Abstract

For the past fifty years, U.S. Air Force repairable inventory has been allocated based on an analytic model developed by Dr. Craig C. Sherbrooke. Although versions of his model can be implemented easily with the help of a computer, the analytic approach fundamentally lacks the flexibility to address numerous logistics issues. This body of research will offer a novel alternative approach that will enable researchers to investigate currently unsolved logistics problems such as quantifying the benefits of lateral resupply.

Acknowledgments

I once had a professor who repeatedly reminded his students that *brevity is the soul of wit* (Irani, 2004). I agree, so I will keep this short and hopefully meaningful.

I want to thank my advisor, Dr. John O. Miller. His flexibility, insight and adventurous spirit have been appreciated throughout this endeavor. Additionally, I thank my reader, Dr. Martha C. Cooper, for her extraordinary attention to detail.

I thank Mr. Richard Moore and Mike Niklas of HQ AFCM/A9A for encouraging me to pursue graduate education and being supportive of me while away from the office.

I owe thanks to Mr. F. Michael Slay of LMI for being a continuous source of inspiration, knowledge and friendship.

I owe gratitude to my wife. Her patience, understanding and unconditional love have been tremendously valuable to me.

I need to thank my daughter. In seven months of life, she has already given a lot. I hope to return that favor for the rest of our lives.

SIMULATED MULTI-ECHELON READINESS-BASED INVENTORY LEVELING
WITH LATERAL RESUPPLY

Introduction

Chapter Overview

At any given time, the United States Air Force (USAF) accounts for the use of over 100,000 types of reparable spare parts. Each of these parts requires a forecast to drive the provisioning process to maintain a level of stock to buffer against future demands.

In 2007, the Government Accountability Office (GAO) reported that the Air Force's on-hand inventory averaged \$31.4 billion during 2002-2005 (Defense Inventory, 2007: 9). During the same years, on average, 64.6% of on-hand inventory was not used to support requirements (Defense Inventory, 2007: 13). The USAF spends approximately six billion dollars on replenishment, annually.

These statistics demonstrate two key concepts. First, the USAF spends a lot of money on inventory. Second, there appears to be a great deal of potential for improvement.

The primary function of this chapter is to provide general background material useful for understanding the problem statement and research objectives.

Background

The Repairable Asset Pipeline

The number of parts required in an inventory system is referred to as a level; this differs with serviceable stock because some stock may be undergoing repair or undergoing shipment. The stock being repaired or shipped contributes to fulfilling the level, but is not immediately available for weapon system application.

As failed parts are removed from weapon systems (e.g. aircraft), they may be repaired onsite or shipped to another location with greater repair capability. Similarly, serviceable stock may be stored onsite or requested from a larger distribution center. This is known as a multi-echelon supply model. The Air Force's repair/supply system has historically been modeled as a dual-echelon model consisting of bases and depots. The base repair is often referred to as an intermediate maintenance location.

As shown in Figure 1, when an aircraft's repairable components fail they are routed from the flight line to a base for triage, the determination of the ultimate repair source. If the base makes the repair, the newly serviceable part is sent to base supply for storage or applied to an existing backorder.

In general, if the base cannot make the repair (determined at triage, or after a failed repair attempt at the base), the failed component is sent to a depot where the part will be repaired or condemned. If the repair is successful, the serviceable asset is stocked in depot supply to be warehoused or applied to an existing depot backorder.

The NRTS% (not reparable this station percentage) or *NRTS rate* is the likelihood that the repair must be outsourced to the depot. Similarly, the *RTS rate* is the probability that the part is repaired at the base. This describes the maintenance portion of the reparable asset pipeline.

Figure 1. The Reparable Asset Pipeline (Adapted from Miller, 1995: 16)

The supply portion of the reparable asset pipeline begins with the broken component being turned in at the base. At turn-in, the base will attempt to issue a serviceable part. If the broken part must be sent to the depot for repair, the base will request a serviceable part in exchange that can be stocked or applied to the weapon system after the order and ship time (OST) delay.

During this process, the depot will inevitably encounter parts that are damaged or used to the point where a repair is not feasible. The depot will choose to condemn these parts, thus reducing the quantity of parts in the pipeline. Generally, new parts are requisitioned from external supply sources to maintain prescribed stock levels.

A base backorder occurs when a base cannot issue a serviceable part to the flight line at turn-in. A depot backorder occurs when the depot is unable to issue a serviceable

part to a base. A backorder is filled when maintenance fixes a part and it undergoes the appropriate transit time, or when supply is able to locate and procure the asset from another location – if a base procures the asset from another base, this is termed *lateral resupply*. An aircraft waiting for serviceable parts is maintained in NMCS (not mission capable – supply) status; this decreases aircraft availability (AA).

A depot backorder simply means that a part is owed to a base; this does not have any implication about aircraft status. Base backorders are more severe in terms of aircraft availability because the flight line is in need of a part (Abell, 1993: 6).

