ABSTRACT

A repair technology based on the use of adhesively bonded electroformed nickel reinforcements was successfully developed to repair the trails of light field guns operated by ADF that had been damaged by fretting or mechanical contact in service. The success was judged by the measured reduction in strain in the reinforced regions (~40%) and the durability of these repairs in service over a period exceeding five years, including three years of active field exercises in a humid tropical environment.

APPROVED FOR PUBLIC RELEASE

Bonded Repair of a Gun Carriage Using Electroformed Nickel Reinforcements

Executive Summary

A repair technology based on the use of adhesively bonded electroformed nickel reinforcements was successfully developed to repair the trails of 105 mm light field guns operated by ADF which had been damaged by fretting or mechanical contact in service. The success was judged by the measured reduction in strain in the reinforced regions (~40%) and the durability of these repairs in service for a period exceeding five years, including three years of active field exercises in a humid tropical environment.

The repair approach was based on the composite bonded repair technology previously developed in DSTO to repair ADF aircraft. The nickel reinforcements were shown to be sufficiently durable to withstand the severe mechanical and environmental service conditions experienced by the trails. It is very doubtful, based on the surface damage observed, that composite reinforcements (carbon or boron fibres in an epoxy polymer matrix) would have survived.

Simple methods of analysis were used to estimate the loading experienced by the trails, and later verified by experimental strain analysis. Similarly, simple methods of analysis and experimental testing were used to estimate the effect of the damage and to design the reinforcements.

Electroformed nickel reinforcements with excellent surface matching were successfully manufactured from moulds taken from the damaged surfaces of the trails. Whilst electroforming is a very slow process, it requires relatively low cost equipment and can produce a reinforcement with excellent mechanical properties.

Wedge tests showed that the standard grit–blast silane treatment developed in DSTO for composite bonded repair of aluminium alloy components was a suitable process to provide durable adhesive bonding of the reinforcements with film adhesive FM 73. Finally, methods, based on the use of vacuum bags and electrical-resistance heating were shown to be a suitable procedure for bonding the reinforcements to the trails.

Authors

Dr Alan Baker
Air Vehicles Division

Dr Alan Baker prior to retiring from DSTO was Research Leader Aircraft Materials. On retiring he was given the honorary title of Emeritus Research Leader Aircraft Composite Structures. He continues to particpate in DSTO research in his specialist area through his current position as Program Leader in the CRC for Advanced Composite Structures.

Dr Richard Chester
Air Vehicles Division

Dr Richard Chester is the Research Leader for Aircraft Materials in the Air Vehicles Division with responsibility for both metallic and composite materials research as well as smart materials and forensic engineering. His research interests include durability and damage tolerance of aircraft composite materials and all aspects of composite bonded repair technology including surface preparation methods.

Dr Richard Solly
Air Vehicles Division

In an international career spanning 40 years, Dr Richard Solly has contributed to the science of synthesis of unique molecules, chemical reaction mechanisms, the utilzation of alternative energies, hydrocarbon fuel component reactions and bonding processes for electroformed nickel.

Contents

1. Introduction

This paper describes a study and demonstration program to develop bonded repairs for a Hamel 105 mm light field gun used extensively by the Australian Defence Force (ADF) largely because of its portability. However, the procedures described are of generic relevance to the repair of metallic structures used in severe physical environments.

The weight of the Hamel gun is minimised by the use of high-strength steel hollow tubular and box sections in the carriage assembly (the gun trail), Figure 1. The steel used is a weldable corrosion-resistant precipitation-hardened steel with the specification[1] STA60. Table 1 lists some of the properties specified.

Guidelines provided by the original equipment manufacturer (OEM) state that visible damage to the trail is unacceptable. This is because of the high-impulse loads experienced by the trail when the gun is fired. Thus when visible damage occurs, typically from severe mechanical contact, the trail must be repaired or replaced.

The cost of replacing a damaged trail is significant and this makes repair an attractive option. Repair by welding using a similar alloy as a filler wire is a possibility, but results in a reduced strength caused by over aging of the surrounding region and also to high levels of residual stress caused by thermal contraction on cooling. To restore the original strength the trail would have to be heat treated; however, this process requires a large facility and may lead to unacceptable distortion.

Another alternative is the use of adhesively-bonded reinforcements to recover lost strength and stiffness. Bonded reinforcements (or patches) have been extensively used to repair or extend the life of aluminium alloy aircraft structures[2] as well as much larger steel structures including bridges and ships[3]. In many repair applications, high strength and stiffness fibre composites, generally carbon/epoxy or boron/epoxy (carbon or boron fibres in an epoxy resin matrix), are used. The composites are chosen for the reinforcements as they are highly fatigue resistant and immune to corrosion; importantly, they can readily be formed, at relatively low temperatures and pressures, to the shape of the prospective repair area and then adhesively bonded to form a light-weight structurally efficient reinforcement.

