$ for each analysis).

Table 20-3. Analysis of Asthma

20.2.2.1.3 Pneumonia

Both the unadjusted and adjusted Model 1 analyses of a history of pneumonia displayed a significant difference between Ranch Hands and Comparisons within the enlisted flyer stratum (Table 20-5(a,b): Unadjusted Relative Risk [RR]=1.91, p=0.049; and Adjusted RR=1.94, p=0.046). A total of 19.7 percent of Ranch Hand enlisted flyers exhibited a history of pneumonia compared to 11.4 percent of Comparison enlisted flyers. All other Model 1 contrasts and all unadjusted and adjusted results from Models 2 through 4 were each nonsignificant (Table 20-5(a-h): p>0.09 for all remaining analyses).

20.2.2.2 Physical Examination Variable

20.2.2.2.1 Thorax and Lung Abnormality

The Model 1 unadjusted analysis of thorax and lung abnormality revealed a significant difference between Ranch Hands and Comparisons when examined across all occupations and within the enlisted flyer stratum (Table 20-6(a): Unadjusted RR=1.28, p=0.039; and Unadjusted RR=1.68, p=0.041 for all participants and for enlisted flyers, respectively). Each significant result was nonsignificant after adjusting for covariates (Table 20-6(b): p=0.226 and p=0.141 for all participants and for enlisted flyers,

respectively). All other Model 1 unadjusted and adjusted contrasts and each result from the analyses of Model 2 were nonsignificant (Table 20-6(a-d): $p > 0.19$ for each result).

A significant difference between Ranch Hands in the low and high dioxin categories combined and Comparisons was revealed within the unadjusted Model 3 analysis of thorax and lung abnormality (Table 20-6(e): Unadjusted RR=1.37, $p=0.025$). The difference was nonsignificant after adjusting for covariates (Table 12-6(f): $p=0.479$). All other Model 3 unadjusted and adjusted contrasts, as well as each result from Model 4, were nonsignificant (Table 20-6(e-h): $p > 0.07$ for each analysis).

20.2.2.3 Laboratory Examination Variables

20.2.2.3.1 X-ray Interpretation

The Model 2 unadjusted analysis of the x-ray interpretation revealed a significant inverse association between initial dioxin and the x-ray interpretation (Table 20-7(c): Unadjusted RR=0.80, p=0.040). After adjusting for covariates, however, the association was nonsignificant (Table 20-7(d): p=0.117). All other results of the unadjusted and adjusted analyses of the x-ray interpretation were nonsignificant for Models 1, 3, and 4 (Table 20-7(a,b,e-h): p>0.09 for each analysis).

20.2.2.3.2 FVC (Continuous)

Results from the unadjusted and adjusted analyses of the continuous form of FVC were nonsignificant for Models 1 and 2 (Table 20-8(a-d): $p > 0.29$ for each analysis).

The Model 3 unadjusted analysis of the continuous form of FVC displayed significant differences in means between Ranch Hands in the low dioxin category and Comparisons and between Ranch Hands in the low and high dioxin categories combined and Comparisons (Table 20-8(e): difference of adjusted means=-3.86 percent, $p=0.001$; and difference of adjusted means=-2.58 percent, $p=0.005$, respectively). In the adjusted analysis, the contrast between Ranch Hands in the low dioxin category and Comparisons remained significant (Table 20-8(f): difference of adjusted means=-2.52 percent, $p=0.031$), while the contrast between Ranch Hands in the low and high dioxin categories combined and Comparisons became nonsignificant (Table 20-8(f): $p=0.052$). Ranch Hands in the low dioxin category had a lower adjusted mean FVC (93.22 percent) than Comparisons (95.74 percent). All other Model 3 contrasts, both unadjusted and adjusted, were nonsignificant (Table 20-8(f): $p > 0.26$ for all remaining contrasts).

A significant inverse association between FVC and 1987 dioxin levels was found in the Model 4 unadjusted analysis (Table 20-8(g): Slope=-1.419, $p < 0.001$). After adjusting for covariates, the association was nonsignificant (Table 20-8(h): $p=0.109$).

^aRelative risk for a twofold increase in 1987 dioxin.

20.2.2.3.4 FEV₁ (Continuous)

The Model 3 unadjusted analysis of the continuous form of FEV₁ revealed significant differences in adjusted means between Ranch Hands in the low dioxin category and Comparisons and between Ranch Hands in the low and high dioxin categories combined and Comparisons (Table 20-10(e): difference of adjusted means=-4.11 percent, p=0.002; and difference of adjusted means=-2.12 percent, p=0.033, respectively). Both results became nonsignificant after adjusting for covariates (Table 20-10(f): p=0.064 and p=0.203, respectively). All other Model 3 results, as well as all other results from the unadjusted and adjusted analyses of FEV₁ from Models 1, 2, and 4, were each nonsignificant (Table 20-10(a-h): p>0.12 for each analysis result).

20.2.2.3.5 FEV₁ (Discrete)

A significant difference between Ranch Hands in the low dioxin category and Comparisons was found within the unadjusted Model 3 analysis of the discrete form of FEV₁ (Table 20-11(e): Unadjusted RR=1.39, p=0.039). After adjusting for covariates, the difference was nonsignificant (Table 20-11(f): p=0.390). Similar to the analysis of the continuous form of FEV₁, all other Model 3 contrasts, as well as all contrasts from Models 1, 2 and 4, were each nonsignificant from the unadjusted and adjusted analyses of the discrete form of FEV₁ (Table 20-11(a-h): p>0.22 for each result).

20.2.2.3.6 Ratio of Observed FEV₁ to Observed FVC

All Model 1 unadjusted and adjusted analyses of the ratio of observed FEV₁ to observed FVC were nonsignificant (Table 20-12(a,b): p>0.07 for each contrast).

Both the unadjusted and adjusted Model 2 analyses of the ratio of observed FEV₁ to observed FVC displayed significant results (Table 20-12(c,d): Slope=-0.032, p=0.004; and Adjusted Slope=-0.023, p=0.039, respectively). Because of the transformation used, this result indicated that the ratio of observed FEV₁ to observed FVC increased as initial dioxin increased. The adjusted mean ratio of observed FEV₁ to observed FVC was 0.729 for the low initial dioxin category, 0.740 for the medium initial dioxin

category, and 0.752 for the high initial dioxin category. A significant difference of means between Ranch Hands in the high dioxin category and Comparisons was found within the Model 3 unadjusted analysis of the ratio of observed FEV₁ to observed FVC (Table 20-12(e): difference of adjusted means=0.013, p=0.027). After adjusting for covariates, the difference became nonsignificant (Table 20-12(f): p=0.220). All other unadjusted and adjusted Model 3 contrasts were also nonsignificant (Table 20-12(e,f): p>0.05 for each remaining contrast).

The unadjusted Model 4 analysis of the ratio of observed FEV₁ to observed FVC was significant (Table 20-12(g): Slope=-0.031, p<0.001). After adjusting for covariates, however, the association was nonsignificant (Table 20-12(h): p=0.083).

20.2.2.3.7 Loss of Vital Capacity

All results from the unadjusted and adjusted analyses of loss of vital capacity from Models 1, 2, and 4 were nonsignificant, both unadjusted and adjusted for covariates (Table 20-13(a-d,g,h): p>0.12 for each contrast).

The unadjusted Model 3 analysis showed significantly more Comparisons than Ranch Hands in the background dioxin category with a mild loss of vital capacity (Table 20-13(e): Unadjusted RR=0.47, p=0.027). After adjusting for covariate effects, however, the contrast was nonsignificant (Table 20-13(f): p=0.075), as were all other unadjusted and adjusted Model 3 contrasts (Table 20-13(e-h): p>0.14 for each remaining contrast).

Table 20-13. Analysis of Loss of Vital Capacity**(a) MODEL 1: RANCH HANDS VS. COMPARISONS – UNADJUSTED**

^aRelative risk for a twofold increase in 1987 dioxin.

20.2.2.3.8 *Obstructive Abnormality*

The Model 1 adjusted analysis showed fewer Ranch Hands than Comparisons with a mild obstructive abnormality within the enlisted flyer stratum (Table 20-14(b): Adjusted RR=0.59, $p=0.046$). Ranch Hand enlisted flyers had fewer mild obstructive abnormalities (34.1%) than Comparison enlisted flyers (43.1%). All other Model 1 unadjusted and adjusted contrasts were nonsignificant (Table 20-14(a,b): $p>0.08$ for each remaining contrast).

Each contrast examined in the unadjusted Model 2 analysis displayed an inverse significant association between initial dioxin and obstructive abnormality (Table 20-14(c): mild vs. none, Unadjusted RR=0.82, $p=0.019$; moderate vs. none, Unadjusted RR=0.67, $p=0.016$; and severe vs. none, Unadjusted RR=0.50, $p=0.022$). Each of these results indicated a decrease in obstructive abnormality as initial dioxin increased. In the adjusted analysis the contrasts of moderate and severe obstructive abnormality remained significant (Table 20-14(d): Adjusted RR=0.64, $p=0.023$; and Adjusted RR=0.44, $p=0.036$, respectively). The mild obstructive abnormality contrast became nonsignificant in the adjusted analysis (Table 20-14(d): $p=0.470$). More Ranch Hands in the low dioxin category had moderate (11.7%) or severe obstructive abnormalities (4.4%) than Ranch Hands in the medium dioxin category (8.6% and 4.3% for moderate and severe obstructive abnormalities, respectively) or Ranch Hands in the high dioxin category (2.9% and 0.0% for moderate and severe obstructive abnormalities, respectively).

All Model 3 contrasts examined in both the unadjusted and adjusted analyses of obstructive abnormality were nonsignificant (Table 20-14(e, f): $p>0.05$ for each contrast).

An inverse significant association between obstructive abnormality and 1987 dioxin levels was seen in the Model 4 unadjusted analysis when a mild occurrence of obstructive abnormality was contrasted with no obstructive abnormality (Table 20-14(g): Unadjusted RR=0.88, $p=0.009$). The association became nonsignificant after adjusting for covariate effects (Table 20-14(h): $p=0.901$). All other Model 4 unadjusted and adjusted contrasts were nonsignificant (Table 20-14(g,h): $p\geq 0.07$).

20.3 DISCUSSION

The AFHS assessed respiratory health by investigating the occurrence of asthma, bronchitis, and pneumonia, and the presence of an abnormality on physical examination of the thorax and lungs and as seen on a chest x-ray film. The pulmonary assessment also investigated lung function as measured by FVC, FEV₁, the FEV₁ to FVC ratio, and the severity of obstructive abnormality and loss of vital capacity. The criteria for an abnormal physical exam—any extraneous sound or percussion abnormality—may have led to the classification of more participants as abnormal than those who truly have chronic lung disease. Therefore, verified pulmonary diseases, radiographic abnormality, or spirometric abnormality may be more useful as a measure of compromised lung function than of abnormality on the physical examination. Respiratory endpoints were adjusted for the covariates of age, race, military occupation, body mass index, current and lifetime smoking history, and exposure to industrial chemicals.

Tests of association were performed between the dependent variable and each of the covariates used in the adjusted analyses. Many of the associations observed in the AFHS were consistent with patterns seen in clinical practice in pulmonary medicine. Age was associated with most of the respiratory endpoints. As expected, bronchitis, pneumonia, thorax or lung abnormalities, and radiographic abnormalities were all more prevalent in older participants. The decreased FEV₁ and FEV₁ to FVC ratio that was observed in older participants was consistent with published data and the known biologic loss of FEV₁ with increasing age (49). As expected, race was significantly associated with pulmonary function. FVC and FEV₁ were lower among Blacks compared to non-Blacks. Current smoking history and lifetime smoking history were associated with greater thorax and lung abnormalities, radiographic abnormalities, loss of vital capacity, loss of FEV₁, and obstructive abnormality. The associations observed in univariate analyses may be influenced by associations with other covariates, particularly smoking history.

The 2002 pulmonary assessment found no association between herbicide or dioxin exposure and asthma. This was consistent with prior follow-up examinations in which no differences in the prevalence of asthma between Ranch Hands and Comparisons have been seen.

The association between herbicide or dioxin exposure and the occurrence of respiratory infections was sporadic and inconsistent. The 2002 assessment found an increased history of pneumonia between Ranch Hand enlisted flyers compared with Comparison enlisted flyers; however, no dose-response effect was observed because there was no increased occurrence among enlisted groundcrew, who had the highest median dioxin level, and other models of dioxin exposure did not show a positive dose-response. The difference in the history of pneumonia between Ranch Hand and Comparison enlisted flyers also was observed during the 1992 physical examination, but was not significant in other AFHS examinations.

No differences in thorax and lung abnormalities on the physical examination or on an inspection of the chest x-ray film were found between Ranch Hands and Comparisons. Ranch Hands were more likely to have thorax and lung abnormalities in the 1987 and 1992 AFHS follow-up examinations, but no difference was observed in the 1997 and 2002 examinations. Chest x-ray abnormalities did not differ in any of the AFHS examinations.

In the 2002 examination, some differences in pulmonary function were observed. A statistically significant decrease in FVC was observed in the Ranch Hands in the low dioxin category relative to the Comparisons (93.22 percent vs. 95.74 percent). There was no clear dose response, because Ranch Hands in the high dioxin category had higher mean FVC levels than Ranch Hands in the low dioxin category. No significant differences in FVC were observed in the other models. No difference in FEV₁ was observed in any of the analyses. The ratio of FEV₁ to FVC increased among Ranch Hands as the initial dioxin level increased and the 1987 dioxin level increased. None of these statistically significant

differences in pulmonary function were clinically significant and the results of the ratio of FEV₁ to FVC analyses do not indicate an adverse dose-response effect.

No positive dose response relation was observed in the development of an obstructive abnormality between Ranch Hands and Comparisons. In fact, Ranch Hand enlisted flyers were less likely to have a mild obstructive abnormality than Comparison enlisted flyers. In addition, the percentage of participants with moderate and severe obstruction decreased as initial dioxin levels increased.