The pipeline concept is sometimes described by:

$$\mu = \lambda t \tag{1.1}$$

where μ is a part’s pipeline quantity, λ is the mean demand rate and t is the mean resupply time. Further, if we let r be the RTS rate, BRT be the base repair time, and DDT be the depot delay time (DDT accounts for retrograde time, the time it takes to ship from the base to the depot); this equation can be modified (Miller, 1995: 22):

$$\mu = \lambda[(r)BRT + (1 - r)(OST + DDT)] \tag{1.2}$$

Multi-Echelon Models

As discussed previously, the Air Force has historically used a dual-echelon supply model. If more stock is located at the bases, the aircraft requiring the spares will be serviced quickly. However, if the stock is misallocated, a base requiring the parts may have trouble locating a serviceable spare. If lateral resupply is assumed to be non-existent, it would be desirable to hold stock at the depot to be shipped (requiring an OST

delay) to the proper location. If too much stock is held at the depot, the OST delay would regularly impact aircraft availability. Stock allocation tradeoffs are necessary in this scenario; some stock should be held at a centralized location for ease of distribution, and some should be held at the point of use.

In recent years, Centralized Intermediate Repair Facilities (CIRFs) have been implemented to act as a common repair organization for specific types of parts for a number of bases. This system is outlined in figure 2.

Figure 2. Multi-Echelon Model with CIRF and Lateral Resupply

In this scenario an additional transportation delay may be incurred in the pipeline process due to the CIRF. This has the effect of decreasing availability over the Air Force as a whole. Higher stock levels can make up for the loss in availability, but can be costly. The rationale is that centralizing repair activities saves more money than what is lost due to maintaining availability targets with the additional inventory and transportation delays.

Expected Backorders

A backorder (BO_i) can be explicitly defined as the inventory condition that a serviceable part i is requested for which there is no stock. The expected backorder ($EBO_i(s_i)$) is the expected number of outstanding backorders at a random point in time for a given stock level s for part i . To elicit the probabilities used in the $EBO_i(s_i)$ calculation, distributional assumptions are made regarding each part's pipeline (undergoing procurement, repair or in transit) for each location (Miller, 1995:18). There is a direct link between EBO minimization and maximizing availability (O'Malley, 1983: 2-6).

Aircraft Availability

In 1954, the Department of Defense (DoD) began examining ways to standardize the spares provisioning process (Orsburn, 1991: xiii). With the advent of practical computing and digital data storage, the 1960's were the beginning of a new era of logistics-based operations research.

It was during this period that system performance metrics gained popularity. Availability (A) surfaced as the primary performance metric, and is defined as the expected percentage of a fleet of aircraft that is not down for spares at a random point in time (O'Malley, 1983:2-6).

$$A = 100 \prod_{i=1}^I \left\{ \frac{1 - EBO_i(s_i)}{NZ_i} \right\}^{Z_i} \quad (1.3)$$

To measure availability, one must know the specific part types used in the weapon system (l), the fleet size (N), the number of parts per weapon system (Z_i), and the $EBO_i(s_i)$. A key observation is that availability is maximized by minimizing $EBO_i(s_i)$. This concept will be revisited in Chapter 2.

Marginal Analysis

The USAF Materiel Command's overarching goal is to maximize availability through expected backorder minimization; this must be done within budgetary constraints. Consequently, resupply actions are taken based on a technique referred to as marginal analysis. Marginal analysis is a greedy heuristic to determine which part provides the greatest reduction in EBOs per dollar spent. A resupply action (i.e. repair or procure decision) for a single part i with a large sort value (sv) is performed with higher priority than an action with a small sort value where the sort value is defined as:

$$sv_i = \frac{EBO_i(s_i - 1) - EBO_i(s_i)}{c} \quad (1.4)$$

where c is the cost of the action. This is the mathematical tool used to establish requirements and resupply actions, and is often thought of as getting the most “bang for the buck” in terms of availability.

As of 1973, the Air Force's marginal analysis algorithms relied on a near-Poisson demand process assumption (via EBO calculation) that set the variance-to-mean ratio (VMR) for all recoverable parts at 1.01. R.J. Stevens and J.M. Hill performed an empirical analysis that showed VMRs were typically not close to the 1.01 standard (Stevens, 1973: *i*). Since this study, there have been many proposals for changes in the

distributional assumptions, but the negative binomial distribution (a generalization of the Poisson) is used in the majority of models today.

Readiness-Based Sparing

Readiness-based sparing is the process of calculating stock levels for locations with the objective of minimizing system EBOs. The Air Force accomplishes this through a model called Readiness-Based Levels (RBL). After the Aircraft Availability Model (AAM) computes worldwide requirements, the requirements are passed to RBL to be split into levels for each location.

RBL is largely based on the METRIC (Multi-Echelon Technique for Recoverable Item Control) model developed in 1968 by Craig C. Sherbrooke. An expected backorder at one location is weighted the same as an expected backorder for the same part elsewhere. RBL does not account for the impact of lateral resupply, CIRFs, or shipping times (or costs) between locations. The levels are issued quarterly (Long, 1996: 5).

Palm's Theorem

Palm's theorem can be expressed (Muckstadt, 2005: 43):

Suppose demands occur according to a compound Poisson process where λ is the customer order arrival rate. Suppose also that the resupply times are independent and identically distributed with density $g(t)$ with mean τ . Assume when a customer order is received, the resupply time for all units in the order is the same and is drawn from the resupply time distribution. The steady state probability of x units in resupply is given by the compound Poisson distribution with mean $\lambda\tau\mu$, where μ is the average customer order size.

This result has also been extended to logarithmic Poisson processes, where cluster interarrival times are exponentially distributed and cluster size is logarithmic. Despite the desirable *independent increments* property (future states are not dependent on current

states), logarithmic Poisson processes have a constant mean and variance; empirical data has shown that demand means and variances change with time, and further, that clusters are not observed. The negative binomial distribution maintains *independent increments*, necessitates a variance larger than the mean, and is discrete for non-negative values. For these reasons, it is used to model inventory pipelines (Sherbrooke, 2004: 64). Palm's Theorem is assumed to be applicable.