Unfortunately, polymer-matrix composites, although attractive for most repair or reinforcement applications, are prone to damage by mechanical impact or abrasion, so are unsuited to the physically aggressive environment in which the Hamel guns operate.

Structural metals, although lacking many of the attributes of the composites as reinforcements, are a much more rugged option, but generally lack the formability required. There are, however, processes where metals can be formed at ambient temperatures and pressures to provide suitable reinforcements; these include computer numerical control (CNC) machining, rapid prototyping and electroforming.

CNC machining is an excellent option where suitable digitizing and machining facilities are available. But this process is expensive and may not provide sufficient fidelity in some applications. Rapid prototyping, based on sintering metal powders, similarly requires expensive equipment and may not provide the highest level of fidelity; further, the resulting reinforcement will be limited in strength.

In contrast electroforming, the process chosen for this study, produces the highest surface fidelity of almost any metal-forming process and, depending on the process, the resulting material has excellent mechanical properties at modest temperatures.

The electroforming process is similar to electroplating in which ions derived from a metallic anode suspended in electrolytic solution are deposited on a cathode – the work piece. Electroforming differs from conventional electroplating in that the deposit is much thicker and is stripped from the cathode – the mould.

The most usual material electroformed is nickel[4] and the electrolyte used is generally a nickel sulfamate solution; this electrolyte allows rapid deposition of nickel with low internal stress and excellent mechanical properties. The main disadvantage is that electroforming is a very slow process, taking several days to accomplish; the deposition rate is of the order of 0.01mm/ hour. Whilst equipment costs compared with the two previous options are fairly modest, considerable knowledge and skill in the process are required to achieve an acceptable result.

Although considerable emphasis has been placed in this section on the reinforcement, the key issue in bonded repairs is the formation of a strong, environmentally durable adhesive bond. The inability to guarantee the formation of environmentally durable bonds has, far more than any other issue, held back the use of bonded repairs in critical applications[5]. The problem of developing durable bonds lies not with the availability of suitable adhesives, but with the development of effective methods of preparing the surfaces for bonding. Structural metals, as a result of their inherent reactivity with environmental moisture pose a difficult problem – particularly in repair situations.

In a repair situation the surface treatment must be reasonably simple as it often has to be accomplished in relatively primitive conditions, using simple equipment. The treatment itself must not cause corrosion or other problems in surrounding regions or present a health hazard.

This paper describes the type and significance of damage to the gun trails, the design approach for the bonded reinforcements, and then materials engineering aspects, including the manufacture of the reinforcements, development of pre-bonding surface treatments and adhesive bonding of the reinforcements to the gun trails. Experimental strain measurements conducted to measure reinforcement efficiency are then presented. Finally, the current condition of the reinforcement and the status of the trails are described.

2. Damage to the Gun Trails

Gun trails are subject to damage from several sources. An example is fretting or abrasion caused by metal chains used inadvertently to immobilize the trails during transportation. Figure 2 shows a particularly severe example of damage caused in this way to the boss region circled in Figure 1; the damage is somewhat less severe than it appears in the figure as it is highlighted by damage to the paint film. Repair of damage in this trail was not attempted, but a trail with similar but less severe damage, Figure 3, was repaired.

Other examples of damage, shown in Figure 4, likely caused by boulder impact and in Figure 5 caused by abrasion to the trail from metal fittings by contact with metal fittings. Further damage was caused by spikes in the firing platform when the platform was being manipulated for transportation. Whilst, in most cases the damage was quite shallow so did not appear to be a serious threat to the integrity of the trails, on the basis of the advice provided by the OEM, any visible damage is grounds for rejection or repair. However, the sharp grooves caused by the firing platform spikes were smoothed out by sanding to reduce the stress concentration.

Table 2 lists damage to the two trails for which repairs were developed in this program.

3. Estimating Design Stresses

Knowledge of the maximum design stresses is one of the pre-requisites when assessing the significance of damage and designing a repair. In most practical situations this information is unavailable and "reverse engineering" approaches[6] have to be taken to make an estimate.

In the case of the gun trail, the magnitude and distribution of stresses developed are difficult to assess since they depend on several variables, including the size of the charge, the elevation of the gun and the reaction through the trail arms – which will depend on ground resistance.