From the results of the 2002 data alone and in conjunction with the results from earlier AFHS follow-up examinations, there was no consistent evidence to suggest that herbicide or dioxin exposure was associated with ill effects on respiratory health.

20.4 SUMMARY

The pulmonary assessment was based on questionnaire data, which was subsequently verified by a review of medical records, physical examination data, and pulmonary laboratory data. Associations with herbicide exposure (i.e., group – Model 1), initial dioxin (Model 2), categorized dioxin (Model 3), and 1987 dioxin levels (Model 4) were examined for each variable in the pulmonary assessment. The significant adjusted results are discussed in the sections below.

20.4.1 Model 1: Group Analysis

The results of the group analysis are provided in Table 20-15. A significantly greater percentage of Ranch Hand than Comparison enlisted flyers had a history of pneumonia. Significantly fewer Ranch Hand enlisted flyers than Comparison enlisted flyers were judged to have a mild obstructive abnormality.

D: Discrete form of dependent variable.

The p-value was given if $p \leq 0.05$. The relative risk was given in parentheses for a significant result from the analysis of a discrete dependent variable.

A capital "NS" denotes a nonsignificant positive association. A lowercase "ns" denotes a nonsignificant inverse association.

20.4.2 Model 2: Initial Dioxin Analysis

Associations between initial dioxin and the dependent variables were examined in the Model 2 analyses. The results are shown in Table 20-16. As initial dioxin increased, the ratio of the observed FEV₁ to the observed FVC increased. The percentage of Ranch Hands with a moderate obstructive abnormality decreased as initial dioxin increased. The percentage of Ranch Hands with a severe obstructive abnormality decreased as initial dioxin increased.

^aA negative slope was considered adverse for this variable.

^bA positive slope was considered adverse for this variable; a negative slope implies an increase in the ratio because of the data transformation used.

Note: NS or ns: Not significant ($p > 0.05$).

C: Continuous form of dependent variable.

D: Discrete form of dependent variable.

The p-value was given if $p \leq 0.05$. The relative risk was given in parentheses for a significant result from the analysis of a discrete dependent variable. The slope was given in parentheses for a significant result from the analysis of a continuous dependent variable.

A capital "NS" denotes a nonsignificant positive association. A lowercase "ns" denotes a nonsignificant inverse association.

20.4.3 Model 3: Categorized Dioxin Analysis

The results of the categorized dioxin analysis are presented in Table 20-17. Ranch Hands in the low dioxin category had a significantly lower mean FVC than Comparisons. No other significant differences between Ranch Hands and Comparisons were found in Model 3 analyses.

^aA negative slope was considered adverse for this variable.

^bA positive slope was considered adverse for this variable; a negative slope implies an increase in the ratio because of the data transformation used.

Note: NS or ns: Not significant ($p > 0.05$).

C: Continuous form of dependent variable.

D: Discrete form of dependent variable.

The p-value was given if $p \leq 0.05$. The relative risk was given in parentheses for a significant result from the analysis of a discrete dependent variable. The slope was given in parentheses for a significant result from the analysis of a continuous dependent variable.

A capital "NS" denotes a nonsignificant positive association. A lowercase "ns" denotes a nonsignificant inverse association.

20.4.5 Summary of Significant Results

Table 20-19 summarizes the significant results ($p \leq 0.05$) for the adjusted analyses that were performed for the pulmonary assessment. The dependent variable and its table reference are listed, along with the model and the contrast or description of the model. The p-value is provided along with analysis statistics that correspond to the type of analysis that was performed (either continuous or discrete). A description of the analysis and the statistics that are presented is referenced under the "Note" column and is explained in footnotes.

Table 20-19. Summary of Results from Significant Adjusted Analyses in the Pulmonary Assessment

Dependent Variable (Table Reference)	Model	Contrast or Description	p-Value	Analysis Statistics	Adjusted Mean or Percent Abnormal	Note
Pneumonia (20-5)	1	RH vs. C, Enlisted Flyer	0.046	1.94 (1.01,3.72)	RH: 19.7% C: 11.4%	(a)
FVC (20-8) ^a	3	Low RH vs. C	0.031	-2.52 (-4.81,-0.23)	RH: 93.22 percent C: 95.74 percent	(b)
Ratio of Observed FEV ₁ to Observed FVC (20-12) ^b	2	RH (1987 dioxin >10 ppt): Initial Dioxin	0.039	-0.023 (0.011)	Low: 0.729 Medium: 0.740 High: 0.752	(c)
Obstructive Abnormality (20-14)	1	RH vs. C, Enlisted Flyer – mild vs. none	0.046	0.59 (0.35,0.99)	RH: 34.1% C: 43.1%	(a)
	2	RH (1987 dioxin >10 ppt): Initial Dioxin – moderate vs. none	0.023	0.64 (0.43,0.94)	Low: 11.7% Medium: 8.6% High: 2.9%	(d)
	2	RH (1987 dioxin >10 ppt): Initial Dioxin – severe vs. none	0.036	0.44 (0.20,0.95)	Low: 4.4% Medium: 4.3% High: 0.0%	(d)

Table 20-19. Summary of Results from Significant Adjusted Analyses in the Pulmonary Assessment (Continued)

- (a): Discrete variable: adjusted relative risk and 95% confidence interval were presented; percent abnormal was presented for each exposure group in contrast.
- (b): Continuous variable: difference of adjusted means and 95% confidence interval were presented; adjusted means were presented for each dioxin category in contrast.
- (c): Continuous variable: slope and standard error were presented and were based on natural logarithm of 1.0 - dependent variable) versus \log_2 (initial dioxin); adjusted means were presented for each of three initial dioxin categories.
- (d): Discrete variable: adjusted relative risk and 95% confidence interval were presented for a twofold increase in initial dioxin; percent abnormal was presented for each of three initial dioxin categories.

^aA smaller group mean was considered adverse for this variable.

^bA positive slope was considered adverse for this variable; a negative slope implies an increase in the ratio because of the data transformation used.

Note: RH = Ranch Hand.
C = Comparison.

Model 2: Low = 32–79 ppt; Medium = >79–199 ppt; High = >199 ppt (Ranch Hands who had a 1987 dioxin measurement greater than 10 ppt).

Model 3: Background (Ranch Hand): 1987 dioxin \leq 10 ppt.
Low (Ranch Hand): 1987 dioxin > 10 ppt, 10 ppt < initial dioxin \leq 118 ppt.
High (Ranch Hand): 1987 dioxin > 10 ppt, initial dioxin > 118 ppt.

20.5 CONCLUSION

The AFHS assessed respiratory health by investigating the occurrence of asthma, bronchitis, and pneumonia, and the presence of an abnormality on physical examination of the thorax and lungs and as seen on a chest x-ray film. The pulmonary assessment also investigated lung function as measured by FVC, FEV₁, the FEV₁ to FVC ratio, and the severity of obstructive abnormality and loss of vital capacity.

Statistically significant findings indicating adverse effects on Ranch Hands were limited to pneumonia and FVC. A significantly greater percentage of Ranch Hand than Comparison enlisted flyers had a history of pneumonia. Ranch Hands in the low dioxin category had a significantly lower mean FVC than Comparisons. No other significant findings adverse to Ranch Hands were observed.

No consistent evidence suggested that herbicides or dioxin were associated with ill effects on respiratory health.

21 CONCLUSIONS

21.1 INTRODUCTION

This section summarizes the conclusions drawn from the statistical analyses of data from the 2002 follow-up examination of the Air Force Health Study (AFHS). This analysis was restricted to participants who attended the 2002 follow-up examination and was an extension of the baseline, 1985, 1987, 1992, and 1997 follow-up examinations. Health endpoints measured at the 2002 examination were analyzed for associations with herbicide exposure and body burden of serum dioxin. In addition, the cumulative disease prevalence from the time of duty in Southeast Asia (SEA) to 2002 was analyzed for associations with herbicide exposure and serum dioxin body burden. A full explanation of the study design and methodology, terminology, and interpretive considerations is provided in Chapters 1 through 8 of this report.

In January 1962, President John F. Kennedy approved a program of aerial herbicide spraying for the purpose of defoliation and crop destruction in support of military operations in the Republic of Vietnam (RVN). This program, code-named Operation Ranch Hand, dispersed herbicides in South Vietnam from 1962 to 1971. Members of the Ranch Hand cohort were responsible for the spraying of the herbicides in the RVN. Comparison veterans flew and serviced C-130 transport planes in SEA during the same time period that the Ranch Hand unit was active but did not engage in spraying operations.

Throughout this report, dioxin levels were used as measures of both exposure to dioxin itself and exposure to dioxin-contaminated herbicides, including Agent Orange. Direct contrasts of Ranch Hand and Comparison veterans address the hypothesis of health effects attributable to any herbicide exposure experienced by Ranch Hand veterans during Operation Ranch Hand. Models involving dioxin levels address the hypothesis that health effects change with the amount of exposure. Serum dioxin levels were used as a measure of exposure to dioxin-contaminated herbicides because it was expected that as exposure to such herbicides increased, serum dioxin levels should increase. The serum dioxin levels, therefore, served as a direct biomarker of exposure to dioxin-contaminated herbicides. Currently, no other direct measure or estimate of herbicide exposure is available to address hypothetical dose-response relations with health. Some indirect measures, such as self-report of skin contact among enlisted groundcrew, or simply being a Ranch Hand enlisted groundcrew member, are valuable alternatives because dioxin measures suggest that enlisted groundcrew experienced the heaviest exposures. Reported skin exposure was not addressed in this report, but enlisted groundcrew status was used in contrasts of Ranch Hand and Comparison veterans. The use of dioxin as a surrogate measure of exposure to dioxin-contaminated herbicides is consistent with the goal of the study, which is to determine whether health effects exist and can be attributed to occupational exposure to Agent Orange.

21.2 STUDY PERFORMANCE ASPECTS

A total of 1,951 veterans participated in the 2002 follow-up examination. Participation was voluntary and consent forms were signed at the examination site. Of the 1,043 eligible Ranch Hands, 777 (74.5%) participated in the 2002 follow-up examination. A total of 737 of the 1,093 eligible Original Comparisons (67.4%) and 437 (46.0%) of the 951 eligible Replacement Comparisons participated in the 2002 follow-up examination. There was no evidence of compliance bias in this study.

Nearly the same percentages of Ranch Hands, Original Comparisons, and Replacement Comparisons refused due to health reasons. The number of Ranch Hands who refused for health reasons, logistical

reasons, passive refusals, and hostile refusals were approximately equal. The Comparisons, however, were classified as passive refusals or refused for logistical reasons more often than being classified as a hostile refusal or providing health concerns as the reason for refusal.

Reported health status (excellent, good, fair, or poor) differed with age, military rank, and compliance status among those reporting their health status at the time of scheduling for the 2002 follow-up examination. After adjusting for age, military rank, race, and compliance status, Ranch Hands were found to be more likely to report fair or poor health than Comparisons. This pattern of Ranch Hands reporting poorer health had been observed since the baseline examination.

Work loss due to illness or injury in the 6 months prior to the 2002 follow-up physical examination and participant-reported medication were used as alternative indicators of health. No difference was seen in reported work loss or in medication use between Ranch Hands and Comparisons. A further analysis of self-perception of health, as reported by fully compliant participants at the 2002 follow-up examination, is given in Chapter 9, General Health Assessment.

21.3 STATISTICAL MODELS

The analysis of the 2002 follow-up examination results used four statistical models to evaluate the relation between the health status of study participants and their herbicide exposure or serum dioxin levels. The first model specified contrasts between Ranch Hands and Comparisons using these groups as a proxy for herbicide exposure and did not incorporate serum dioxin measurements. The remaining three models all incorporated serum dioxin measurements in either 1987 dioxin levels or an estimate of an initial dioxin level based on a first-order extrapolation to the end of the qualifying tour of duty in SEA. The four models are summarized as follows:

- Model 1: Ranch Hands versus Comparisons, for all military occupations (officer, enlisted flyer, enlisted groundcrew) combined and for each military occupation separately
- Model 2: Estimated initial serum dioxin levels at end of qualifying tour using Ranch Hand participants with greater than 10 parts per trillion (ppt) of first-measured lipid-adjusted dioxin
- Model 3: Ranch Hands categorized according to 1987 and initial serum dioxin levels (background, low, and high) versus Comparisons
- Model 4: First-measured lipid-adjusted serum dioxin using Ranch Hands only. The measurement was extrapolated to 1987 only if the measurement was over 10 ppt.

Statistical analyses often were applied to clinical endpoints in continuous form (i.e., original measurements), as well as in discrete form (i.e., measurements grouped into categories based on abnormal levels). Analyses also were performed to account for the effects that demographic and personal characteristics (covariates) may have had on the clinical measurements. Such analyses were termed “adjusted analyses.” The relation between health and the measures of herbicide exposure or dioxin level in the four models described above are summarized in the next section. The relation between covariates and measures of herbicide exposure or dioxin level are described in Chapter 8.

21.4 CLINICAL RESULTS

This section provides the conclusions from the analyses of the 12 clinical areas—general health, neoplasia, neurology, psychology, gastrointestinal, dermatology, cardiovascular, hematology, renal, endocrine, immunology, and pulmonary. Tables G-1 through G-24 of Appendix G present the results of

the exposure analyses for each of the four models for more than 300 health endpoints analyzed in the 12 clinical chapters. Appendix H contains a summary of significant results ($p \leq 0.05$) for the adjusted analyses that were performed for the group and dioxin analyses (Models 1-4) in the 12 clinical areas. All findings described in the subsequent sections were significant and adjusted for covariates.

21.4.1 General Health Assessment

Four variables were included in the general health assessment: self-perception of health, appearance of illness or distress during the examination, relative age, and body mass index. For the evaluation of self-perception of health, each participant was asked to rate his health (excellent, good, fair, poor) compared to other people his age. In addition, a board-certified internist examined the participants for the appearance of acute illness or distress (yes or no). The internist assessed whether each subject appeared younger than, older than, or the same as his stated age to determine relative age. Body mass index was computed based on height and weight recorded at the physical examination.