As a result of Palm's Theorem, the Air Force does not attempt to model the repair or transportation time distributions. Demand rates are exclusively used to model the pipeline distributions that are used for EBO estimation. If the demand distribution and repair distribution are not independent, Palm's Theorem is violated; this can occur with repair capacity constraints or with a small number of aircraft (Cochran, 2002: 530).

As discussed previously, the EBO estimates are used to calculate inventory levels and to make resupply decisions via marginal analysis. It should be noted that the Palm's Theorem assumption is fundamental to building the distributions used in marginal analysis.

Problem Statement

As the Air Force continues to transform its business processes to more efficiently use its budget to provide support to the warfighter, a need exists to provide rapid what-if analysis regarding policy or procedural changes in operations, as well as to test the sensitivity of underlying model assumptions to efficiently guide future research initiatives. The goal of this research project is to provide a flexible model of reparable

asset supply chain processes that can assess a change's impact on base expected backorders (an established proxy for aircraft availability) and optimal stock levels.

Research Questions

Can a tool be built to assess the impact of policy or procedural changes (such as lateral resupply) on reparable assets in terms of warfighter support?

Investigative Questions

- 1.) Does simulation-based marginal analysis provide opportunities to improve supply chain and weapon system support?
- 2.) Does modeling base lateral resupply enable more realistic projections of system availability and improved inventory solutions? Previous attempts to answer this question have been unsuccessful (Sherbrooke, 2004: 258).
- 3.) Can a variance/bias reduction technique be used to improve the model output?

Scope and Limitations

The investigative questions posed above are only a small fraction of the breadth of questions that can be addressed with the appropriate simulation model. The purpose of this project is to make progress towards a new method of inventory leveling that will enable research of many more topics than is possible with legacy models. After this research project concludes, future research topics will be left for other students' undertaking.

Literature Review

Chapter Overview

The first chapter provided background information necessary for understanding the problem statement, objectives and scope of this research. This chapter will serve to provide a detailed summary of previous work relevant to this project's objectives, methodologies and future applications.

The Air Force currently sets stock levels using an approach developed over the past five decades. Researchers have gone to great length to analytically model multi-indenture, multi-echelon systems. Attempts have also been made to analytically describe item cannibalization and lateral resupply. A description of these approaches (with details of limiting assumptions) is provided in this chapter. The reader should note the escalating complexity with respect to modest modeling gains. This chapter will reinforce the need for an alternative way to model EBOs and perform readiness based leveling.

Setting Stock Levels

METRIC

The Multi-Echelon Technique for Recoverable Item Control (METRIC) model was proposed to the Air Force by Craig C. Sherbrooke in 1968 while employed at the RAND Corporation. The model seeks to minimize worldwide expected base backorders

for reparable first-indenture items. These parts are typically expensive and ordered individually.

Sherbrooke outlines five key model assumptions (Sherbrooke, 2004: 46-47):

- 1.) *The decision as to whether a base repairs an item does not depend on stock levels or workload.*
- 2.) *The base is resupplied from the depot, not by lateral supply from another base.*
- 3.) *The (s-1, s) inventory policy is appropriate for every item at every echelon; subsequently administrative and holding costs are not needed for optimization.*
- 4.) *Optimal steady-state stock levels are determined.*
- 5.) *Repair cost is always less than purchase cost.*

The first assumption implies that a base will always make a repair when it has the capability, and that any parts needed for the repair will be ordered from the depot and received in a timely fashion. Sherbrooke makes the second assumption because he believes bases are rarely supplied from other bases and it simplifies the transportation cost structure. The (s-1, s) policy is simply one-for-one ordering; when a part breaks, another is requisitioned to increase stock back to the prescribed level. Because the one-for-one policy specifies the order quantity, administrative and holding costs are considered the same for all orders and not needed for optimization. The fourth assumption relates to a belief that the number of aircraft and flying hours remain constant over some time horizon. The final assumption results in favoring repairing broken items before purchasing new ones.

The stock balance equation forms a basis for future discussion, it shows that the stock level (s) is equal to the on-hand inventory (OH) plus the inventory due in (DI) minus any existing backorders, or (Sherbrooke, 2004: 24):

$$s = OH + DI - BO \quad (2.1)$$

where due-ins for a depot are from repair, and for a base can be from resupply (the depot) or base repair.

For a single first-indenture item, Sherbrooke defines the following variables and system of equations; a subscript of zero refers to the depot, whereas a positive subscript j refers to a base (Sherbrooke, 2004: 48):

m_j = average annual demand at base j
 t_j = average repair time (in years) at base j
 μ_j = average pipeline at base j
 r_j = probability of repair at base j
 O_j = average order-and-ship time from depot to base j

A depot's average annual demand is the percentage of base demands that could not be repaired at the base, or:

$$m_0 = \sum_{j=1}^J m_j (1 - r_j) \quad (2.2)$$

The METRIC model assumes that demands from each base is a Poisson process, thereby allowing the processes to sum into a larger Poisson process. The resulting average depot pipeline is $m_0 t_0$; subsequently, depot expected backorders can be expressed: $EBO(s_0 | m_0 t_0)$. This permits formulation of the average pipeline for a part at base j (where $j > 0$):

$$\mu_j = m_j \left(r_j t_j + (1 - r_j) \left\{ O_j + \frac{EBO(s_0 | m_0 t_0)}{m_0} \right\} \right) \quad (2.3)$$

It is worth noting that because an expected depot backorder is a time-weighted average number of backorders, dividing by average demand yields the average depot delay to obtain a serviceable part to ship. If sufficient depot OH stock is kept, the

expected backorders should be small, and the base must only wait the O_j to receive the part.