Estimates of stress in complex components and loading situations are generally made by using finite-element (F-E) modelling, which is a costly procedure and generally requires validation by experimental strain analysis. Unfortunately, effort was not available in this program to conduct an F-E analysis. However, it was particularly fortunate that strain measurements had been made on the boss region during early experimental firings. A more comprehensive experimental strain analysis study was undertaken, this time including the arms, following the application of the reinforcements, mainly to assess reinforcing efficiency.

Thus it was decided to take two independent approaches to estimating design stresses: a) based on materials properties, and b) on the experimental strain analysis, although this was only for the boss region.

3.1 Estimation of Design Stresses Based on Material Properties

A repair should restore the static strength of the component to a minimum level plus a margin of safety. In terms used in the design of aircraft (and the philosophy used here, even through we are dealing with a completely different structure and requirements) the highest load expected to be experienced by the component in its lifetime is called the design limit load (DLL) and the margin of safety is often 1.5 × DLL; sometimes 1.2 × DLL is considered sufficient for a repair. During subsequent service (due to cyclic loading and environmental degradation) it is often mandated that the static strength of the repaired structure must not fall below ~ 1.2 DLL.

DLL, in aircraft terminology, is the load which can be withstood by the structure without significant yielding or permanent deformation and the design ultimate load (DUL) is the load that can be withstood without catastrophic failure. Generally DUL = 1.5 × DLL.

Thus in designing a repair an estimate is required of the DLL in the prospective region of the repair. However, in most practical cases stressing information is very difficult to obtain as OEM design information is generally unavailable and FE modelling and/or experimental strain analysis too costly or difficult to undertake. In critical cases where FE modelling is undertaken its predictions are generally validated by experimental strain analysis[7]; however, this can be more limited in extent than when strain analysis is the only source of design data.

In the absence of OEM or FE/experimental data, a simple reversed engineering approach can be made to estimating DLL based on an estimate of the material yield strength[6].

The least conservative estimate is that the stress at DLL (σ_{DLL}) is the metal yield strength divided by 1.5. The logic in making this estimate is based on the (aerospace) requirement that only local yielding is acceptable at DLL the yield stress could be taken as the stress at DUL. Then yielding would only occur where the stress concentration K_T exceeded the relatively low value of 1.5. For example, K_T is around 3 at the edges of an open hole subjected to direct tension or compression.

An over-conservative assumption is that the stress at DUL (σ_{DUL}) is the material ultimate strength so that σ_{DLL} is the material ultimate strength/1.5 (which is often approximately the yield strength). This assumption implies that at DLL regions with K_T of 1.5 or higher would be stressed to ultimate material strength.

Table 1 lists the assumed properties of the steel used in the gun trail. Taking the yield strength (0.2% proof) to be 800 MPa (the lowest likely value) equivalent to DUL the least conservative estimate of σ_{DLL} is 533 MPa and the most conservative estimate, based on a materials ultimate strength of 990 is that σ_{DLL} is 660MPa.

3.2 Estimation of Design Stresses Based on Strain-Gauge Measurements

Two experimental stress analysis studies were made on the trails by the Army Engineering Agency, Australia, at the Graytown Firing Range in Victoria.

The first study[8] focused only on the boss region using strain-gauge rosettes to estimate the principal stresses. Strain measurements were made at various gun barrel elevations and shot charges. The highest principal tensile stress experienced, based on measured strain, was 324MPa and the highest principal compressive stress was – 258MPa. Thus taking a margin of safety of 20% to allow for the possibility of higher loads not measured in these tests gives 389 MPa as a reasonable estimate for the stress at DLL from these tests.

The second experimental strain analysis made after the application of the reinforcements[9] was more comprehensive since it included the trail arms. Measurements on the arms were mostly made from single gauges, whereas those on the boss region were made from rosettes, as in the first study. The aim of using two guns in the second study was to compare stresses in prospective repair regions with those after implementation of the reinforcements. It will also be shown that excellent agreement was obtained between the two trials in the unreinforced regions.

Figure 6 and Figure 7 present the results for the unreinforced boss and arm regions, respectively, from the second study. Figure 6 shows the principal stresses in the boss region are quite similar to those found in the first study. However, as shown in Figure 7 higher stresses are experienced by the arms; only gauge E1 is a rosette, so the principal stress is recorded. All the other gauges on the arms were single, so the only the stress measured by that gauge is recorded. The highest stress measured was – 439 MPa so on a similar basis (20% margin) the stress at DLL would have been taken as - 527 MPa.

3.3 Assumed Stress Levels

As previously mentioned, only the results of strain measurements on the boss region were available at the time of the design of the reinforcements. Since it was considered intuitively that the stresses in the arms would be significantly greater than those in the boss region the materials-based estimate of 550 MPa was taken as a conservative value for σ_{DLL} for the trail arms and (based on the strain gauge measurements) a stress of 400 MPa was taken as a conservative estimate of the σ_{DLL} for the boss. The second experimental strain analysis provided later justifications for these conclusions.