Self-perception of health, appearance of illness, and relative age appearance were not found to be associated with herbicide exposure (Ranch Hand versus Comparison) or dioxin level. Body mass index was positively associated with 1987 dioxin, possibly reflecting the pharmacokinetics of dioxin elimination.

21.4.2 Neoplasia Assessment

During the 2002 health interview, each study participant was asked a series of questions on the occurrence of cancer since the date of his last health interview. The self-reported conditions were verified by a medical records review and combined with cancer information collected at previous AFHS examinations. For chest x-ray findings that were reported as needing follow-up at the 2002 physical examination, the AFHS made every effort to contact and encourage participants to see their physicians. The participants were recontacted to determine a final diagnosis. Some possible neoplastic conditions were discovered by the physicians at the physical examination. Contingent upon participant authorization, suspicious skin lesions were biopsied and the pathology determined; no other invasive procedures were used to detect systemic neoplasms.

Skin neoplasms were analyzed by behavior type and cell type. Systemic neoplasms were analyzed by behavior and anatomical site. All skin and systemic neoplasms and all malignant skin and systemic neoplasms also were analyzed. Analyses were conducted on prostate-specific antigen, which was used to detect prostate enlargement and prostate cancer.

Contrasts of Ranch Hands with Comparisons by military occupation showed significant results only for officers. Ranch Hand officers had an increased risk of basal cell carcinoma and, consequently, nonmelanoma skin cancers. Ranch Hand officers also had an increased risk of malignant systemic neoplasms. The analysis of malignant systemic neoplasms of the colon and rectum and of the urinary system showed a greater risk for Ranch Hand officers.

The prevalence of a malignant systemic neoplasm of the urinary system increased as initial dioxin in Ranch Hands increased.

When comparing categorized levels of dioxin, significant results were primarily found when comparing Ranch Hands in the low dioxin category with Comparisons. Ranch Hands in the low dioxin category had an increased risk of a basal cell carcinoma and, consequently, this pattern was also seen in nonmelanoma skin cancers, malignant skin cancers, and all skin neoplasms (benign, malignant, and uncertain behavior).

The risk of a skin neoplasm of uncertain behavior or unspecified nature was also increased for Ranch Hands in the low dioxin category.

The prevalence of a malignant systemic neoplasm, combined across sites, also was increased for Ranch Hands in the low dioxin category relative to Comparisons. Results of the site-specific analyses included increased risks to Ranch Hands in the low dioxin category for malignant systemic neoplasms of the bronchus or lung, colon or rectum, and prostate. These findings led to an increased risk for Ranch Hands in the low dioxin category for all neoplasms and all malignant neoplasms (combining skin and systemic). Ranch Hands in the background category had an increased risk of a malignant systemic neoplasm of the urinary system. Ranch Hands in the low and high dioxin categories combined had an increased prevalence of a skin neoplasm of any type.

The associations between dioxin levels and the likelihood of developing cancer were seen primarily for Ranch Hand officers and Ranch Hands in the low dioxin category, which were the lower-exposed subgroups, on average. Some of these associations also may have been due to chance or to a lack of adjustment for a factor not considered in these analyses.

21.4.3 Neurology Assessment

The neurology assessment included the evaluation of cranial nerve function, peripheral nerve status, and central nervous system (CNS) coordination processes based on a physical examination. The cranial nerve function incorporated smell, visual fields, light reaction, ocular movement, facial sensation, corneal reflex, jaw clench, smile, palpebral fissure, balance, gag reflex, speech, tongue position relative to midline, palate and uvula movement, and shoulder shrug. Peripheral nerve status was assessed by light pinprick, light touch (with cotton sticks), visual inspection of muscle mass (and palpation, if indicated), three deep tendon reflexes (patellar, Achilles, and biceps), and the Babinski reflex. In addition, indices of bilateral symmetric distal sensory or sensorimotor polyneuropathy were analyzed based on testing of ankle and toe flexor strength, equilibrium (Romberg sign), Achilles reflex, light touch, pinprick, vibration at the ankle, and joint position of the left and right great toes. The evaluation of CNS coordination processes was based on tremor, coordination, Romberg sign, and gait.

Ranch Hands were more likely to have abnormal visual fields and an abnormal cranial nerve index than Comparisons. More Ranch Hand officers had hereditary or degenerative diseases and sluggish or absent Achilles reflexes than Comparison officers.

Positive associations were seen between balance and coordination and extrapolated initial dioxin levels.

Analyses based on dioxin category showed an increased risk of abnormal visual fields in the background dioxin category and an increased risk of abnormal facial sensation for Ranch Hands in the low dioxin category. Ranch Hands in both the background and low dioxin categories showed an increased risk of abnormalities for the cranial nerve index, a composite index of the individual 15 cranial nerve endpoints studied in this assessment. More Ranch Hands in the high dioxin category had an abnormal reaction to pinprick and absent patellar reflexes than Comparisons.

Analyses of 1987 dioxin levels showed a positive association with the absence of the patellar reflex.

Based on the results of the analysis of pinprick, balance, and the patellar reflex in this follow-up examination, there was some limited support of an association between dioxin levels and neurological disease related to the peripheral nerves. In conclusion, there was no clinical evidence to support a relation between dioxin and cranial nerve function or other CNS processes.

21.4.4 Psychology Assessment

The Symptom Checklist-90-Revised (SCL-90-R) and the Wechsler Memory Scale-Revised (WMS-R) were used in the psychology assessment. The SCL-90-R was used to measure symptomatic psychological distress in terms of anxiety, depression, hostility, interpersonal sensitivity, obsessive-compulsive behavior, paranoid ideation, phobic anxiety, psychoticism, and somatization. The SCL-90-R was also used to measure three global distress indices: global severity index, positive symptom total, and positive symptom distress index. The WMS-R was an instrument used for appraising major dimensions of memory functions in adolescents and adults, including memory for verbal and figural stimuli, meaningful and abstract material, and delayed as well as immediate recall. The psychological disorders of psychoses, alcohol and drug dependence, anxiety, and other neuroses, which were verified through a review of medical records, also were studied.

Ranch Hands had a smaller percentage of abnormally high scores on the SCL-90-R interpersonal sensitivity, paranoid ideation, and positive symptom total scales. Ranch Hand enlisted groundcrew had an increased mean score on the delayed recall portion of the WMS-R Logical Memory test. The percentage of abnormally high scores on the SCL-90-R phobic anxiety scale score decreased with increased 1987 dioxin levels. None of the memory functioning and psychopathology scales was adversely associated with exposure to herbicides or dioxin.

21.4.5 Gastrointestinal Assessment

The gastrointestinal assessment consisted of the analysis of (1) 7 categories of liver disorders, (2) hepatomegaly (enlarged liver), as determined at the 2002 physical examination, and (3) 28 laboratory measurements. Laboratory tests are generally considered the most reliable method for identifying acute liver disease because digestive symptoms are frequently nonspecific and intermittent and liver disorders are commonly asymptomatic. Furthermore, the detection of liver enlargement on the sole basis of a physical examination may be confounded by factors such as obesity or obstructive airway disease.

Positive stool hemoccult results were increased and mean C4 complement was decreased among Ranch Hand officers. Among enlisted groundcrew, Ranch Hands had greater percentages of abnormal alkaline phosphatase and triglyceride values than Comparisons. Ranch Hand enlisted groundcrew had a higher mean haptoglobin level.

As initial dioxin increased, C4 complement levels decreased and the percentage of Ranch Hands with abnormally low C4 complement values increased.

Ranch Hands in the low dioxin category, high dioxin category, and low and high dioxin categories combined had increased percentages of abnormally high triglyceride values. Ranch Hands in the low dioxin category and low and high dioxin categories combined had an increased prevalence of abnormally high α -1-antitrypsin values than did Comparisons. In the background dioxin category, Ranch Hands had a higher mean prothrombin time than Comparisons. In the low and high dioxin categories combined, Ranch Hands had a higher mean haptoglobin level than Comparisons.

The percentage of Ranch Hands with abnormal triglyceride values increased as 1987 dioxin increased.

There was no clear relation between herbicide exposure or dioxin levels and any of the abnormalities, although based on the analysis of triglycerides, a subtle relation between dioxin and lipid metabolism cannot be excluded.

21.4.6 Dermatology Assessment

The dermatology assessment included the occurrence of self-reported acne and physical examination. Data collected included the lifetime occurrence of acne, the occurrence of acne in relation to time of duty, and the location of acne (e.g., temples, eyes, ears). Acneiform lesions, acneiform scars, comedones, inclusion cysts, depigmentation, and hyperpigmentation were analyzed, as determined by a dermatologic examination.

The lifetime occurrence of acne and the occurrence of acne after service in SEA were greater for Ranch Hand enlisted groundcrew, the subgroup with the highest median dioxin level. Increases in self-reported acne in all Ranch Hand dioxin categories relative to Comparisons also were observed. Further study of reported lifetime acne showed that acne after service in SEA (post-SEA acne) was greater in all Ranch Hand dioxin categories relative to Comparisons only for participants who did not have acne prior to service in SEA (pre-SEA acne). As dioxin levels increased, the duration of acne increased for participants who reported acne only after service in SEA.

There were no findings of chloracne in the Ranch Hand and Comparison groups. The reasons for the higher occurrence of acne in Ranch Hand enlisted groundcrew are unknown. Reported acne was increased in Ranch Hand enlisted groundcrew, in parallel with an increase found at the 1992 physical examination. The interpretation of the increased reporting of acne among enlisted groundcrew is uncertain. Physical examination for acneiform lesions, acneiform scars, comedones, inclusion cysts, depigmentation, and hyperpigmentation, which may be suggestive of chloracne, revealed no patterns supporting a relation with herbicide exposure or dioxin.

21.4.7 Cardiovascular Assessment

In the cardiovascular assessment, data regarding cardiac function and heart disease history were studied. Variables evaluated included the lifetime history of essential hypertension, heart disease, myocardial infarction, and stroke or transient ischemic attack. The physical examination included indices of central cardiac function and peripheral vascular function. Assessment of central cardiac function was made by measuring systolic and diastolic blood pressures, heart sounds, and a resting electrocardiograph. Peripheral vascular function was assessed by presence or absence of carotid bruits, various pulse-point readings, a resting blood pressure index, measures of intermittent claudication and vascular insufficiency, and funduscopic examination of small vessels. Major risk factors for cardiovascular disease included male gender, family history, high blood cholesterol, high blood pressure, diabetes mellitus, cigarette smoking, and physical inactivity.

The presence of heart disease was found to be higher among Ranch Hands than Comparisons in enlisted flyers. Ranch Hands were found to have a lower presence of abnormal pulses, both in all participants and in the officer stratum.

An increased percentage of Ranch Hands in the high dioxin category were found to have abnormally high diastolic blood pressure. Ranch Hands in both the low dioxin category and the low and high dioxin categories combined were found to have a lower mean systolic blood pressure. Similarly, a smaller percentage of Ranch Hands in both the low dioxin category and the low and high dioxin categories combined had an abnormally high systolic blood pressure.

A lower percentage of Ranch Hands in both the background dioxin category and the low dioxin category had abnormal posterior tibial pulses. In addition, abnormal peripheral pulses were found among a lower percentage of Ranch Hands in the low dioxin category. As the 1987 dioxin level increased, the percentage of participants with abnormally high systolic blood pressure decreased.

The prevalence of cardiovascular disease was not increased in the Ranch Hand cohort. In only one analysis, that of diastolic blood pressure noted above, was there any evidence of an increased risk with increased body burden of dioxin.

21.4.8 Hematology Assessment

The hematology assessment included data from the laboratory examination. Fourteen hematologic variables were examined, including red blood cell (RBC) count, white blood cell (WBC) count, hemoglobin, hematocrit, and platelet count. The following absolute WBC counts were examined: segmented neutrophils, neutrophilic bands, lymphocytes, monocytes, eosinophils, and basophils. Fibrinogen, erythrocyte sedimentation rate (ESR), and RBC morphology were also analyzed.

The mean platelet count was increased among Ranch Hand enlisted flyers. Ranch Hand enlisted groundcrew experienced an increased risk of abnormal RBC morphology.

Ranch Hands in the high dioxin category and in the low and high dioxin categories combined had a higher percentage of abnormal RBC morphology results. In addition, Ranch Hands in the low and high dioxin combined category had an increased mean ESR. Ranch Hands in the low dioxin category had a decreased risk of abnormally low hematocrit levels.

For both the continuous and discrete forms of WBC, an inverse relation between WBC counts and 1987 dioxin levels was observed.

These data did not suggest an association between dioxin and any hematologic condition.

21.4.9 Renal Assessment

The 2002 follow-up examination included several laboratory measures of renal function and a questionnaire to ascertain historic renal disease among participants. Urinary protein and urine specific gravity were determined by dipstick methods, and hematuria and leukocyturia were measured by high-powered microscopic examination. Serum creatinine, blood urea nitrogen, urinary microalbumin, and urinary creatinine were assayed based on specimens collected from all participants. A creatinine clearance estimate was estimated using serum creatinine, age, and weight. The questionnaire provided data that identified participants with a history of kidney disease, defined as kidney trouble, kidney stones, or kidney infections, which was confirmed by a review of medical records. High values were considered adverse for all of the laboratory measurements except creatinine clearance.

Ranch Hands had a lower mean serum creatinine level, as well as a lower mean urinary microalbumin to urinary creatinine ratio. The mean urinary microalbumin to urinary creatinine ratio was higher for Comparisons than for Ranch Hands in the low dioxin category. Lower mean creatinine clearance values were observed more often among Comparisons than among Ranch Hands in the low dioxin category. An increase in mean creatinine clearance values was observed as 1987 dioxin levels increased.

The results from the renal assessment indicated no association between any marker of kidney disease and dioxin. In particular, there was no evidence that exposure to dioxin was associated with renal dysfunction, kidney stones, reduction in glomerular filtration rate, incidence of proteinuria or albuminuria, or cells in the urine.