To optimize levels, METRIC begins by setting worldwide base and depot stock levels to zero. It increments worldwide base or depot stock levels by a single unit to greedily reduce worldwide base EBOs via marginal analysis. Subsequently, the worldwide base stock must then be subdivided amongst individual bases; this is also accomplished through marginal analysis in the RBL system.

Multi-Indenture Theory

An aircraft part's indenture is its location on a bill of materials in relation to the airframe. For example, a first-indenture part is a large assembly taken directly off the aircraft such as an engine. This part is typically held and repaired at the base, and is subsequently called a line replaceable unit (LRU). On the LRU, there are smaller components that may be taken off that are repaired at the base if possible, but may be easily shipped to the depot for repair. These types of components are called shop replaceable units (SRU) and represent the second level of indenture. A common modeling assumption is that the failure of an LRU is due to the single failure of an SRU (Sherbrooke, 2004: 65).

Using Sherbrooke's notation, a zero subscript for the index i refers to an LRU and $i > 0$ refers to an indentured SRU. If one assumes that the average demand rate for an LRU (m_0) is Poisson, then each of its SRUs must have average demand rates (m_i) that are also Poisson and independent of each other (Sherbrooke, 2004: 65).

$$m_0 = \sum_{i=1}^I m_i \quad (2.4)$$

Equation 2.4 is interesting, because in practice a single m_i can exceed the value of m_0 . An example of this provided by F. Michael Slay is when a lightbulb fails and can be replaced without generated a demand for the LRU. Sherbrooke assumes this equation sufficiently models reality; others disagree.

Additionally, Sherbrooke defines t_0 as the LRU average repair time and t_i as the SRU average repair time. The expected pipeline for an LRU is (Sherbrooke, 2004: 66):

$$E[X_0] = m_0 t_0 + \sum_{i=1}^I EBO(s_i | m_i t_i) \quad (2.5)$$

This is just the LRU demand rate multiplied by the LRU repair time plus the expected number of LRUs waiting on SRUs from the depot.

VARI-METRIC Multi-Echelon Theory

The VARI-METRIC model is a multi-echelon, multi-indenture model that was built by Slay in 1984 and was based on the METRIC model. Whereas METRIC focused primarily on pipeline means, VARI-METRIC also used pipeline variances to calculate improved estimates of backorders.

Discussion regarding this topic begins with the definition of conditional variance. The variance for the number of parts in the pipeline at base j is dependent on the number of parts in repair at the depot, x_0 (Sherbrooke, 2004: 103-106):

$$Var[X_j] = E[Var(X_j | X_0)] + Var[E(X_j | X_0)] \quad (2.6)$$

Because base pipelines are partially composed of a time segment dependent on the number of units in depot repair x_0 , the expected pipeline for base j can be written as a conditional expectation:

$$E[X_j] = \sum_{x_0=1}^{\infty} E[X_j | X_0] \Pr\{X_0 = x_0\} \quad (2.7)$$

Given a number of units in depot repair C , one can compute the conditional expectation for the number of units in the base pipeline. If $x_0 \leq s_0$ there are no depot backorders due to the depot repair time because depot stock can supply the base over the order and ship time. Therefore, the expected number of units in the base pipeline is the average demand rate multiplied by the order and ship time (assumed to be the same for all bases for reasons to be discussed later).

$$E[X_j | x_0] = m_j O \quad \forall \quad x_0 \leq s_0 \quad (2.8)$$

When x_0 exceeds s_0 , a finite number of backorders occur; the fraction of backorders allocated to a base is proportional to the base's average demand and is constant because of the use of rates. This allows use of the binomial distribution to allocate the backorders amongst bases, and will be used later.

$$E[X_j | x_0] = m_j O + \frac{m_j (x_0 - s_0)}{m_0} \quad \forall \quad x_0 > s_0 \quad (2.9)$$

After taking the expectation with respect to x_0 :

$$E[X_j] = m_j O + \frac{m_j EBO(s_0)}{m_0} \quad \forall \quad x_0 > s_0 \quad (2.10)$$

By employing the variance operator with respect to x_0 , the first term is equal to zero; this leaves the following:

$$\text{Var}[E(X_j | X_0)] = \frac{m_j^2 VBO(s_0)}{m_0^2} \quad \forall \quad x_0 > s_0 \quad (2.11)$$

To satisfy the requirements for the conditional variance equation, $\text{Var}(X_j | X_0)$ must also be defined. $E(X_j | X_0)$ has previously been determined; using this and that base backorders are binomially distributed amongst bases, applying the variance operator to terms containing x_0 results in:

$$\text{Var}[X_j | x_0] = \begin{cases} m_j O & \forall \quad x_0 \leq s \\ m_j O + \frac{m_j}{m_0} \left(1 - \frac{m_j}{m_0}\right) (x_0 - s_0) & \forall \quad x_0 > s \end{cases} \quad (2.12)$$

After an additional use of the expectation operator, the conditional variance can be shown to be:

$$\text{Var}[X_j] = m_j O + \frac{m_j}{m_0} \left(1 - \frac{m_j}{m_0}\right) EBO(s_0) + \frac{m_j^2 VBO(s_0)}{m_0^2} \quad (2.13)$$