4. Estimating the Influence of Damage

Complications caused by the highly variable shape of the damage, the structure of the gun trail (in the region of the boss) and the complex loading preclude anything other than a very approximate assessment of the K_T. Unfortunately no readily available solutions could be found for K_T which approximated the geometries of interest in the trail problem. Again

a detailed F-E analysis would have been a much superior approach, but problematic for the reasons previously mentioned.

Taking a very approximate approach, a "ball-park" figure for the stress concentration[10] caused by a shallow elliptical notch or groove in a thin semi-infinite element under direct tension is given by:

$$K_T = 0.855 + 2.21\sqrt{\frac{d}{r}} \qquad (1)$$

where d is the depth of the notch and r the radius of curvature at bottom of the notch.

A further factor F_t is required in estimating the approximate stress in the notch region at DLL, $\sigma_{NotchDLL}$ since the sheet is of finite depth to allow for the reduced section of the skin of thickness t:

$$F_t = t/(t-d) \qquad (2)$$

Thus the approximate maximum stress in the notch is given by:

$$\sigma_{NotchDLL} = K_T F_t \sigma_{DLL} \qquad (3)$$

Based on assumed DLL stresses for the boss and arm region of 400 and 550 MPa respectively, and using the appropriate geometry detailed in equation 3, the peak notch stresses were calculated and are detailed in Table 2.

The values taken for the notch radius r in the Table are estimates based on various assumptions; for example for chain abrasion the diameter of the chain links. As mentioned earlier, sharp grooves made by the firing-platform spikes were smoothed out prior to reinforcement.

This shows that, on the basis of assumptions made in this very simple analysis, stresses exceeding the yield strength of the steel used for manufacturing the trail are possible in rare cases. The stress situation for the unrepaired trails would be of much greater concern if the notch radius r was smaller or the damage of penetration d was deeper.

Fatigue is an important issue that must also be considered when assessing the influence of damage on the structural integrity of the gun trail. The trail is subjected to low-cycle fatigue of several cycles of diminishing load per firing (depending on the degree of damping) which could lead to crack initiation at the base of the notches. Thus it is prudent to ensure that the stresses at stress raisers do not approach the yield stress of 800 MPa.

These estimations are admittedly extremely approximate, but they do seem to bear out the OEMs guidance that visible damage to the gun trail is not acceptable.

5. Reinforcement Design

Since the damage is small compared to the length required to transmit loads from the trail to the reinforcement[11], it is conservatively assumed that the reinforcement has little effect on reducing K_T.

The basic design parameters for the reinforcement are then simply the thickness required to provide the desired strain reduction in the damaged region and the length required to transfer the loads from the trail into the reinforcement.

It is then necessary to check that the adhesive and reinforcement are stressed within their allowable limits, both for static strength and fatigue. To minimise the shear and peel stresses in the adhesive, it is generally necessary to taper the ends of the reinforcement; tapering also reduces the stress concentration in the parent structure at the ends of the reinforcement.

The input parameters are the stresses in the trail and the assumed materials properties for the trail, the reinforcement and the adhesive. A critical assumption in this analysis is that the predominant failure mode in the adhesive is cohesive – failure within the adhesive, not adhesive at the interface of the adhesive and the trail or the reinforcement. For this assumption to be justified, the use of effective bonding processes and procedures are critical.

5.1 Assumed Materials Properties

There are three sets of materials properties to be used in the design process; these are the trail steel, the electroformed nickel and the adhesive. Table 3 and Table 4 respectively provide the assumed design properties for the STA60 steel and electroformed nickel, obtained as described later. Based on our long-term experience with other repairs the epoxy-nitrile film adhesive FM 73 (by Cytec) was chosen for this application; Table 5 provides relevant mechanical properties of this adhesive at ambient temperature. These Tables include the nomenclature used in the analysis.

5.2 Estimation of Reinforcement Thickness

The simplest approach to designing the repair is to make the reinforcement of equal stiffness to the material removed in the damaged region. That is:

$$t_R = \frac{E_T}{E_R} d \qquad (4)$$

where E, t and d refer to Youngs Modulus thickness and nominal notch depth respectively and the subscripts R and T refer to the reinforcement and trail. A more sophisticated approach, not undertaken here, would allow for the load attraction by the stiffer reinforced region.

Based on equation 4 the required thickness of nickel is thus given by 1.23d where the d values are provided in Table 2, which results in a t_R well below one mm in most cases. However, to ensure handleability in the reinforcements and to maintain profile it was decided to choose 2mm as the thickness of the nickel for all reinforcements.