21.4.10 Endocrinology Assessment

Questionnaire, physical examination, and laboratory data collected at the AFHS 2002 follow-up examination were used in the endocrinology assessment. Information from the questionnaire, which was

subsequently verified, included data on thyroid function and disease and diabetes and diabetic control. The physical examination of endocrine function included manual palpation of the thyroid gland and testes. Results from laboratory assays included data on 17 laboratory variables related to diabetes, glucose, insulin, gonadotropins, and thyroid hormones.

Ranch Hands had a higher mean thyroid-stimulating hormone level than Comparisons, primarily due to an increased mean among Ranch Hand officers. Ranch Hand officers also exhibited an increased mean luteinizing hormone level, an increased risk of abnormal 2-hour postprandial urinary glucose, and abnormal free testosterone.

Mean fasting insulin and the risk of diabetes requiring insulin control increased with initial dioxin. C-peptide and time to diabetes onset decreased as initial dioxin increased.

The risk of diabetes requiring insulin control was increased in the Ranch Hand high dioxin category.

An increase in the risk of diabetes requiring oral hypoglycemic or insulin control was observed as 1987 dioxin levels increased. Time to diabetes onset decreased as 1987 dioxin levels increased. The risk of an abnormally high hemoglobin A1c increased with 1987 dioxin levels.

Some findings appeared inconsistent with the results presented above, such as a decrease in the risk of 2-hour postprandial urinary glucose abnormalities with 1987 dioxin levels.

These findings appeared consistent with the previously noted association between Type 2 diabetes and dioxin in Ranch Hand veterans. Increased risks of diabetes requiring insulin control were found with initial dioxin, in the high dioxin category, and with 1987 dioxin levels. In contrast, associations between dioxin level and thyroid or gonadal hormone abnormalities were unlikely to be clinically important.

21.4.11 Immunology Assessment

The assessment of the immune system included the results of cell surface marker studies, absolute lymphocytes, quantitative immunoglobulins, and a lupus panel. Quantification of cell surface marker (phenotypic) studies was carried out with the use of reagent mouse monoclonal antibodies. Absolute lymphocytes, which indicate the density of lymphocytes in the blood, and immunoglobulins, which measure the ability of a specific B-cell subgroup to secrete a specific antibody class of molecules, were studied. Six measures from a lupus panel, which was considered a screening assay for a wide spectrum of autoimmune disorders, such as rheumatoid arthritis or systemic lupus erythematosus, also were analyzed.

Analyses revealed a positive correlation between initial dioxin level and CD20+ cell counts and a lower mean IgM level for Ranch Hand enlisted flyers.

In the lupus panel, a positive association was found between initial dioxin level and the presence of the antinuclear antibody (ANA), but the association did not appear to support a dose-response relation. Analyses of the rheumatoid factor and the anti-smooth muscle antibody revealed several differences, but the prevalence of abnormalities decreased as dioxin increased.

There was an increasing prevalence of a positive ANA in Ranch Hands with increasing initial dioxin levels. When looking at the individual autoantibodies, however, there were no consistent findings to support the presence of the ANA. Overall, there was no consistent or interpretable association between any measure of immune function and herbicide or dioxin exposure.

21.4.12 Pulmonary Assessment

The AFHS assessed respiratory health by investigating the occurrence of asthma, bronchitis, and pneumonia, and the presence of an abnormality on physical examination of the thorax and lungs and as seen on a chest x-ray film. The pulmonary assessment also evaluated lung function as measured by forced vital capacity (FVC), forced expiratory volume in 1 second (FEV₁), the FEV₁ to FVC ratio, and the severity of obstructive abnormality and loss of vital capacity.

An increased percentage of Ranch Hand enlisted flyers had a history of pneumonia. Ranch Hands in the low dioxin category had a decreased mean FVC. No other significant findings adverse to Ranch Hands were observed.

No consistent evidence suggested that herbicides or dioxin were associated with ill effects on respiratory health.

21.5 STRENGTHS AND LIMITATIONS OF THIS REPORT

This study was limited by the sample size (preventing the study of rare diseases), imperfect exposure metrics, and the possible existence of other confounding factors that have not been measured. Study strengths included complete record verification of most health conditions, rigorous quality control, good participant compliance, complete population ascertainment, many years of follow-up, and adjustment for many known confounding factors.

Although many covariates were considered in this report, there are others that may be unknown and some that were measured but not used in this report. Some of the analyses in this report, therefore, may be biased due to lack of adjustment for an important confounding covariate. Recent studies of cancer in Ranch Hand veterans found that the calendar period of service in the Ranch Hand unit is an important covariate, for example, but this fact was discovered after the analytical plan for this report was already in place.

The study benefited from a two-tiered management structure based on separate but parallel program management and technical teams, an independently appointed and administered Advisory Committee, periodic review by the Institute of Medicine, and collaboration through interagency agreements between the Air Force and the Centers for Disease Control and Prevention, making the dioxin measurements possible. The management structure, oversight, carefully managed funding and contracting, and outstanding contractors all contributed to uniformly rigorous quality assurance, attention to detail, and timely task completion.

21.6 SUMMARY

Consistent with previous reports, current data indicate a significant and potentially meaningful adverse relation between serum dioxin levels and diabetes. A significant dose-response-related association was found with 1987 dioxin levels in Ranch Hands. The finding was supported by a dioxin-related increase in disease severity, a decrease in the time from exposure to first diagnosis, and an increase in fasting glucose and hemoglobin A1c in Ranch Hands. Similar patterns were observed in 1987, 1992, and 1997.

Based on the analysis of triglycerides, a subtle effect of dioxin on lipid metabolism cannot be excluded.

21.7 CONCLUSION

Diabetes represents the most important dioxin-related health problem seen in the AFHS.

APPENDIX A

APPENDIX A. POLICIES AND PROCEDURES FOR BLOOD COLLECTION AND PROCESSING FOR DIOXIN ASSAY

This appendix contains the following Scripps Clinic Policies and Procedures documents:

1. Specimen Processing
2. Shipping Specimens to Brooks City-Base.

POLICIES AND PROCEDURES

Scripps Clinic
Department of Pathology (211C)
10666 N. Torrey Pines Rd.
La Jolla, CA 92037

LABORATORY SECTION: **SPECIMEN PROCESSING**

TITLE: **AIR FORCE HEALTH STUDY - SPECIMEN PROCESSING**

AUTHOR: _____ ISSUE DATE: **March-92**

REVISED BY: **Sharon Bodmer and Kathy Parker** REVISION DATE: **June-02**

1.0 PURPOSE

- 1.1 To ensure all specimens are processed in a standardized consistent manner throughout the AFHS.

2.0 SCOPE

- 2.1 Applies to medical laboratory assistants who process blood and urine specimens for the AFHS.

3.0 MATERIALS

- 3.1 60-mL (2-oz.) glass jar (provided by AF)
- 3.2 1.8-mL nunc vial (provided by AF)
- 3.3 Test tubes
- 3.4 Electric pipetter
- 3.5 Disposable pipettes (provided by AF)
- 3.6 Test tube racks
- 3.7 Caps for aliquot tubes
- 3.8 13 x 100 mm aliquot tubes
- 3.9 1.0-mL nunc vials
- 3.10 Clear protective tape
- 3.11 Centrifuge
- 3.12 Scale
- 3.13 Ziplock freezer bags
- 3.14 Wipes

4.0 PROCEDURE

- 4.1 Processing will begin when the first specimens are drawn at approximately 0645 day 1.
- 4.2 Serum specimens should be allowed to clot for a minimum of 15 minutes.
- 4.3 Specimens that need to be centrifuged should be balanced and centrifuged at 3,000 revolutions per minute at 2 to 8 °C for 10 minutes.
- 4.4 Fasting first-morning urines will be collected from all participants on day 1 at their hotel.

Laboratory Section: Specimen Processing

Title: Air Force Health Study - Specimen Processing Day 1

- 4.4.1 Specimen processors will aliquot urines from screw-cap collection cups into one KOVA tube and one urine collection tube.
- 4.4.2 Place one KOVA tube in test tube rack labeled **Air Force UA**. Place the urine collection tube in test tube rack labeled **Air Force MA**. Deliver the **Air Force UA** to hematology and deliver the **Air Force MA** to chemistry once all fasting urines are aliquoted.
- 4.5 One lavender tube of blood labeled **AFCBCC**, **AFCBCD**, and **AFESR** will be drawn and placed in a test tube rack labeled **Air Force Hematology**.
 - 4.5.1 These specimens will be delivered to hematology once they are all drawn, along with their aliquot labels (**AFCBCC**) and two slide labels.
 - 4.5.2 These specimens will be kept at room temperature until delivery.
- 4.6 One blue (citrate) tube of blood labeled **AFPTP** and **AFFIB** will be drawn and placed in a test tube rack labeled **Air Force Coagulation**.
 - 4.6.1 This specimen will be delivered to coagulation once it is drawn.
 - 4.6.2 These specimens will be kept at room temperature until delivery.
- 4.7 One lavender tube of blood labeled **AFTCEL** will be drawn and placed in a test tube rack labeled **Air Force TCEL**.
 - 4.7.1 These specimens will be delivered to flow cytometry once they are drawn.
- 4.8 It is essential that these specimens remain at room temperature from draw time until delivery.
- 4.9 One 7-mL SST tube of blood labeled **AFCHEM** will be drawn and placed in a rack labeled **Air Force Chemistry**.
 - 4.9.1 Once clotted, these tubes will be centrifuged first.
 - 4.9.2 Once centrifuged, these tubes will be returned to the rack labeled **Air Force Chemistry** and delivered to a designated bench in Chemistry.
- 4.10 Four 7-mL SST tubes labeled **AFPRPF** and **AFRIA** will be drawn and placed in a rack labeled **Air Force PRPF & RIA**.
 - 4.10.1 Once clotted, these tubes will be centrifuged.
 - 4.10.2 Once centrifuged, these tubes will be returned to the rack labeled **Air Force PRPF & RIA** and delivered to a designated bench in Chemistry.
- 4.11 Two 7-mL SST tubes of blood labeled **AFLP** and **AFTH** will be drawn and placed in a rack labeled **Air Force LP&TH**.
 - 4.11.1 Once clotted, these tubes will be centrifuged.
 - 4.11.2 Once centrifuged, these tubes will be returned to the rack labeled **Air Force LP&TH** and delivered to a designated bench in Chemistry.
- 4.12 One 4-mL SST tube labeled **AFHA** will be drawn and placed in a rack labeled **Air Force HA**.
 - 4.12.1 Once clotted, these tubes will be centrifuged.
 - 4.12.2 Once centrifuged, these tubes will be returned to the rack labeled **Air Force HA** and delivered to a designated bench in Chemistry.
- 4.13 One 7-mL SST, one 10-mL plain red-top, and one lavender tube of blood labeled **AFDIA** will be drawn for diabetic testing and placed in three racks labeled **Air Force DIA (Lavender)**, **Air Force DIA (SST 7 mL)**, and **Air Force DIA (Plain Red 10 mL)**.
 - 4.13.1 Once the 7-mL SST and the plain red-top tubes are clotted, they will be centrifuged. The lavender tube should not be centrifuged.
 - 4.13.2 Once the 7-mL SST tube is centrifuged it will be returned to a rack labeled **Air Force DIA (SST 7 mL)** and delivered to a designated bench in Chemistry.

Laboratory Section: Specimen Processing

Title: Air Force Health Study - Specimen Processing Day 1

- 4.13.3 The lavender tube should also be delivered to a designated bench in Chemistry.
- 4.13.4 Once centrifuged the 10-mL plain red-top tube must be aliquoted into two aliquot tubes and placed into the three racks labeled **Air Force Proinsulin, Air Force Proinsulin Unknown, and Air Force Proinsulin Save**. Fill out sendout paperwork for the Air Force Proinsulin tests and place each specimen and requisition into a ziplock freezer bag.
- 4.14 One yellow tube of blood labeled **AFW** will be drawn for archive, kept at room temperature, and placed in a rack labeled **Air Force Whole Blood (Yellow)**.
 - 4.14.1 Gently agitate tube by hand two times immediately after blood is drawn. Label each of the 10 nunc vials with slide labels. Mix well just before pipetting into nunc vials.
 - 4.14.2 Cover label on nunc vial with clear protective tape.
 - 4.14.3 Pipette 1 mL into each of nine 1.2 nunc vials with the remainder of blood going into the tenth vial.
 - 4.14.4 Place in nunc tube box and freeze at -70 °C.
- 4.15 Six 10-mL plain red-top and one 4-mL lavender tubes (furnished by the Air Force) of blood labeled **AFX** will be drawn on all participants for dioxin testing and placed in a rack labeled **Air Force Dioxin**.
 - 4.15.1 Once clotted (approximately 20 to 30 minutes), centrifuge all specimens for 15 minutes.
 - 4.15.2 Label one 1.8-mL nunc vial (furnished by the Air Force) with a slide label. Cover the label of the nunc vial using clear protective tape. Pipette 1.8 mL of plasma from lavender top tube and transfer it into the 1.8-mL prelabeled nunc vial (furnished by the Air Force).
 - 4.15.3 Label the 60-mL (2-oz.) glass jar furnished by the Air Force with **TRANS1** aliquot label. Initial this label. Cover the label with clear protective tape.
 - 4.15.4 Transfer all serum from the six red-top tubes into the glass jar. Any serum that has become mixed must be transferred into a clean 10-mL red-top tube and recentrifuged. If tubes are recentrifuged, transfer remaining serum into glass jar.
 - 4.15.5 Replace the Teflon-lined, green screw cap and freeze.
 - 4.15.6 Place upright in a -70 °C freezer and store at the same temperature until shipment to Brooks City-Base.
- 4.16 Eight 10-mL SST tubes labeled **AFSAVE** will be drawn for serum storage and placed in a rack labeled **Air Force SAVE**.
 - 4.16.1 Once clotted, these tubes will be centrifuged.
 - 4.16.2 Once centrifuged, these tubes will be matched up with four previously labeled Mylar[®]-covered aliquot tubes (three 13 x 100 mm and one small aliquot tube).
 - 4.16.3 Serum in amounts on label for **Air Force SAVE** will be aliquoted into the tubes prelabeled as follows:
 - SAV10A**
 - SAV10B**
 - SAV10C**
 - SAV5D**.
 - 4.16.4 Once aliquoted, these specimens will be placed in a rack labeled **Air Force SAVE** (keeping all four tubes together). Rack will be placed in a designated -70 °C freezer for storage until shipped to Brooks City-Base.