To be consistent with prior notation we define the following terms with SRU i ($i = 0$ represents an LRU) and base j ($j = 0$ refers to the depot) (Sherbrooke, 2004: 106):

m_{ij} = average annual demand for SRU i at base j
 t_{ij} = average repair time (in years) for SRU i at base j
 r_{ij} = probability of repair for SRU i at base j
 q_{ij} = conditional probability that an LRU repaired at base j will result in SRU i being identified as the cause
 O_i = order and ship time from depot to any base of SRU i (assuming the depot has stock available and the time is the same for all bases)
 s_{ij} = stock level for SRU i at base j
 X_{ij} = number of units of SRU i at base j in resupply at any point in time
 $EBO(s | \mu, Var)$ = expected backorders for stock level s with pipeline mean μ and variance Var

The average annual demand for SRU i can be shown to be the average annual LRU demand rate multiplied by the probability it is repaired at base j and that the SRU i has been identified as the cause of the failure (Sherbrooke, 2004: 107-111).

$$m_{ij} = m_{0j} r_{0j} q_{ij} \quad (2.14)$$

The depot's average annual LRU demand is the sum of the base LRU average annual demands multiplied by the probability they are outsourced to the depot.

$$m_{00} = \sum_{j=1}^J m_{0j} (1 - r_{0j}) \quad (2.15)$$

The depot's average annual demand for SRU i can be shown similarly, but contains a portion for when an SRU is demanded for a repair of an LRU already at the depot.

$$m_{i0} = \sum_{j=1}^J m_{ij} (1 - r_{ij}) + m_{00} q_{i0} \quad (2.16)$$

Of all the SRU i demanded at the depot, the fraction that is due to LRU depot demand is:

$$f_{i0} = \frac{m_{00}q_{i0}}{m_{i0}} \quad (2.17)$$

The expected number of LRUs in depot repair is a combination of the average LRU demand rate at the depot with the associated repair time and the LRUs that are being delayed due to SRU i depot backorders.

$$E[X_{00}] = m_{00}t_{00} + \sum_{i=1}^I f_{i0} EBO(s_{i0} | m_{i0}t_{i0}) \quad (2.18)$$

For a given total number of SRU i depot backorders and the fixed probability f_{i0} of a particular backorder delaying an LRU at the depot, the binomial distribution is used to describe the probability of any number of the backorders delaying an LRU. This permits formulation of the variance of the number of LRUs in depot repair.

$$Var[X_{00}] = m_{00}t_{00} + \sum_{i=1}^I f_{i0}(1-f_{i0})EBO(s_{i0} | m_{i0}t_{i0}) + \sum_{i=1}^I f_{i0}^2 VBO(s_{i0} | m_{i0}t_{i0}) \quad (2.19)$$

Of all the SRU i demanded at the depot, the fraction that is needed at base j is:

$$f_{ij} = \frac{m_{ij}(1-r_{ij})}{m_{i0}} \quad (2.20)$$

The expected number of SRU i in base repair or resupply is a combination of the average SRU i demand rate at base j and the time it takes to obtain a serviceable part directly from the depot or for the base to repair it, and the expected delay from the depot for SRU i depot backorders.

$$E[X_{ij}] = m_{ij}[(1-r_{ij})O_i + r_{ij}t_{ij}] + f_{ij} EBO(s_{i0} | m_{i0}t_{i0}) \quad (2.21)$$

For a given total number of SRU i depot backorders and the fixed probability f_{ij} of a particular SRU i backorder being for base j , the binomial distribution is used to describe the probability of any number of the backorders belonging to base j . This permits formulation of the variance of the number of SRU i in repair or resupply for base j .

$$Var[X_{ij}] = m_{ij}[(1-r_{ij})O_i + r_{ij}t_{ij}] + f_{ij}(1-f_{ij})EBO(s_{i0} | m_{i0}t_{i0}) + f_{ij}^2VBO(s_{i0} | m_{i0}t_{i0}) \quad (2.22)$$

Of all the LRUs demanded at the depot, the fraction that is due to LRU demand at base j is:

$$f_{0j} = \frac{m_{0j}(1-r_{0j})}{m_{00}} \quad (2.23)$$

The expected number of LRUs in base repair or resupply for base j is a combination of the average LRU demand rate at base j and the time it takes to obtain a serviceable part directly from the depot or for the base to repair it, the expected delay from the depot for LRU depot backorders, and the expected delay for each of the LRU's indentured SRUs' backorders at base j .

$$E[X_{0j}] = m_{0j}[(1-r_{0j})O_0 + r_{0j}t_{0j}] + f_{0j}EBO(s_{00} | E[X_{00}], Var[X_{00}]) + \sum_{i=1}^I EBO(s_{ij} | E[X_{ij}], Var[X_{ij}]) \quad (2.24)$$

For a given total number of LRU depot backorders and the fixed probability f_{0j} of a particular LRU backorder being for base j , the binomial distribution is used to describe the probability of any number of the backorders belonging to base j . This permits formulation of the variance of the number of LRUs in repair or resupply for base j .

$$\begin{aligned} Var[X_{0j}] = & m_{0j}[(1-r_{0j})O_0 + r_{0j}t_{0j}] + f_{0j}(1-f_{0j})EBO(s_{00} | E[X_{00}], Var[X_{00}]) + \\ & f_{0j}^2 VBO(s_{00} | E[X_{00}], Var[X_{00}]) + \sum_{i=1}^I VBO(s_{ij} | E[X_{ij}], Var[X_{ij}]) \end{aligned} \quad (2.25)$$