5.3 Static Stress Allowable for the Adhesive Joint

Having chosen the thickness of the reinforcement (t_R) as 2 mm it is important to check that the loads to be transmitted from the parent structure into the reinforcement do not exceed the shear or peel strength of the adhesive. Here (as previously mentioned) the important assumption is made that the lowest stress failure mode in the joint is cohesive failure of the adhesive layer. Adhesive failure caused by environmental degradation at the metal/adhesive interface is potentially a very much weaker mode, which must be guarded against by using effective pre-bond treatments.

The critical region for the joint is generally at the ends of the reinforcement; local strain concentration in the adhesive caused by the notch is ignored as, compared with that experienced at the reinforcement ends, it will be minor. Also the influence of residual stress is not considered as the nickel reinforcement and steel have similar coefficients of thermal expansion. However, there will be a small level of residual stress as the reinforcement can undergo unrestrained expansion during the bonding process, whereas the heated region in the trail will be constrained by the surrounding cool structure[12].

Figure 8 is a sketch of two end configurations for the reinforcement: a) the simplest having no end (90°) taper and b) with suitable end taper. This section considers case a) where simple equations[13] can be used.

The maximum stress σ_{max} that can be carried by the trail without exceeding the allowable capacity of the adhesive in shear for the 90 ° end geometry shown in Figure 8a is given by:

$$\sigma_{max} = \left\{\left[2t_A E_T\left(1 + E_T t_T / E_R t_R\right)\right]\left[\tau_p\left(\gamma_e/2 + \gamma_p\right)\right]\right\}^{\frac{1}{2}} \qquad (5)$$

Where γ_e and γ_P refer respectively to the shear yield strain and strain to failure of the adhesive taken from shear stress/shear strain curves and t_A is the adhesive thickness. Note that the last term in square brackets is the area under the shear stress/ shear strain curve for the adhesive. It is of interest to note that this area stays approximately constant over the working temperature range of the adhesive.

Based on the adhesive properties listed in Table 5 and the values for E_R and E_T listed in Table 3 and Table 4, Equation 5 shows that the allowable stress before adhesive damage exceeds 1000 MPa, thus failure in shear of the adhesive at a static stress σ_{DLL} of 550 or 400 MPa is not anticipated.

However, it is known that the adhesive is more vulnerable to failure under peel stresses which are not well characterised in terms of simple equations. Previous work[14] showed that the magnitude of the peel stress was very similar to the shear stress, and the level of both are greatly reduced by appropriate tapering as illustrated in Figure 8b.

5.4 Experimental Estimation of Fatigue Stress Allowable

It is known that adhesive systems (particularly the bond interfaces) are vulnerable to cracking (disbonding) under cyclic loading – damage seems to result mainly from peel rather than shear stresses. [This fact is illustrated by the much larger fatigue resistance in these joints under compression loading where peel stresses are negative]. Thus it was decided to check the repair durability with some limited tensile dominated fatigue tests, similar to those described in more detail in Reference 14.

Tests were conducted on specimens with configurations similar to those shown in Figure 8. The reinforcement was electroformed nickel but in this case the parent material was 2024 T3 aluminium alloy.

For these tests a flat plate of nickel was electroformed to a thickness of 2 mm. From this plate, twelve specimens were cut each 130 mm long by 20 mm wide. Following the surface preparation outlined later in Section 7, these were bonded with FM-73 adhesive to each face of a central 2024 T3 aluminium adherend 230 mm by 20 mm wide by 6.4 mm thick. Three taper angles at the ends of the reinforcements were investigated, just two specimens at each level: (a) a 90^o taper or flat end, (b) a 6^o degree (1:10) linear taper, and (c) the FE optimized taper from Reference 15. The optimized taper is non-linear, having a long thin section at the end of the nickel which approximates the end of a linear 3° taper.

Fatigue tests were conducted in a 100 kN Instron test machine under 3Hz tensile cyclic (sinusoidal) loading at a load ratio (minimum/maximum) R of 0.1. The technique used to detect bond failure involves bonding strain gauges to the tip of the reinforcements and monitoring strain response as a function of cycles. Disbond initiation was defined to have occurred when the strain registered by of one of the gauges dropped by 10%.

Commencing at the initial load, 100000 cycles were applied with a strain gauge measurement each 100 cycles. If the output from the strain gauges decreased by less than 10%, the load amplitude was increased by 2 kN and the loading applied for a further 100000 cycles. For a decrease in strain gauge output of more than 5%, digital images of the edges were carefully monitored.

The drop in strain coincided with the formation of a distinct crack of 0.5 mm in length, generally very close to the nickel/adhesive interface.