Laboratory Section: Specimen Processing

Title: Air Force Health Study - Specimen Processing Day 1

- 4.17 One 4-mL SST tube of blood labeled **AF2HIN** will be drawn for 2-hour postprandial glucose and insulin level and placed in a rack labeled **Air Force 2HIN**.
 - 4.17.1 Once clotted, these tubes will be centrifuged.
 - 4.17.2 Once centrifuged, these tubes will be returned to the rack labeled **Air Force 2HIN** and delivered to a designated bench in Chemistry.
- 5.0 Urines for 2-hour postprandial glucose will be collected in screw-cap collection cups. Specimen processor will pour urine into KOVA tube and place in the rack labeled **Air Force 2HUR** and delivered to a designated bench in Hematology.
- 6.0 Blood tubes that have been aliquoted will be stored in the specimen processing freezer for 2 days.
- 7.0 Restock and inventory all supplies.

POLICIES AND PROCEDURES

Scripps Clinic
Department of Pathology (211C)
10666 N. Torrey Pines Rd.
La Jolla, CA 92037

LABORATORY SECTION: **SPECIMEN PROCESSING**

TITLE: **AFHS - SHIPPING SPECIMENS TO BROOKS CITY-BASE**

AUTHOR: _____ ISSUE DATE: **April-92**

REVISED BY: **Sharon Bodmer & Kathy Parker** REVISION DATE: **April-02**

1.0 PURPOSE:

- 1.1 To ensure the consistent packaging and shipping of all specimens to Brooks City-Base.

2.0 SCOPE:

- 2.1 Applies to all medical laboratory assistants who pack and ship specimens for the Air Force Health Study (AFHS).

3.0 PROCEDURE

- 3.1 Serum for dioxin labeled **TRANS1**, serum for archive labeled **SAVE**, 10 1-mL nunc vials of whole blood for archive, and 1 1.8-mL nunc vial of serum for lipid studies will be shipped twice a week to Brooks City-Base.
- 3.2 Specimens will be shipped Tuesdays and Thursdays and include all specimens from that week.
- 3.3 Each participant should have 4 serum aliquots, 10 whole blood aliquots, 1 60-mL (2-oz.) glass jar of serum for dioxin, and 1 1.8-mL nunc vial unless specimens were unattainable.
 - 3.3.1 If specimens were unattainable, indicate on participant group list the reason for reduced number of specimens or lack of specimens (i.e., no show, short draw, patient refused).
- 3.4 Specimens will be stored at -70 °C until shipped.
 - 3.4.1 On Tuesdays and Thursdays, all specimens obtained from the previous day's participants will be shipped.
 - 3.4.1.1 As each participant's specimens are packed for shipping, check off the name of the participant on the participant group list. This will become the participant shipping list. When completed, fax this participant shipping list to Brooks City-Base, attention Vince Elequin at (210) 536-3567. Make a copy of the shipping list and give to Sharon Bodmer. Send original copy of shipping list with specimens.
 - 3.4.2 Once all specimens are packed, add a sufficient amount of dry ice (approximately 15 lbs.) on top of the specimens to keep them frozen during overnight shipment. Buffer with additional bubble pack as needed. Seal the Styrofoam® container with tape.
 - 3.4.3 Put the participant shipping list in a ziplock bag and place the bag on top of the Styrofoam container inside the shipping box. Close the shipping box and seal with strapping tape.
 - 3.4.4 Specimens will be mailed via FedEx® overnight mail.

Laboratory Section: Specimen Processing

Title: Air Force Health Study – Shipping Specimens to Brooks City-Base

Fill out the overnight mail slip as follows:

Deputy Chief, Air Force Health Study
AFRL/HEDA
2655 Flight Nurse, Bldg 807
Brooks City-Base, TX 78235-5137
ATTN: Vince Elequin

This will be billed to acct. #20-227-7530.

- 3.4.5 Take all shipping boxes to shipping department before 1430 on Tuesdays and Thursdays.

APPENDIX B

APPENDIX B. PHYSICAL EXAMINATION METHODS

This appendix contains the following items:

1. The Examiners' Handbook *
2. The data collection forms.

** The Examiners' Handbook presented here is as it appeared in the Air Force Health Study Statement of Work dated 27 August 2001 with updates through 31 January 2002. Some minor changes and procedural modifications were made prior to the commencement of the physical examinations and are not reflected here.*

ADDENDUM A

STATEMENT OF WORK

FOR THE

AIR FORCE HEALTH STUDY

2002 FOLLOW-UP EXAMINATION

AIR FORCE HEALTH STUDY
EXAMINERS HANDBOOK

31 January 2002

Air Force Health Study Examiner's Handbook

A. General Instructions

The Air Force Health Study is a multiyear prospective study to determine whether Air Force personnel who were engaged with spraying herbicides in Vietnam have developed adverse health effects from exposure to herbicides and their contaminant, 2,3,7,8-tetrachlorodibenzo-p-dioxin (dioxin). Detailed surveys of the scientific literature have been used to design the questionnaires, the physical examination protocol and select laboratory tests.

This phase of the study involves a follow-up cross-sectional assessment of each subject's health at the time of the examination. It is important that examiners remain unaware of the subject's exposure status (Ranch Hand, Comparison). The physician examiner is tasked to examine each subject and objectively record findings. The examining physician is not, and cannot be expected to arrive at any definitive diagnoses, since the full history and physical examination findings and laboratory results shall not be available. An independent diagnostician employed by the contractor shall evaluate medical history, laboratory results and physical examination findings. The diagnostician shall formulate diagnoses and differential diagnoses, if appropriate. Additional procedures to treat or evaluate emergency or urgent medical conditions shall be directed only by the diagnostician. In addition, the diagnostician shall present a detailed analysis and debriefing to each study subject and provide a copy of the analysis for the subject's personal physician, if authorized by the subject.

The physicians performing examinations for the study should be aware that the report of the examination will become a permanent record. The report shall be referenced not only in the near future as the cross-sectional data is analyzed, but also during future follow-up phases of the study. These examinations shall define the health status of the subjects at a point in time and shall establish the presence or absence of abnormal physical findings. After statistical review of the study groups, these findings may permit definition of chronic or latent effects due to exposure. An inaccurate examination may lead to fallacious results in two ways: a presumed syndrome may be defined which does not in fact exist, or a syndrome which in fact exists may not be defined with enough validity to warrant further action.

The examining physician is responsible for recording a complete and detailed report of the physical examination. The examining physician shall fill out all forms and check the forms for completeness and logical consistency before the patient leaves the examining room. In this role, the examining physician is tasked with collecting evidence of the presence or absence of physical signs of abnormality only. All items on the physical examination report form must be completed. It is imperative that physicians make such additional remarks as may be required to adequately describe existing physical abnormalities. Since clinical endpoints have not been well-defined following exposure to Agent Orange, the examining physician and the diagnostician must not definitively ascribe abnormalities to herbicide exposure during the course of the examination or during the debriefings. If, during the examination, the physician discovers evidence of acute serious illness requiring immediate treatment, the normal emergency or urgent care procedure of the medical facility would apply. The Air Force is not responsible for the cost of such emergency or urgent care.

The debriefing physician shall ask each participant if he received additional testing or additional medical treatment during the physical examination time period and shall annotate any such circumstances or results on the debriefing form. The ultimate value of the study will lie in the collection of complete, accurate and, whenever possible, quantitative data permitting the most stringent and powerful statistical analysis. For this reason, the physical examination protocol requires, whenever possible, exact measurements and well defined semi-quantitative indicators of abnormalities.

B. Conduct of the Examination

1. OVERVIEW

Upon arrival at the examining facility, a representative of the contractor on the nature, time and location of each appointment shall brief the subject. Consent forms covering all examination procedures will be provided to each subject. The subject may decline to participate in any individual portion of the examination, even if he previously signed a consent form. The examination shall be conducted in a manner identical to that used in prior phases of the study and in accord with detail in subsequent sections of this handbook and the Statement of Work.

2. GENERAL PHYSICAL EXAMINATION

The general physical examination shall include an assessment of

1. Appearance (well nourished, obese, under nourished),
2. Appearance relative to stated age (same as, older than, younger than),
3. Appearance of illness or distress (no, yes),
4. Hair distribution (normal, abnormal),
5. Vital signs (height in centimeters, weight undressed in kilograms, oral temperature),
6. Systolic and diastolic blood pressure,
7. Pulse rate,
8. An eye examination (fundoscopic and external observation),
9. An ENT/neck examination,
10. A thorax and lung examination,
11. Waist, hip, chest and neck measurements in centimeters,
12. A heart examination including an overall diagnosis (normal, abnormal, refused),
13. An examination of the abdomen, extremities and peripheral pulses, musculature and spine,
14. An examination of the genitourinary system,
15. A rectal examination,
16. An assessment of the lymph nodes (normal, enlarged, tender, hard, fixed, confluent, other), and
17. A summary of follow-up indicated or recommended.

3. DERMATOLOGIC EXAMINATION AND BIOPSY

The examination shall include

1. An examination of the skin,
2. Skin biopsy, if indicated,
3. Physical features, and
4. Mapping of lesions on an anatomical chart.

4. NEUROLOGICAL EXAMINATION

The examination shall include

1. An examination of the head and neck,
2. An examination of motor systems,
3. An examination of muscle status,
4. An assessment of abnormal movements,
5. An assessment of tremors,
6. An assessment of coordination,
7. An assessment of deep tendon reflexes,
8. An assessment of cranial nerves and mental status,
9. An assessment of meningeal irritation and sensory system,
10. An examination of cranial nerves (I, VII),
11. An examination of cranial nerves (II),
12. An examination of cranial nerves (III, IV, VI),
13. An examination of cranial nerves (V, IX, XI, XII),
14. An impression of the entire neurological examination,
15. Measurement of nerve conduction velocities.

5. PSYCHOLOGICAL TESTING

The Symptom Check List 90-Revised (SCL90R) and Wechsler Memory Scale [Version 1] shall be administered to all study subjects. These tests were chosen to ensure adequate analysis of possible psychological and cognitive manifestations of herbicide toxicity. The psychologist in charge will interpret the results of the test, record those interpretations on a form and provide them to the debriefing physician. The contractor shall forward all test materials as scored with annotations, interpretations and impressions to the diagnostician for inclusion in the subject's file.

6. ELECTROCARDIOGRAM

A standard 12-lead scalar electrocardiogram is required. If an arrhythmia is observed, a 1-minute rhythm strip is additionally requested. This electrocardiogram will be accomplished after a test-specific abstinence from smoking, food and liquid intake. The tracing shall be mounted in the usual manner of the laboratory for the recorder used. Cardiologists at the examination facility will interpret the electrocardiograms. The cardiologist shall forward the interpretation, mounted tracing and rhythm strip, if obtained, to the diagnostician.

7. PULMONARY FUNCTION TESTING

Standard evaluation of pulmonary function will be conducted on each subject following a test-specific abstention from the use of tobacco products and will include, as minimum, forced expiratory volume at 1 second, total vital capacity, and the ratio of the two measurements.

8. AUTOMATED BLOOD PRESSURE DETERMINATION

An electronic device will be used to measure blood pressure. The device to be used will be selected by the contractor, subject to approval by the Air Force.

9. STOOL EXAMINATION FOR OCCULT BLOOD

Three stool smears from each subject will be tested for the presence of occult blood. Subjects with positive tests will be advised and appropriate follow-up will be recommended.

10. RADIOGRAPHIC EXAMINATION

A standard 14×17 inch, standing, roentgenogram in the PA position will be administered to all subjects. A board-certified radiologist at the examining facility will interpret the roentgenogram, record the results and forward them to the diagnostician.

11. DOPPLER TESTING OF PERIPHERAL PULSES

A Doppler device shall be used to quantitatively measure peripheral pulses. Peripheral blood pressures shall be measured. These procedures shall be conducted after a test-specific abstinence from smoking and caffeine.

12. MEASUREMENT OF HEIGHT, WEIGHT, WAIST, HIP, TEMPERATURE

The contractor shall determine the height in centimeters and weight in kilograms following a standard protocol on each subject. The contractor shall also measure the circumference of the waist at the navel, hip, and the circumference of the neck in centimeters. The contractor shall measure temperature in degrees Fahrenheit.

13. LABORATORY PROCEDURES - GENERAL INSTRUCTIONS

On the first day, the subject should report in the morning in a fasting state having had only water after midnight. Blood for the serum dioxin measurement will be drawn on subjects who consent to this procedure. Sufficient blood for the dioxin measurement will be drawn to bring the total volume collected over the 2 days to not more than 450 cc from these volunteers. All study subjects shall be informed that they should abstain from alcohol for 24 hours prior to the start of the physical examination. The contractor shall propose as part of the Biomedical Test Plan, the specific times for abstention requirements of any tests needing abstentions from caffeine, nicotine, food or liquid intake. The ADA fasting glucose criteria shall be used to identify new diabetics.