The overarching goal is to allocate stock in such a manner as to maximize aircraft availability. The availability at base j for a particular LRU is (Sherbrooke, 2004: 111):

$$A_{0j} = 100 \left\{ 1 - \frac{EBO(s_{0j} | E[X_{0j}], Var[X_{0j}])}{N_j Z_0} \right\}^{Z_0} \quad (2.26)$$

where N_j is the number of aircraft residing at base j and Z_0 is the number of occurrences of the LRU on the aircraft (quantity per application, or QPA). To find the availability for a group of similar aircraft, the equation must be adjusted to consider all LRUs and the number of aircraft. Marginal analysis is used to make tradeoffs between depot stock and worldwide-base stock, and then to subdivide worldwide-base stock amongst bases.

Modifying this logic is possible, but may lessen the model's accuracy somewhat. For example, using base-specific order and ship times will violate the binomial backorder allocation assumption (each base could have a different shipping lead time, therefore the depot backorder status would be dependent on when shipping must take place). This problem only affects the variance calculations and dissipates with a small number of backorders or a large number of bases (Sherbrooke, 2004: 112).

DRIVE

In 1995, Louis Miller with the RAND Corporation developed an alternative approach to METRIC-based stock leveling. His method was rooted in DRIVE (Distribution and Repair in Variable Environments), a program that was originally intended to provide prioritization for depot repair and distribution (Miller, 1995: iii).

This differs with respect to METRIC-based approaches in several ways. Most importantly, METRIC-based approaches have objective functions that minimize base EBOs, whereas DRIVE's objective is to repair and distribute parts to maximize the probability that all bases meet their availability goal at the end of a planning horizon. Also, DRIVE's logic assumes that item cannibalization is performed by assuming that broken parts are consolidated on as few aircraft as possible at each location (Miller, 1995: 29).

Miller compared DRIVE leveling against METRIC leveling and indicated that the performances were similar (Miller, 1995: 40 & 68). VARI-METRIC is known to be superior to METRIC (Sherbrooke, 2004: 102) and if either METRIC or VARI-METRIC were to also implement cannibalization, it would almost certainly gain an advantage to DRIVE.

Additionally, DRIVE is better suited for issuing stock to bases rather than determining an appropriate quantity to retain at the depots (Reynolds, 1995: 11). As a result, further study of the DRIVE-based solution was not pursued. Miller's mathematics are not shown here but can be found in the literature (Miller, 1992: 16-19).

Cannibalization

Although this particular topic was not investigated in this thesis, a brief discussion of relevant cannibalization research is included to give a further understanding of the DRIVE model, as well as to serve as a basis for continued student research emanating from this endeavor.

Cannibalization is the process of taking parts from an inoperable aircraft to install on another aircraft to increase the total number of mission capable planes. It is particularly attractive because it increases the effectiveness of the inventory policy and minimizes the monetary investment required for a given level of warfighter support (Abell, 1993: xii). However, there is a maintenance cost associated with the practice that may ultimately act as detriment to aircraft availability (Fisher, 1989: 154).

Donald P. Gaver, of the RAND Corporation, wrote a detailed cannibalization model in 1993 for LRUs. A description of his work follows.

If one assumes that there are n types of LRUs on a weapon system, that LRU _{i} is a particular type of LRU, and that there are q_i of LRU _{i} installed on each aircraft, and B_i represents a backorder for LRU _{i} , then no more than k aircraft can be down at any time if cannibalization is performed to its maximum extent. This is shown in the following equation (Gaver, 1993: 14):

$$B_i \leq kq_i \tag{2.27}$$

Further, letting D_c be the number of aircraft for cannibalizable parts and X_i be the number of LRU _{i} in the pipeline, the probability distribution of the number of aircraft non-operational because they could not be fixed through cannibalization is (Gaver, 1993: 15):

$$P\{D_c \leq k\} = \prod_{i=1}^n P\{X_i \leq kq_i + s_i\}, \quad k = 0, 1, 2, \dots, a \quad (2.28)$$

Of course, planes can also be non-operational for broken parts that are non-cannibalizable; the number of planes fitting this criteria is D_{nc} . Let the total number of non-operational planes be $D^\#$. Because of cannibalization, $D^\#$ must be equal to the larger of D_{nc} and D_c . If \underline{s} is defined as the vector of all stock levels for a type of plane, then through independence on the ability to cannibalize different types of parts (Gaver, 1993: 16):

$$P\{D^\# \leq l \mid \underline{s}\} = P\{D_{nc} \leq l \mid \underline{s}\} \cdot P\{D_c \leq l \mid \underline{s}\} \quad (2.29)$$

If there are a planes, then the expected number down is (Gaver, 1993: 16):

$$E(D^\# \mid \underline{s}) = a - \sum_{l=0}^a P\{D_{nc} \leq l \mid \underline{s}\} \cdot P\{D_c \leq l \mid \underline{s}\} \quad (2.30)$$

Consequently, the expected number of planes operational, or the expected availability is (Gaver, 1993: 16):

$$E(A \mid \underline{s}) = \sum_{l=0}^a P\{D_{nc} \leq l \mid \underline{s}\} \cdot P\{D_c \leq l \mid \underline{s}\} \quad (2.31)$$

Lateral Resupply

Lateral resupply is the process of a base, centralized intermediate repair facility (CIRF) or depot procuring a part from another location of the same echelon, and could perhaps be extended to mean any order and shipment that does not move a serviceable part to a lower echelon.