As expected, it was found that the load in the parent structure for damage formation was increased by tapering, increasing from ~ 18 kN for the 90 ° taper to 27 kN for the optimal taper. The simple linear 6 ° taper performed almost as well (at 25 kN) as the optimum. Using Equation 5 for the 90 ° taper this corresponds to a total fatigue shear strain in the adhesive of 0.27. The 90 °equivalent shear strain for the 6 ° taper and optimium taper 0.67 and 0.77 respectively.
Again using Equation 5, for the 90 ° equivalent strain for t_T = 5.5 mm this gives:

$\sigma_{maxfatigue}$ = 547 MPa for a 90 ° taper

$\sigma_{maxfatigue}$ = 699 MPa for a 6 ° taper

$\sigma_{maxfatigue}$ = 750 MPa for the Optimum taper

Thus, taking into account that σ_{DLL} is nominally the once in a lifetime stress, it can be concluded that fatigue cracking in the bond line should not be a concern; nevertheless, because of the large number of unknowns it was decided the ends of the reinforcements would be tapered to ~ 6 ° to improve the margin on fatigue strength.

6. Electroforming the Nickel Reinforcements

6.1 Preparation of the Moulds of the Damaged Surface

A mould is required to make an electroformed component. The mould, which is made a cathode in the electroplating bath must either be conducting or coated with a conducting layer.

It is important that the electroformed part can be removed from the mould without distortion - this requirement can be a problem with thin electroforms or electroforms of complex shapes. Stainless or chrome-plated steel is a suitable material for making very simple moulds that can be made by machining. For more complex moulds, as required here, formable materials such as plaster or fibreglass may be used; these materials are rendered conducting, generally by depositing a layer of electroless silver.

The first step in making a mould from a pre-existing component is to make a surface cast or 'splash'. In the second step the mould is then made from this splash by making a counter cast in a durable material such as fibreglass (glass-reinforced epoxy or polyester). The splash material itself must be sufficiently durable to allow formation of the mould. Moulding plaster is the most common material used but silicone rubber or casting resins are often more suitable.

An alternative for electroforming reinforcements is to use the part itself as the mould. To take this approach the part must be removable and small enough to fit into the electroforming bath. In a metallic component, areas where the electrodeposited coating is not required are "stopped off" with a suitable paint.

To make the moulds for the two damaged Hamel gun trails all attachments were removed and the coating removed by sand blasting to bare steel. An area equal to the proposed reinforcement size was marked on the trail and two layers of wax sheeting of thickness 0.25 mm to allow for the adhesive thickness were moulded onto the trail. Moulding plaster was then applied over the wax in sufficient thickness to provide structural integrity.

A female fibreglass mould, again of sufficient thickness to provide structural integrity, was reproduced from the plaster mould. The resulting fibreglass mould, Figure 9, was an excellent reproduction of the surface of the trail.

Finally, to make the mould conductive for electroplating an electroless silver conductive film was deposited from an ammoniacal solution onto the fibreglass mould to an area extending approximately two centimetres beyond the size of the required nickel electroform to allow for clean up of the edges.

6.2 Electroforming the Nickel Reinforcements

Electroforming is accomplished in a nickel sulfamate bath heated to 50° C and agitated with air. The mould is the cathode and the deposit (unlike electroplating where the thickness is in the order of microns) is thick in the order of several millimetres. The anode is generally nickel, which is consumed during the process. The nickel sulfamate solution is continuously purified from organic contaminants by circulating over activated charcoal. The ability of an electroplating bath to produce a uniform deposit in a mould with deep recesses is called its throwing power – compared to other nickel plating baths the sulfamate bath is quite good.

Compared with other baths for electroplating nickel, the sulfamate bath produces deposits with relativity low internal stress that are not prone to distortion when released from the mould.

In deep moulds plating uniformity can be improved by several means, including the use of shields and auxiliary anodes and pulsed current. These techniques also minimise the formation of dendrites or nodules at current density hot spots. Software is available to design electroforming systems in complex cases. Since the surface contour of the prospective repair region was relatively shallow no such refinements were attempted for forming the reinforcements.

After a short time (strike) at low current density to build up the conducting coating, nickel was deposited at a current density of one Amp/mm^2 corresponding to a build up rate of 0.01 mm/h. At this rate of deposition electroformed nickel has a fine crystalline structure, resulting in excellent mechanical properties.

During electroforming it was found that several nodules had formed at the edges of the electroform in regions of local high current density – mainly at the outer edges. These were removed by grinding - an extra 20 mm had been included in the length of electroform for this purpose.

Figure 10 shows the resulting reinforcements. Note the high level of fidelity in the larger electroform, including the damage indentation (which ideally should have been filled in prior to making the mould).