14. LABORATORY PROCEDURES - SPECIFIC TESTS TO BE PERFORMED

1. α -1-C hemoglobin (percent) (diabetics only)
2. Absolute basophils (thousand/cu mm)
3. Absolute eosinophils (thousand/cu mm)
4. Absolute lymphocytes (thousand/cu mm)
5. Absolute monocytes (thousand/cu mm)
6. Absolute neutrophils (bands) (thousand/cu mm)
7. Absolute neutrophils (segs) (thousand/cu mm)
8. Alkaline phosphatase (U/L)
9. ALT (U/L)
10. Antibodies for hepatitis A (present, absent)
11. Anti-thyroid antibodies (present, absent)
12. AST (U/L)
13. Blood urea nitrogen (mg/dl)
14. CD16+CD56+ (cells/cu mm and percent)
15. CD20 (cells/cu mm and percent)
16. CD3 (cells/cu mm and percent)
17. CD3 + CD4+ (cells/cu mm and percent)
18. CD4 (cells/cu mm and percent)
19. CD45+/CD14+ (%) [quality control marker]
20. CD8 (cells/cu mm and percent)
21. Cholesterol (mg/dl)
22. C-peptide (ng/ml) [diabetics only]
23. Creatine phosphokinase (U/L)
24. Direct bilirubin (mg/dl)
25. Erythrocyte sedimentation rate (mm/hr)
26. Estradiol (pg/ml)
27. Fasting glucose (mg/dl)
28. Fibrinogen (mg/dl)
29. Follicle stimulating hormone (mIU/ml)
30. Free testosterone (pg/ml)
31. GGT (U/L)
32. Glutamic acid decarboxylase antibodies (presence, absence) [diabetic only]
33. HDL cholesterol (mg/dl)
34. Hematocrit (percent)
35. Hemoglobin (gm/dl)
36. IgA (mg/dl)
37. IgG (mg/dl)
38. IgM (mg/dl)
39. Islet cell antibodies (presence, absence) [diabetic only]
40. Lactate dehydrogenase (U/L)
41. Lupus panel: ANA test (presence, absence)
42. Lupus panel: ANA thyroid microsomal antibody (presence, absence)
43. Lupus panel: MSK mitochondrial antibody (presence, absence)
44. Lupus panel: MSK parietal antibody (presence, absence)

45. Lupus panel: MSK smooth muscle antibody (presence, absence)
46. Lupus panel: Rheumatoid factor
47. Luteinizing hormone (mIU/ml)
48. Microalbumin (mg/dl)
49. Platelet count (thousand/cu mm)
50. Proinsulin (ng/ml) [diabetics only]
51. Prostate specific antigen (ng/ml)
52. Protein profile: α -1-antitrypsin (mg/dl)
53. Protein profile: α -1-glycoprotein (mg/dl)
54. Protein profile: α -2-macroglobulin (mg/dl)
55. Protein profile: albumin (mg/dl)
56. Protein profile: apolipoprotein (mg/dl)
57. Protein profile: C3 complement (mg/dl)
58. Protein profile: C4 complement (mg/dl)
59. Protein profile: haptoglobin (mg/dl)
60. Protein profile: pre-albumin (mg/dl)
61. Protein profile: transferrin (mg/dl)
62. Prothrombin time (seconds)
63. RBC morphology (abnormal, normal)
64. Red blood cell count (million/cu mm)
65. Serum amylase (U/L)
66. Serum creatinine (mg/dl)
67. Serum insulin (μ IU/ml) (2 hr. pp, non-diabetics only)
68. Serum insulin (μ IU/ml) (fasting)
69. Thyroid stimulating hormone (μ IU/ml)
70. Thyroid T₃ (low TSH, normal T₄)
71. Thyroid T₄ (μ g/dl) (free)
72. Total bilirubin (mg/dl)
73. Total testosterone (ng/dl)
74. Triglycerides (mg/dl)
75. Two-hour postprandial glucose (mg/dl) (non-diabetics only)
76. Two-hour postprandial urinary glucose (present, absent) (non-diabetics only)
77. Uric Acid (mg/dl)
78. Urinary occult blood (RBC/HPF)
79. Urinary creatinine
80. Urinary protein (present, absent)
81. Urine specific gravity
82. Urine white blood cell count (WBC/HPF)
83. White blood cell count (thousand/cu mm)

PARTICIPANT LABEL	CASE NUMBER	GROUP NUMBER

FINAL REPORT

Leonard R. Derogatis, PhD

MICROTEST QTM Assessment System

NAME (Optional)

DIRECTIONS:

1. When you record your responses on this answer sheet, use a No. 2 pencil only, and fill in the circles with a heavy, dark mark.
2. Print your identification number in the box to the left. Then find the circle below each space that has the same number and blacken it. In a similar way, complete the Birth Date and Test Date boxes.
3. Blacken the appropriate circle for your gender.
4. If you want to change a response, erase it carefully and then fill in your new choice.
5. Do not make any marks outside the circles.

IDENTIFICATION NUMBER

0	0	0	0	0	0	0	0	0	0
1	1	1	1	1	1	1	1	1	1
2	2	2	2	2	2	2	2	2	2

INSTRUCTIONS:

Below is a list of problems people sometimes have. Please read each one carefully, and blacken the circle that best describes HOW MUCH THAT PROBLEM HAS DISTRESSED OR BOTHERED YOU DURING THE PAST 7 DAYS INCLUDING TODAY. Blacken the circle for only one

number for each problem and do not skip any items. If you change your mind, erase your first mark carefully. Read the example before beginning, and if you have any questions please ask them now.

APPENDIX D

APPENDIX D. COEFFICIENTS OF VARIATION FOR LABORATORY QUALITY CONTROL

This appendix contains a table of the coefficients of variation for each of 54 laboratory quality control assays. Included in this table are the target coefficients of variation and actual coefficients of variation. The targets are given for low, medium, and high level controls. “Target” coefficients of variation are those coefficients of variation sought by the Air Force, based on currently available lab methods. “Actual” coefficients of variation are those coefficients of variation actually achieved during the period of time given in the column labeled “Time Period” for Low, Medium, and High control levels. A different time period is given when the control lot for at least one of the levels was changed. If a control lot covers more than one time period, as listed in separate rows of the table, the coefficient of variation is repeated and annotated with an asterisk (*). The asterisk notes that a single coefficient of variation covers the adjacent time periods.

List of Tables

Table D-1. Coefficients of Variation for Laboratory Quality Control–Tri-level Control Data for the 2002 Air Force Health Study Follow-up Examination Assays Performed at Scripps Clinic.....	D-1

APPENDIX F

APPENDIX F. DEPENDENT VARIABLE-COVARIATE ASSOCIATIONS

This appendix contains results of tests of association between each dependent variable and covariates for the adjusted analysis of each dependent variable. Pearson's chi-square test (continuity-adjusted for 2x2 tables) is used for significance testing of the associations between each discrete dependent variable and the covariate (see Chapter 7, Table 7-5). When a covariate is continuous in nature (e.g., age), the covariate is put in its discrete form prior to the analysis of the discrete dependent variable. Pearson's correlation coefficient is used for significance testing of the associations between each continuous dependent variable and a continuous covariate (see Chapter 7, Table 7-5). When a covariate is discrete in nature, means (transformed back to the original scale, if necessary) are presented and an analysis of variance is used to investigate the difference between the means (see Chapter 7, Table 7-5).

Table F-2. Dependent Variable-covariate Associations for the Neoplasia Assessment (Continued)

Dependent Variable	Level	Lifetime Alcohol History (drink-years)			p-Value
		0	>0-40	>40	
PSA (ng/mL)		(n=98)	(n=1,140)	(n=557)	
(continuous) ^a	--		r = -0.018		0.448
(discrete)	High	6.1%	4.6%	5.8%	0.505

^aAnalysis performed on natural logarithm scale; means transformed from natural logarithm scale.

--: The covariate was not applicable for this dependent variable.

Note: Correlations (r) are based on total sample size and are not category-specific.

Please see Section 10.1.3 and Table 10-1 for a further discussion of the dependent variables and covariates shown in this appendix.

Table F-3. Dependent Variable-covariate Associations for the Neurology Assessment

Dependent Variable	Level	Age			Race		
		Born ≥1942	Born <1942	p-Value	Black	Non-Black	p-Value

Table F-8. Dependent Variable-covariate Associations for the Hematology Assessment (Continued)

^aAnalysis performed on natural logarithm scale; means transformed from natural logarithm scale.

^bAnalysis performed on square root scale; means transformed from square root scale.

^cAnalysis performed on natural logarithm (x+0.1) scale; means transformed from natural logarithm (x+0.1) scale.

Note: Correlations (r) are based on total sample size and are not category-specific.

Please see Section 16.1.3 and Table 16-1 for a further discussion of the dependent variables and covariates shown in this appendix.

^a Analysis was performed on natural logarithm scale; means were transformed from natural logarithm scale.

^b Analysis was performed on square root scale; means were transformed from square root scale.

Note: Correlation coefficients (r) are based on total sample size and are not category-specific.

Please see Section 17.1.3 and Table 17-1 for a further discussion of the dependent variables and covariates shown in this appendix.

^a10th percentile of distribution of time to onset of diabetes. For diabetics, time to diabetes onset was determined as the difference between the date on which a participant was first diagnosed with diabetes and the end date of the last qualifying tour of duty in SEA. For nondiabetics, time to diabetes onset was determined as the difference between the date of the participant's 2002 physical examination and the end date of the last qualifying tour of duty in SEA.

^bAnalysis performed on natural logarithm scale; means transformed from natural logarithm scale.

^cData was collected for nondiabetics only.

^dData was collected for diabetics only.

^eAnalysis performed on square root scale; means transformed from square root scale.

Note: Correlations (r) are based on total sample size and are not category-specific.

Please see Section 18.1.3 and Table 18-1 for a further discussion of the dependent variables and covariates shown in this appendix.

^a Analysis performed on natural logarithm of (1 – ratio of observed FEV₁ to observed FVC) scale; means transformed from natural logarithm of (1 – ratio of observed FEV₁ to observed FVC) scale. Because of this transformation, a positive (or negative) correlation implies a negative (or positive) association between the ratio and the covariate.

Note: Correlations (r) are based on total sample size and are not category-specific.

Please see Section 20.1.3 and Table 20-1 for a further discussion of the dependent variables and covariates shown in this appendix.

APPENDIX G. SUMMARY OF ANALYSIS RESULTS

This appendix contains a summary of the results from the exposure analyses performed for this report and contained in Chapters 9 through 20. This summary is organized into 24 tables, grouped by analysis (unadjusted or adjusted), data form (continuous, dichotomous, or polytomous), and model (1, 2, 3, or 4). Each table contains a reference to its corresponding table in Chapters 9 through 20 and a description of the clinical parameter being summarized. The summary statistics, grouped by model and presented for each analysis and data form, are described below.

G.1 Model 1

For analyses of continuous data using Model 1 (Tables G-1 and G-13), the occupational category, Ranch Hand mean, Comparison mean, difference of Ranch Hand and Comparison means along with the associated 95-percent confidence interval (referred to as “C.I.” throughout the following tables), and p-value are given for the unadjusted and adjusted analyses. For analyses of dichotomous data using Model 1 (Tables G-5 and G-17), the occupational category, unadjusted or adjusted relative risk and associated 95-percent C.I., and p-value are given for the unadjusted and adjusted analyses. The number and percentage of abnormalities within the Ranch Hand and Comparison groups are given for the unadjusted analyses. For analyses of polytomous data using Model 1 (Tables G-9 and G-21), the contrast (of the specified abnormal category versus the normal category), occupational category, unadjusted or adjusted relative risk and associated 95-percent C.I., and p-value are given for the unadjusted and adjusted analyses. The number and percentage of Ranch Hands and Comparisons within each abnormal level are given for the unadjusted analyses.

G.2 Models 2 and 4

For analyses of continuous data using Models 2 and 4 (Tables G-2 and G-14 for Model 2, Tables G-4 and G-16 for Model 4), the coefficient of determination (R^2), slope, standard error, and p-value are given for the unadjusted and adjusted analyses. For analyses of dichotomous data using Models 2 and 4 (Tables G-6 and G-18 for Model 2, Tables G-8 and G-20 for Model 4), the unadjusted or adjusted relative risk and associated 95-percent C.I., and p-value are given for the unadjusted and adjusted analyses. For analyses of polytomous data using Models 2 and 4 (Tables G-10 and G-22 for Model 2, Tables G-12 and G-24 for Model 4), the contrast (of the specified abnormal category versus the normal category), the unadjusted or adjusted relative risk and associated 95-percent C.I., and p-value are given for the unadjusted and adjusted analyses.

G.3 Model 3

For analyses of continuous data using Model 3 (Tables G-3 and G-17), the R^2 , dioxin category, dioxin category sample size (n) and mean, difference of Ranch Hand dioxin category and Comparison dioxin category means along with the associated 95-percent C.I., and p-value are given for the unadjusted and adjusted analyses. For analyses of dichotomous data using Model 3 (Tables G-7 and G-19), the dioxin category, sample size, unadjusted or adjusted relative risk and associated 95-percent C.I. for each Ranch Hand category versus Comparison contrast, and p-value are given for the unadjusted and adjusted analyses. The number and percentage of abnormalities within each dioxin category are given for unadjusted analyses. For analyses of polytomous data using Model 3 (Tables G-11 and G-23), the

contrast (of the specified abnormal category versus the normal category), dioxin category, sample size, unadjusted or adjusted relative risk and associated 95-percent C.I. for each Ranch Hand category versus Comparison contrast, and p-value are given for the unadjusted and adjusted analyses. The number and percentage of each abnormal level within each dioxin category are given for the unadjusted analyses.

A summary of the analysis (unadjusted or adjusted), data form (continuous, dichotomous, or polytomous), and model (1, 2, 3, or 4) for each table in Appendix G is given below.

Appendix G Table	Analysis	Data Form	Model
G-1	Unadjusted	Continuous	1

**Table G-3. Summary of Unadjusted Results for Continuous Variables – Model 3
(Ranch Hands and Comparisons by Dioxin Category) (Continued)**

^aAdjusted for body mass index at the time of the blood measurement for dioxin.

^bMeans transformed from natural logarithm scale; difference of means after transformation to original scale; confidence interval not given because analysis was performed on natural logarithm scale; p-value based on difference of means on natural logarithm scale.

^cMeans transformed from square root scale; difference of means after transformation to original scale; confidence interval not given because analysis was performed on square root scale; p-value based on difference of means on square root scale.