Sherbrooke states that lateral resupply has resulted in backorder reduction of more than 70% for low demand items in simulations when repair is restricted to the depot (Sherbrooke, 2004: 245). His work towards developing an analytic model for base repairable items was unsuccessful and was not documented (Sherbrooke, 2004: 257).

Business rules are often employed to determine from where the base backorder is resupplied. For example, one set of rules found in the literature is (Lee, 1987: 1305):

- 1) *Random source rule. The source base is chosen randomly from among members with stock on hand.*
- 2) *Priority source rule 1. The base with the maximum stock on hand is chosen as the source base. Ties are broken randomly.*
- 3) *Priority source rule 2. The base with the maximum stock on hand is chosen as the source base. If there are ties, then the base with the fewest backorders is chosen. Ties are broken randomly.*

The calculations for Lee's method require that bases capable of lateral resupply have identical demand rates. This assumption is not practical for USAF logistics applications.

Another approach is to create *pooling mechanisms*. These are rules that dictate how locations share resources to simplify or attempt to eliminate the lateral resupply problem. Cohen defines pools as (Cohen, 1986: 25-28):

- 1) *Each group is disjoint.*
- 2) *The collection of groups form a covering of the set of locations at each echelon.*
- 3) *All members of a group have a single antecedent at the next highest echelon.*
- 4) *The intragroup emergency shipment cost is less than the emergency cost from a location outside of the group.*
- 5) *Pooling within a group is controlled by a sharing rate parameter.*

Heuristics have been developed to make an economic case for when lateral resupply is beneficial (Evers, 2001, 312). The Air Force is only secondarily concerned with the cost of transportation in the case of lateral resupply. The deeper issue is how to

construct stock levels (subject to a budget) given that some parts benefit more from lateral resupply than others.

Simulation-Based Leveling

Simulation based leveling on the industrial scale has only recently become computationally possible. There is very little published research in this area; the large majority of related articles focus on the multi-echelon aspects of traditional supply chain relationships, typically modeling resource attributes such as utilization, queue length and shipping time variances. Additionally, industry generally uses normally distributed random variables; this assumption has undesirable consequences for AF supply chain modeling (Chakravorty, 1992: 165). Due to limited applicability, these articles will not be discussed further here.

One notable body of research, by Roberto Carlos Borges de Abreu, used Arena-based simulation to calculate EBOs that were numerically similar to METRIC. His method, called P-METRIC, uses the gamma distribution to model the number of items in the repairable asset pipeline (Abreu, 2002: 46). The majority of Abreu's research focused on describing the sensitivity of his model relative to changes in input parameters.

He did not argue that his method was an improvement to the traditional methods of EBO calculation and did not describe a process to use his simulation model to allocate spares. Further, his choice of the gamma distribution was because of its ability to change shape with adjustments to its shape and scale parameters; optimizing these parameters may have distorted or obscured important output information (Abreu, 2002: 50).

Investigations of the impacts of cannibalization and lateral resupply were deliberately avoided (Abreu, 2002: 43).

Another unpublished article describes how simulation's natural variability interferes with the marginal analysis process (Slay, 2007: 1). To overcome this issue, Slay recommends a trace-driven (externally supplied discrete event list) simulation and develops a novel variance reduction technique he refers to as the Distribution Enforcement Method.

Slay acknowledges that use of common random numbers, or other variance reduction techniques have been shown to improve simulation results in some circumstances, but still do not achieve the desired effect in a reasonable amount of time. The Distribution Enforcement Method (DEM) uniformly assigns event times to all demands that occur within all replications of a simulation. It then assigns each of these events to a particular replication such that the variance of demands occurring amongst replications is consistent with the variance of the demand distribution, and the mean number of demands per replication is correct (Slay, 2007: 2-7).

He notes that this method may be used to address currently unsolved analytic problems such as describing the impacts of lateral resupply, prioritized repair, expedited resupply and optimizing spares by when sorties are flown (Slay, 2007: 9). Additionally, steady state determination and base-depot interactions are left as future research issues (Slay, 2007: 11).

Methodology

Chapter Overview

This chapter outlines the research plan and provides a description of the analysis tools and methods used for model verification. The modeling process will take place in three phases shown in Figure 3. Each phase will build upon the previous one. The result will be a simulation model capable of building optimal stock levels and estimating the associated base backorders. This model will be the basis for investigating implications of Sherbrooke's modeling assumptions, such as insignificant lateral resupply.