Finally, the edges of the electroform were machined to form a linear taper of 6 ° in the long axis and 11 ° in the short axis.

6.3 Mechanical Properties of the Electroformed Nickel

Measurements of stress strain behaviour were made on strips of electroformed nickel using the test procedure set out in ASTM E08. Three of the large reinforcements, Figure 10, were manufactured and two were sectioned in the flat region to provide four specimens which complied with the procedure prescribed in ASTM E08-86a.

These specimens were strain gauged and tested to provide the results listed in Table 6. A fairly wide range of mechanical properties for electroformed nickel are quoted in the literature, probably depending on the deposition variables eg current density, bath composition and operating temperature etc; the properties listed in Table 6 fall well within the quoted range.

7. Surface Treatment Procedures

Previous work on the development of surface-treatment procedures for the repair of aluminium airframe alloys[16] had resulted in a procedure based on the use of grit-blasting followed by use of an epoxy-compatible silane (γGPS) – and, for optimum performance, coating with a suitable corrosion-resistant primer.

Since the grit-blast silane surface-treatment procedure was found to be effective for low-alloy steels (for example the F111 aircraft wing-pivot fitting[17]) as well as other structural alloys it was assumed that it would also be suited for bonding the nickel electroforms to the gun-trail steel.

Grit blasting is an important pre-requisite for the silane-based surface treatment of aluminium alloys. However, as both the nickel and the steel are very much harder than aluminium alloy, alternative methods to grit blasting of activating the metal surface were investigated. The most promising was etching in an aqueous solution of nitric acid. Although, as shown later, nitric-acid etching offered no major advantage over grit-blasting this process would be chosen if grit-blasting facilities were unavailable.

7.1 Measurement of Bond Durability

The environmental durability of the bonds produced by these surface treatments was assessed using the Long-Crack Extension Specimen shown in Figure 11, based on ASTM D3433.

In the test one of the lever arms was made of D6AC steel plated with the nickel from the sulfamate bath, so was a good representation of the nickel electroform. Unfortunately the trail steel was not available for the other lever arm, so D6AC steel was used as a substitute. This is a low alloy steel (composition 0.43 % C, 0.85 % Mn, 0.90 % Cr, 0.75 % Ni and 0.50 % Mo) and is thus not representative of the trail steel. Thus these tests are

representative only of the durability of the bond to nickel. However, other studies showed that the grit-blast silane process was an effective treatment for stainless steel which is more similar in composition to the steel used in the trails.

In the long-crack extension test the specimen is exposed to a 95 % relative humidity at 50° C and, as shown in Figure 11, screws are used to create the fixed displacement of the lever arms to develop the crack driving force G_1. From the resulting growth of the crack in the adhesive bond line the Mode 1 fracture energy G_{1c} is estimated as a function of time. Thus the G_{1c} value is a quantitative estimate of fracture energy of the bond line and therefore the instantaneous resistance to bond failure. Figure 12 plots results obtained for the silane process with and without the primer and with prior nitric acid etching or grit blasting.

After some considerable time, growth decreases to a low value then the value of G_{1c} is taken to be an estimate of long-term bond durability. For crack growth which occurs after the initial displacement of the lever arms bond failure is generally mainly interfacial or adhesive, compared with the initial failure which is generally within the adhesive layer or cohesive. However, as adhesive joints are optimally designed to subject the adhesive predominantly to shear loading, $G_{1c,}$ whilst an excellent indicator of bond durability, is of limited value as a design parameter.

The value for G_{1c} obtained for the nickel-coated specimens compares very well with results for aluminium alloys obtained using the grit-blast silane process[18], Figure 13. This is encouraging as the grit-blast silane process has been shown to provide excellent long-term durability with bonded repairs to aluminium alloys[5].

8. Bonding the Reinforcements to the Gun Trails

The reinforcements were bonded to the gun trails using a silicon-rubber heater blanket to heat the structure and a vacuum bag to apply atmospheric pressure. Two layers of FM73 adhesive were cut to the size of the reinforcement and the adhesive was placed over the damaged region of the trail. The heater blanket was placed over the reinforcement with thermocouples to monitor and control temperature and a bleeder cloth was placed over the heater to provide a passage for expulsion of air etc. A nylon vacuum bag was then formed over the assembly and sealed with butyl rubber. The finished vacuum-bag assembly is shown in Figure 14 for the doubler applied to the boss region of the trail. Cure of the adhesive was achieved at a temperature 120° C for four hours under atmospheric pressure.