^dMeans transformed from natural logarithm (clinical parameter + 0.1) scale; difference of means after transformation to original scale; confidence interval not given because analysis was performed on natural logarithm (clinical parameter + 0.1) scale; p-value based on difference of means on natural logarithm (clinical parameter + 0.1) scale.

^eMeans transformed from natural logarithm (1 – clinical parameter) scale; difference of means after transformation to original scale; confidence interval not given because analysis was performed on natural logarithm (1 – clinical parameter) scale; p-value based on difference of means on natural logarithm (1 – clinical parameter) scale.

*: Not adjusted for body mass index at the time of the blood measurement for dioxin.

Note: RH = Ranch Hand.

Background: (Ranch Hand): 1987 dioxin \leq 10 ppt.

Low (Ranch Hand): 1987 dioxin $>$ 10 ppt, 10 ppt $<$ initial dioxin \leq 118 ppt.

High (Ranch Hand): 1987 dioxin $>$ 10 ppt, initial dioxin $>$ 118 ppt.

^aP-value determined using a chi-square test with continuity correction because of the sparse number of participants with abnormalities.

^b10th percentile based on proportional hazards model was given for time to diabetes onset variable.

^cHazard ratio, confidence interval, and p-value, based on proportional hazards model, were given for time to diabetes onset variable.

--: Relative risk, confidence interval, and p-value were not presented because of the sparse number of participants with abnormalities.

^aAdjusted for body mass index at the time of the blood measurement for dioxin.

^bRelative risk for a twofold increase in initial dioxin.

^cHazard ratio, confidence interval, and p-value, based on proportional hazards model, were given for time to diabetes onset variable.

--: Relative risk, confidence interval, and p-value were not presented because of the sparse number of Ranch Hands with abnormalities.

Table G-7. Summary of Unadjusted Results for Dichotomous Variables – Model 3 (Ranch Hands and Comparisons by Dioxin Category)

^aAdjusted for body mass index at the time of the blood measurement for dioxin.

^bRelative risk and confidence interval relative to Comparisons.

^cP-value determined using a chi-square test with continuity correction because of the sparse number of participants with abnormalities.

^d10th percentile based on proportional hazards model was given for time to diabetes onset variable.

^eHazard ratio, confidence interval, and p-value, based on proportional hazards model, were given for time to diabetes onset variable.

**Table G-7. Summary of Unadjusted Results for Dichotomous Variables – Model 3
(Ranch Hands and Comparisons by Dioxin Category) (Continued)**

--: Relative risk, confidence interval, and p-value were not presented because of the sparse number of participants with abnormalities.

Note: RH = Ranch Hand.

Background: (Ranch Hand): 1987 dioxin \leq 10 ppt.

Low (Ranch Hand): 1987 dioxin $>$ 10 ppt, 10 ppt $<$ initial dioxin \leq 118 ppt.

High (Ranch Hand): 1987 dioxin $>$ 10 ppt, initial dioxin $>$ 118 ppt.

**Table G-8. Summary of Unadjusted Results for Dichotomous Variables – Model 4
(Ranch Hands: Log₂ (1987 Dioxin)) (Continued)**

Table Ref.	Clinical Parameter	Unadjusted Relative Risk (95% C.I.) ^a	p-Value
18-36	Free Testosterone	1.08 (0.90,1.29)	0.421
18-38	Estradiol	0.98 (0.76,1.28)	0.905
18-40	LH	0.92 (0.74,1.15)	0.477
18-42	FSH	0.92 (0.76,1.12)	0.407
19-14	Lupus Panel: ANA Test	1.12 (0.99,1.25)	0.067
19-15	Lupus Panel: Thyroid Microsomal Antibody	1.02 (0.79,1.32)	0.895
19-16	Lupus Panel: MSK Antismooth Muscle Antibody	0.62 (0.40,0.95)	0.029
19-17	Lupus Panel: MSK Antimitochondrial Antibody	0.51 (0.22,1.22)	0.141
19-18	Lupus Panel: MSK Antiparietal Cell Antibody	0.95 (0.70,1.30)	0.750
19-19	Lupus Panel: Rheumatoid Factor	0.92 (0.82,1.02)	0.118
20-3	Asthma	0.92 (0.77,1.10)	0.362
20-4	Bronchitis	1.00 (0.91,1.10)	0.973
20-5	Pneumonia	0.95 (0.83,1.08)	0.436
20-6	Thorax and Lung Abnormality	1.02 (0.92,1.14)	0.658
20-7	X-ray Interpretation	0.93 (0.82,1.05)	0.239
20-9	FVC	1.03 (0.89,1.20)	0.673
20-11	FEV ₁	1.02 (0.93,1.12)	0.697

^aRelative risk for a twofold increase in 1987 dioxin.

^bHazard ratio, confidence interval, and p-value, based on proportional hazards model, were given for time to diabetes onset variable.

--: Relative risk, confidence interval, and p-value were not presented because of the sparse number of Ranch Hands with abnormalities.

Table G-9. Summary of Unadjusted Results for Polytomous Variables – Model 1 (Ranch Hands vs. Comparisons)

Table Ref.	Clinical Parameter	Contrast	Occupational Category	Number (%) Abnormal		Unadjusted Relative Risk (95% C.I.)	p-Value
				Ranch Hand	Comparison		
11-24	Patellar Reflex	Active or Very Active vs. Sluggish or Absent	All	196 (25.5)	309 (26.5)	0.94 (0.77,1.16)	0.592

^aP-value determined using a chi-square test with continuity correction because of the sparse number of participants with abnormalities.

--: Relative risk and confidence interval not presented because of the sparse number of participants with abnormalities.

Table G-10. Summary of Unadjusted Results for Polytomous Variables – Model 2 (Ranch Hands: Log₂ (Initial Dioxin))

Table Ref.	Clinical Parameter	Contrast	Unadjusted Relative Risk (95% C.I.) ^{a,b}	p-Value ^a
11-24	Patellar Reflex	Active or Very Active vs. Sluggish or Absent	0.96 (0.82,1.13)	0.630
		Sluggish, Active, or Very Active vs. Absent	1.17 (0.87,1.56)	0.305
11-25	Achilles Reflex	Active or Very Active vs. Sluggish or Absent	0.88 (0.76,1.03)	0.107
		Sluggish, Active, or Very Active vs. Absent	0.93 (0.79,1.10)	0.394
11-26	Biceps Reflex	Active or Very Active vs. Sluggish or Absent	0.92 (0.78,1.07)	0.264
		Sluggish, Active, or Very Active vs. Absent	1.38 (0.94,2.02)	0.107
13-47	α-1-Antitrypsin	Abnormal Low vs. Normal	0.74 (0.23,2.42)	0.622
		Abnormal High vs. Normal	0.99 (0.80,1.22)	0.909
16-4	RBC Count	Abnormal Low vs. Normal	0.93 (0.68,1.26)	0.622
		Abnormal High vs. Normal	1.06 (0.65,1.74)	0.807
16-6	WBC Count	Abnormal Low vs. Normal	1.03 (0.79,1.33)	0.834
		Abnormal High vs. Normal	1.01 (0.50,2.04)	0.972
16-8	Hemoglobin	Abnormal Low vs. Normal	0.97 (0.77,1.22)	0.788
		Abnormal High vs. Normal	0.41 (0.04,4.64)	0.472
16-10	Hematocrit	Abnormal Low vs. Normal	1.23 (0.86,1.75)	0.264
		Abnormal High vs. Normal	1.48 (0.69,3.18)	0.319
16-12	Platelet Count	Abnormal Low vs. Normal	0.66 (0.30,1.44)	0.299
		Abnormal High vs. Normal	1.19 (0.44,3.22)	0.726
18-6	Diabetic Control Indicator (2002 AFHS Diabetes Definition)	No Treatment vs. Nondiabetic	0.69 (0.46,1.03)	0.072
		Diet and Exercise vs. Nondiabetic	0.89 (0.56,1.42)	0.636
		Oral Hypoglycemics vs. Nondiabetic	1.09 (0.86,1.37)	0.476
		Requiring Insulin vs. Nondiabetic	1.76 (1.20,2.58)	0.004
18-7	Diabetic Control (Pre-2002 AFHS Diabetes Definition)	No Treatment vs. Nondiabetic	0.89 (0.65,1.21)	0.462
		Diet and Exercise vs. Nondiabetic	0.91 (0.57,1.44)	0.680
		Oral Hypoglycemics vs. Nondiabetic	1.12 (0.89,1.40)	0.352
		Requiring Insulin vs. Nondiabetic	1.79 (1.22,2.62)	0.003
18-13	TSH	Abnormal Low vs. Normal	1.56 (0.44,5.57)	0.493
		Abnormal High vs. Normal	0.92 (0.56,1.51)	0.752
18-23	Fasting Insulin	Abnormal Low vs. Normal	0.79 (0.55,1.14)	0.209
		Abnormal High vs. Normal	1.31 (1.05,1.65)	0.019
18-25	2-hour Postprandial Insulin (Nondiabetics Only)	Abnormal Low vs. Normal	1.16 (0.74,1.80)	0.514
		Abnormal High vs. Normal	1.10 (0.91,1.32)	0.333
20-13	Loss of Vital Capacity	Mild vs. None	0.84 (0.62,1.14)	0.260
		Moderate or Severe vs. None	0.70 (0.39,1.28)	0.250
20-14	Obstructive Abnormality	Mild vs. None	0.82 (0.70,0.97)	0.019
		Moderate vs. None	0.67 (0.49,0.93)	0.016
		Severe vs. None	0.50 (0.28,0.91)	0.022

^aAdjusted for body mass index at the time of the blood measurement of dioxin.

^bRelative risk for a twofold increase in initial dioxin.

Table G-11. Summary of Unadjusted Results for Polytomous Variables – Model 3 (Ranch Hands and Comparisons by Dioxin Category)

Table Ref.	Clinical Parameter	Contrast	Dioxin Category	n	Number (%) Abnormal	Unadjusted Relative Risk (95% C.I.) ^{a,b}	p-Value ^a

			Low plus High RH	417	12 (2.9)	0.76 (0.32,1.79)	0.535

^aAdjusted for body mass index at the time of the blood measurement of dioxin.

^bRelative risk and confidence interval relative to Comparisons.

^cP-value determined using a chi-square test with continuity correction because of the sparse number of participants with abnormalities.

--: Relative risk and confidence interval were not presented because of the sparse number of participants with abnormalities.

Note: RH = Ranch Hand.

Background: (Ranch Hand): 1987 dioxin ≤ 10 ppt.

Low (Ranch Hand): 1987 dioxin > 10 ppt, 10 ppt < initial dioxin ≤ 118 ppt.

High (Ranch Hand): 1987 dioxin > 10 ppt, initial dioxin > 118 ppt.

Table G-13. Summary of Adjusted Results for Continuous Variables – Model 1 (Ranch Hands vs. Comparisons) (Continued)

^aMeans transformed from natural logarithm scale; difference of means after transformation to original scale; confidence interval not given because analysis was performed on natural logarithm scale; p-value based on difference of means on natural logarithm scale.

^bMeans transformed from square root scale; difference of means after transformation to original scale; confidence interval not given because analysis was performed on square root scale; p-value based on difference of means on square root scale.

^cMeans transformed from natural logarithm (clinical parameter + 0.1) scale; difference of means after transformation to original scale; confidence interval not given because analysis was performed on natural logarithm (clinical parameter + 0.1) scale; p-value based on difference of means on natural logarithm (clinical parameter + 0.1) scale.

^dMeans transformed from natural logarithm (1 – clinical parameter) scale; difference of means after transformation to original scale; confidence interval not given because analysis was performed on natural logarithm (1 – clinical parameter) scale; p-value based on difference of means on natural logarithm (1 – clinical parameter) scale.

			Low plus High RH	419	0.730	0.003	0.572

Table G-15. Summary of Adjusted Results for Continuous Variables – Model 3 (Ranch Hands and Comparisons by Dioxin Category) (Continued)

^aMeans transformed from natural logarithm scale; difference of means after transformation to original scale; confidence interval not given because analysis was performed on natural logarithm scale; p-value based on difference of means on natural logarithm scale.

^bMeans transformed from square root scale; difference of means after transformation to original scale; confidence interval not given because analysis was performed on square root scale; p-value based on difference of means on square root scale.

^cMeans transformed from natural logarithm (clinical parameter + 0.1) scale; difference of means after transformation to original scale; confidence interval not given because analysis was performed on natural logarithm (clinical parameter + 0.1) scale; p-value based on difference of means on natural logarithm (clinical parameter + 0.1) scale.

^dMeans transformed from natural logarithm (1 – clinical parameter) scale; difference of means after transformation to original scale; confidence interval not given because analysis was performed on natural logarithm (1 – clinical parameter) scale; p-value based on difference of means on natural logarithm (1 – clinical parameter) scale.

Note: RH = Ranch Hand.

Background: (Ranch Hand): 1987 dioxin \leq 10 ppt.

Low (Ranch Hand): 1987 dioxin > 10 ppt, 10 ppt < initial dioxin \leq 118 ppt.

High (Ranch Hand): 1987 dioxin > 10 ppt, initial dioxin > 118 ppt.

^aHazard ratio, confidence interval, and p-value, based on proportional hazards model, were given for time to diabetes onset variable.

--: Relative risk, confidence interval, and p-value were not presented because of the sparse number of participants with abnormalities.

^aRelative risk for a twofold increase in initial dioxin.

^bHazard ratio, confidence interval, and p-value, based on proportional hazards model, were given for time to diabetes onset variable.

--: Relative risk, confidence interval, and p-value were not presented because of the sparse number of Ranch Hands with abnormalities.

^aRelative risk and confidence interval relative to Comparisons.

^bHazard ratio, confidence interval, and p-value, based on proportional hazards model, were given for time to diabetes onset variable.

--: Relative risk, confidence interval, and p-value were not presented because of the sparse number of participants with abnormalities.

Note: RH = Ranch Hand.

Background: (Ranch Hand): 1987 dioxin ≤ 10 ppt.

Low (Ranch Hand): 1987 dioxin > 10 ppt, 10 ppt < initial dioxin ≤ 118 ppt.

High (Ranch Hand): 1987 dioxin > 10 ppt, initial dioxin > 118 ppt.

^aRelative risk for a twofold increase in 1987 dioxin.

^bHazard ratio, confidence interval, and p-value, based on proportional hazards model, were given for time to diabetes onset variable.

--: Relative risk, confidence interval, and p-value were not presented because of the sparse number of Ranch Hands with abnormalities.

		Severe vs. None	0.79 (0.57,1.11)	0.177

^aRelative risk for a twofold increase in 1987 dioxin.

APPENDIX H

APPENDIX H. SIGNIFICANT ADJUSTED GROUP AND DIOXIN ANALYSES

This appendix contains a summary of significant results ($p \leq 0.05$) for the adjusted analyses that were performed for the group and dioxin analyses (Models 1-4) in Chapters 9 through 20. The dependent variable and its table reference are listed along with the model and the contrast or description of the model. The p-value is provided along with analysis statistics that correspond to the type of analysis that was performed (either continuous or discrete). A description of the analysis and the statistics that are presented is referenced under the “Note” column and is explained in footnotes.

	4	All RH: 1987 Dioxin	<0.001	1.31 (1.17,1.47)	Low: 21.6% Medium: 38.0% High: 46.5%	(d)

- (a): Continuous variable: difference of adjusted means was presented; confidence interval was not presented because analysis was performed on natural logarithm scale; adjusted means were transformed to original scale and were presented for each dioxin category in contrast.
- (b): Continuous variable: slope and standard error were presented and were based on natural logarithm of dependent variable versus log₂ (1987 dioxin); adjusted means were transformed to original scale and were presented for each of three 1987 dioxin categories.
- (c): Discrete variable: adjusted relative risk and 95% confidence interval were presented; percent abnormal was presented for each dioxin category in contrast.
- (d): Discrete variable: adjusted relative risk and 95% confidence interval were presented for a twofold increase in 1987 dioxin; percent abnormal was presented for each of three 1987 dioxin categories.

Note: RH = Ranch Hand.
C = Comparison.

Model 3: Background (Ranch Hand): 1987 dioxin ≤ 10 ppt.
Low (Ranch Hand): 1987 dioxin > 10 ppt, 10 ppt < initial dioxin ≤ 118 ppt.
High (Ranch Hand): 1987 dioxin > 10 ppt, initial dioxin > 118 ppt.

Model 4: Low = ≤7.8 ppt; Medium = >7.8–19.2 ppt; High = >19.2 ppt (Ranch Hands only).

Table H-2. Summary of Results from Significant Adjusted Analyses in the Neoplasia Assessment

Dependent Variable (Table Reference)	Model	Contrast or Description	p-Value	Analysis Statistics	Percent Abnormal	Note

(a): Discrete variable: adjusted relative risk and 95% confidence interval were presented for a twofold increase in 1987 dioxin; percent abnormal was presented for each of three 1987 dioxin categories.

(b): Discrete variable: adjusted relative risk and 95% confidence interval were presented for a twofold increase in initial dioxin; percent abnormal was presented for each of three initial dioxin categories.

(c): Discrete variable: adjusted relative risk and 95% confidence interval were presented; percent abnormal was presented for each dioxin category in contrast.

Table H-10. Summary of Results from Significant Adjusted Analyses in the Endocrinology Assessment (Continued)

- (d): Discrete variable: adjusted relative risk and 95% confidence interval were presented; percent abnormal was presented for each exposure group in contrast.
- (e): Continuous variable: adjusted hazard ratio and 95% confidence interval were presented; 10th percentile of distribution of time to onset of diabetes was presented for each dioxin category in contrast.
- (f): Continuous variable: adjusted hazard ratio and 95% confidence interval were presented for a twofold increase in 1987 dioxin; 10th percentile of distribution of time to onset of diabetes was presented for each of three 1987 dioxin categories.
- (g): Continuous variable: adjusted hazard ratio and 95% confidence interval were presented for a twofold increase in initial dioxin; 10th percentile of distribution of time to onset of diabetes was presented for each of three initial dioxin categories.
- (h): Continuous variable: difference of adjusted means was presented; confidence interval was not presented because analysis was not performed on original scale; adjusted means were presented for each exposure group in contrast.
- (i): Continuous variable: difference of adjusted means was presented; confidence interval was not presented because analysis was not performed on original scale; adjusted means were presented for each dioxin category in contrast.
- (j): Continuous variable: slope and standard error were presented and were based on natural logarithm of dependent variable versus log₂ (initial dioxin); adjusted means were presented for each of three initial dioxin categories.

^aA smaller group mean or decreasing mean time to onset values as dioxin increased was considered adverse for this variable.

^bA positive difference in means (Comparison mean less than Ranch Hand mean) was considered adverse to Comparisons for this variable.

Note: RH = Ranch Hand.
C = Comparison.

Model 2: Low = 32–79 ppt; Medium = >79–199 ppt; High = >199 ppt (Ranch Hands who had a 1987 dioxin measurement greater than 10 ppt).

Model 3: Background (Ranch Hand): 1987 dioxin ≤ 10 ppt.
Low (Ranch Hand): 1987 dioxin > 10 ppt, 10 ppt < initial dioxin ≤ 118 ppt.
High (Ranch Hand): 1987 dioxin > 10 ppt, initial dioxin > 118 ppt.

Model 4: Low = ≤7.8 ppt; Medium = >7.8–19.2 ppt; High = >19.2 ppt (Ranch Hands only).

Table H-11. Summary of Results from Significant Adjusted Analyses in the Immunology Assessment

Dependent Variable (Table Reference)	Model	Contrast or Description	p-Value	Analysis Statistics	Adjusted Mean or Percent Abnormal	Note

Low (Ranch Hand): 1987 dioxin > 10 ppt, 10 ppt < initial dioxin \leq 118 ppt.
High (Ranch Hand): 1987 dioxin > 10 ppt, initial dioxin > 118 ppt.

Model 4: Low = \leq 7.8 ppt; Medium = >7.8–19.2 ppt; High = >19.2 ppt. (Ranch Hands only)

Table H-12. Summary of Results from Significant Adjusted Analyses in the Pulmonary Assessment

Dependent Variable (Table Reference)	Model	Contrast or Description	p-Value	Analysis Statistics	Adjusted Mean or Percent Abnormal	Note
Pneumonia (20-5)	1	RH vs. C, Enlisted Flyer	0.046	1.94 (1.01,3.72)	RH: 19.7% C: 11.4%	(a)
FVC (20-8) ^a	3	Low RH vs. C	0.031	-2.52 (-4.81,-0.23)	RH: 93.22 percent C: 95.74 percent	(b)
Ratio of Observed FEV ₁ to Observed FVC (20-12) ^b	2	RH (1987 dioxin >10 ppt): Initial Dioxin	0.039	-0.023 (0.011)	Low: 0.729 Medium: 0.740 High: 0.752	(c)
Obstructive Abnormality (20-14)	1	RH vs. C, Enlisted Flyer – mild vs. none	0.046	0.59 (0.35,0.99)	RH: 34.1% C: 43.1%	(a)
	2	RH (1987 dioxin >10 ppt): Initial Dioxin – moderate vs. none	0.023	0.64 (0.43,0.94)	Low: 11.7% Medium: 8.6% High: 2.9%	(d)
	2	RH (1987 dioxin >10 ppt): Initial Dioxin – severe vs. none	0.036	0.44 (0.20,0.95)	Low: 4.4% Medium: 4.3% High: 0.0%	(d)

(a): Discrete variable: adjusted relative risk and 95% confidence interval were presented; percent abnormal was presented for each exposure group in contrast.

(b): Continuous variable: difference of adjusted means and 95% confidence interval were presented; adjusted means were presented for each dioxin category in contrast.

(c): Continuous variable: slope and standard error were presented and were based on natural logarithm of 1.0 - dependent variable) versus log₂ (initial dioxin); adjusted means were presented for each of three initial dioxin categories.

(d): Discrete variable: adjusted relative risk and 95% confidence interval were presented for a twofold increase in initial dioxin; percent abnormal was presented for each of three initial dioxin categories.

^aA smaller group mean was considered adverse for this variable.

^bA positive slope was considered adverse for this variable; a negative slope implies an increase in the ratio because of the data transformation used.

Note: RH = Ranch Hand.
C = Comparison.

Model 2: Low = 32–79 ppt; Medium = >79–199 ppt; High = >199 ppt (Ranch Hands who had a 1987 dioxin measurement greater than 10 ppt).

Model 3: Background (Ranch Hand): 1987 dioxin ≤ 10 ppt.
Low (Ranch Hand): 1987 dioxin > 10 ppt, 10 ppt < initial dioxin ≤ 118 ppt.
High (Ranch Hand): 1987 dioxin > 10 ppt, initial dioxin > 118 ppt.

APPENDIX I

APPENDIX I. ABBREVIATIONS AND ACRONYMS

A	adjusted analysis
ACE	angiotensin-converting enzyme
ADA	American Diabetes Association
AFHS	Air Force Health Study
Ah	aryl hydrocarbon
AIDS	acquired immunodeficiency syndrome
ALT	alanine aminotransferase
ANA	antinuclear antibody
APP	active pedal plantarflexion
AST	aspartate aminotransferase
ATS	American Thoracic Society
BUN	blood urea nitrogen
C	Comparison(s)
C	continuous analysis
CAPI	computer-assisted personal interviewing
CAT	computed axial tomography
CBC	complete blood count
CD	clusters of differentiation
C/D	continuous and discrete analyses for dependent variables; appropriate form for analysis (either continuous or discrete) for covariates
CDC	Centers for Disease Control and Prevention
CI	Cornell Index
C.I.	confidence interval
CMI	Cornell Medical Index
CNS	central nervous system
COPD	chronic obstructive pulmonary disease
COV	covariate
CS	chi-square contingency table analysis (continuity-adjusted)
D	discrete analysis
DEP	dependent variable
DNA	deoxyribonucleic acid

Appendix I. Abbreviations and Acronyms (Continued)

ECG	electrocardiograph
ESR	erythrocyte sedimentation rate
EXC	exclusion
FC	fully compliant at baseline examination
FEF _{max}	forced expiratory flow maximum
FEV ₁	forced expiratory volume in 1 second
FSH	follicle-stimulating hormone
FTA-ABS	fluorescent treponemal antibody absorption
FTI	free thyroxine index
FVC	forced vital capacity
G	good (dioxin) result
GADA	glutamic acid decarboxylase antibodies
GFR	glomerular filtration rate
GGT	gamma glutamyltransferase
GLM	general linear models analysis
GND	good (dioxin) result, but below the limit of detection
GnRH	gonadotropin-releasing hormone
GNQ	good (dioxin) result, but below the limit of quantitation
GSH	(reduced) glutathione
GSI	global severity index
HBsAg	hepatitis B surface antigen
HDL	high-density lipoprotein
HIV	human immunodeficiency virus
HLA-DR	human leukocyte antigen-DR
HPF	high-powered field
HRB	Halstead-Reitan Neuropsychological Test Battery
IARC	International Agency for Research on Cancer
ICD-9-CM	International Classification of Diseases, 9th Revision, Clinical Modification
Ig	immunoglobulins
IL	Interleukin
IOM	Institute of Medicine
IQ	intelligence quotient
IRB	Institutional Review Board

Appendix I. Abbreviations and Acronyms (Continued)

K/DOQI	Kidney Disease Outcomes Quality Initiative
LAB	2002 laboratory results
LBBB	left bundle branch block
LDH	lactate dehydrogenase
LH	luteinizing hormone
LR	logistic regression analysis
MCH	mean corpuscular hemoglobin
MCHC	mean corpuscular hemoglobin concentration
MCMI	Millon Clinical Multiaxial Inventory
MCV	mean corpuscular volume
MIL	Air Force military records
MLC	mixed lymphocyte culture
MMPI	Minnesota Multiphasic Personality Inventory
MRI	magnetic resonance imaging
MR-V	medical records (verified)
MSK	mouse stomach kidney
NIOSH	National Institute for Occupational Safety and Health
NORC	National Opinion Research Center
NR	no (dioxin) result
NS or ns	not significant ($p>0.05$)
OR	odds ratio
OMR	optical mark reading
PC	partially compliant at baseline examination
PCT	porphyria cutanea tarda
PE	physical examination
PH	proportional hazards analysis
PHA	phytohemagglutinin
ppq	parts per quadrillion
ppt	parts per trillion
PR	polytomous logistic regression analysis
PSA	prostate-specific antigen
PSDI	positive symptom distress index

Appendix I. Abbreviations and Acronyms (Continued)

PST	positive symptom total
PTSD	post-traumatic stress disorder
QA	quality assurance
QC	quality control
QRC	Quality Review Committee
Q-SR	AFHS health questionnaires (self-reported)
R	refusal at baseline examination
R ²	coefficient of determination
RBBB	right bundle branch block
RBC	red blood cell
RH	Ranch Hand(s)
RR	relative risk
RVN	Republic of Vietnam
SAIC	Science Applications International Corporation
SCL-90-R	Symptom Checklist-90-Revised
SEA	Southeast Asia
SEER	Surveillance, Epidemiology, and End Results
SHBG	sex hormone-binding globulin
T ₃	triiodothyronine
T ₄	thyroxine
TCDD	2,3,7,8-tetrachlorodibenzo-p-dioxin (or dioxin)
TLC	total lymphocyte count
TSH	thyroid-stimulating hormone
TT	two-sample t-test
U	unadjusted analysis
UNL	unlocatable at baseline examination
USAF	United States Air Force
VDRL	venereal disease research laboratory

Appendix I. Abbreviations and Acronyms (Continued)

WAIS	Wechsler Adult Intelligence Scale
WBC	white blood cell
WMS	Wechsler Memory Scale
WMS-R	Wechsler Memory Scale-Revised