Prior to actually bonding the reinforcements a test was conducted to evaluate adhesive flow and integrity. This was done by setting up the vacuum bag assembly as just described and placing a layer of release film on either side of the adhesive. Following the cure procedure the adhesive was released and inspected for flow and voids. Figure 15 shows that the adhesive layer exhibited good flow and little voiding

Figure 16 shows the nickel reinforcement bonded to the gun trail in the boss region and Figure 17 shows two reinforcements bonded to the underside of the same region.

Finally, the bead of adhesive at the edge of each reinforcements was sanded to an angle of 30 degrees and to provide environmental protection of the exposed edges a layer of a two-pot epoxy-coating system was brushed over the adhesive bead at the edge of the reinforcement, the reinforcement itself and the trail for a distance of 5 cm around the reinforcement.

9. Reinforcement Efficiency in Repaired Trails

After the reinforcements were applied the two repaired trails were fully reassembled with the guns and, as mentioned in Section 3.2, an experimental strain analysis was conducted by the Army Engineering Agency. Strain measurements were made at seventeen combinations gun barrel elevations and shot charges. Full details of the range of firing conditions are provided in Reference 8 and 9.

Figure 6 and Figure 7 show the positions of the gauges and the maximum (single gauges) or principal (rosettes) stresses in un-reinforced regions, Figure 18 and Figure 19 show the corresponding strains in the repaired regions.

Before analysis of these results it is necessary to consider first the validity of comparing results from the two guns. Table 7 lists ratios for strain readings from similar gauges on the arms of two trails at similar firing conditions. The theoretical value is unity for a perfect comparison; as can be seen from the Table the comparison is remarkably good. Thus the conclusion can be made that comparing reinforced with un-reinforced measurements from the two guns is valid.

The second step is to compare the reinforcement efficiency by taking the ratio of reinforced to un-reinforced. This analysis is provided in Table 8, which shows that the reinforcement produces a strain reduction of at least 40% in each region and that the level of strain reduction in each region is insensitive to firing condition.

10. Current Status of Reinforcements

After a period exceeding five years, including three years of active field exercises in a humid tropical environment and relatively harsh mechanical treatment, the repaired trials are currently in storage in preparation for scheduled refurbishment. The opportunity was thus taken to conduct a simple inspection, which consisted of a detailed visual examination and a tap test.

All the reinforcements appeared to be in excellent condition with no evidence of disbonding – indicating that no fatigue or environmental degradation has occurred.

However, as shown in Figure 20 there is evidence of significant mechanical contact in the form of extensive chips and scratches to the paint scheme. The observation justifies the choice of nickel for the reinforcements; if polymer-matrix composite reinforcements had been used severe damage would almost certainly have occurred. Refurbishment of the trails involves removal of the paint scheme by grit blasting followed by steam cleaning prior to re-coating – this could prove damaging to a polymer composite reinforcement, unless very carefully undertaken. For the electroformed reinforcements, the only caution given is to avoid removal of the epoxy coating at the reinforcement edges – or replacement prior to painting if removal occurs.

11. Conclusions

- A repair technology based on the use of adhesively bonded electroformed nickel reinforcements was successfully developed to repair the trails of light field guns operated by the ADF which had been damaged by fretting or mechanical contact in service.

- The success was judged by the measured reduction in strain in the reinforced regions (~40%) and the durability of these repairs in active use over a period of three years.

- The repair approach was based on the composite bonded repair technology previously developed in DSTO to repair ADF aircraft. The nickel reinforcements were shown to be sufficiently durable to withstand the severe service conditions experienced by the trails. It is very doubtful, based on the surface damage observed, that composite reinforcements would have survived.

- Simple methods of analysis were used to estimate the loading experienced by the trails, and later verified by experimental strain analysis. Similarly, simple methods of analysis and experimental testing were used to estimate the effect of the damage and to design the reinforcements.

- Electroformed nickel reinforcements with excellent surface matching were successfully manufactured from moulds taken from the damaged surfaces of the trails. Whilst electroforming is a very slow process it requires relatively low cost equipment and produces a reinforcement with excellent mechanical properties.

- Wedge tests showed that the standard grit–blast silane treatment was a suitable process to provide durable adhesive bonding of the reinforcements with film adhesive FM 73.

- Finally, methods, based on the use of vacuum bags and electrical- resistance heating were shown to be a suitable procedure for bonding the reinforcements to the trails.

Guns, adhesive bonding, reinforcement and repair

19. ABSTRACT

A repair technology based on the use of adhesively bonded electroformed nickel reinforcements was successfully developed to repair the trails of light field guns operated by ADF that had been damaged by fretting or mechanical contact in service. The success was judged by the measured reduction in strain in the reinforced regions (~40%) and the durability of these repairs in service over a period exceeding five years, including three years of active field exercises in a humid tropical environment.