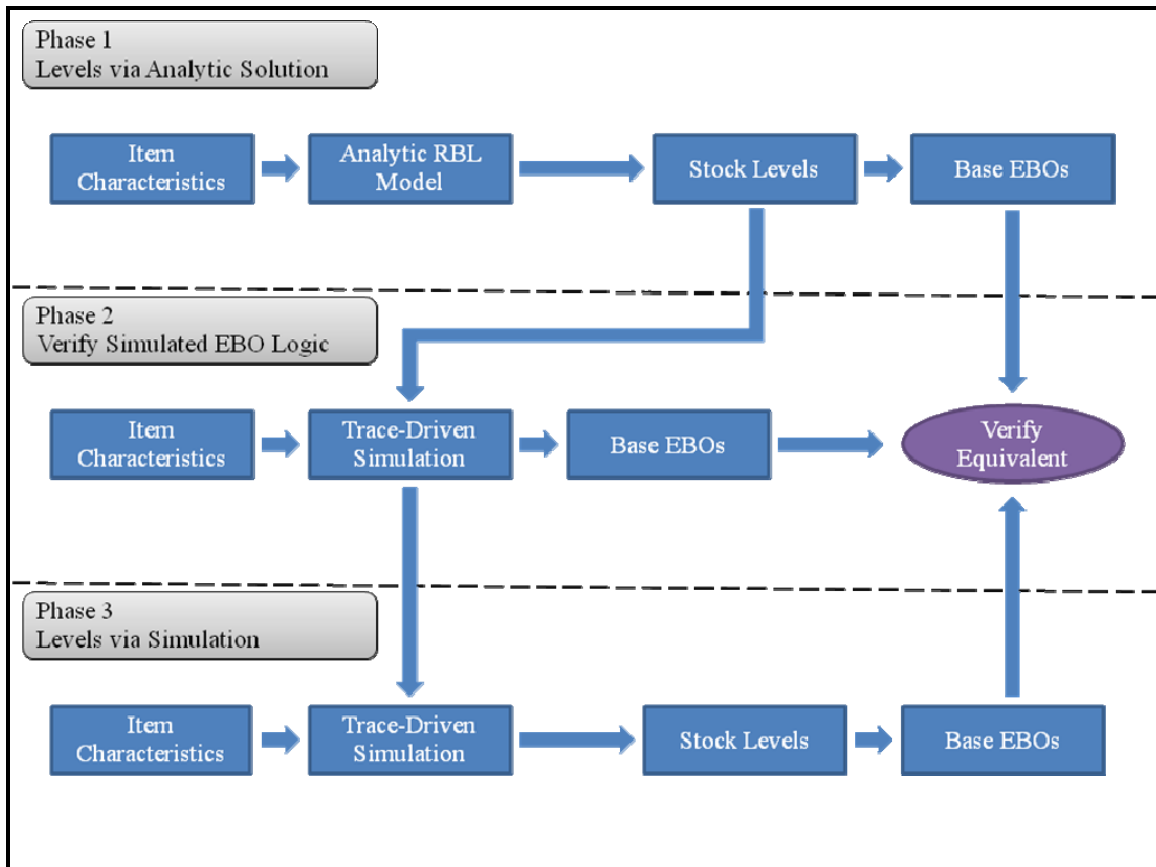

Figure 3. Model Verification Concept

The first phase will be to build a functional readiness-based sparing (RBS) model. This model will consist of a depot and five bases using METRIC logic to optimize sparing, and will result in levels with corresponding expected backorders (EBOs).

The second phase will be a trace-driven simulation to record observed backorders (an estimate of EBOs) at a single depot and five bases. The results of the trace-driven simulation and RBS model will be compared. This step will verify that simulated backorder estimation is being done correctly. Ideal simulation settings (for high accuracy and low run time) will be found and the Distribution Enforcement Method will be tested (Slay, 2007).

The third phase will be to modify the trace-driven simulation to perform readiness based sparing; the simulated levels will result in observed backorders that will be compared with the theoretical estimate from the analytic RBS solution.

All modeling, analytic and simulation-based, will be conducted in MATLAB. Although MATLAB is not typically regarded as a premier simulation package, its flexibility and debugging features make it ideal for this type of research.

Phase 1 – Analytic RBL Model

METRIC-based solutions are currently used in the majority of US Air Force models. The Aircraft Availability Model (AAM) calculates stock levels for worldwide requirements. The pipeline segments for all bases are added together for each part. The AAM uses marginal analysis to determine how many of each part is required to maximize

aircraft availability; the stopping rule is a budgetary constraint. These worldwide levels are then passed to RBL.

RBL takes the worldwide levels and divides them amongst locations with potentially unique pipelines. It accomplishes this by minimizing worldwide EBOs.

If marginal analysis is used to allocate levels instead of a total enumeration of all solutions, the resulting levels can be suboptimal; Sherbrooke mentions when identical bases exist, the marginal analysis solution may result in excessive stock being placed at the depot (Sherbrooke, 2004: 53). He recommends a *flushout* procedure to assess the benefits of removing a unit of stock from the depot and placing it at a base instead.

This project ultimately generates stock levels using a simulation technique. To verify the simulation model is correct, it must be compared against the analytic procedure.

Subsequently, a MATLAB version of the AAM and RBL was built and was augmented with a *flushout* routine. This model is able to generate appropriate levels for a system consisting of one depot and five bases with accurate EBO estimation. Although the literature's examples were constructed using a single aircraft part, the MATLAB model was built to accommodate any number of parts or bases. Further details of this model will be discussed in the Results chapter.

Phase 2 – Trace-Driven Simulated Backorders

This phase focuses on the development of logic for a rudimentary simulation model that mimics the performance of a METRIC-based (analytic) RBL solution. As

pointed out by F. Michael Slay (Slay, 2007), simulation replications for this type of application can be computationally expensive; bias and variance may need to be controlled to maintain adequate fidelity in a reasonable amount of time; he argues that distribution enforcement is superior to other variance reduction techniques.

The Distribution Enforcement Method (Slay, 2007) described in the literature review was also coded into MATLAB. This method provides an event list for all replications, where an event is defined as the demand for a specific type of part. If each replication is meant to represent a possible future time horizon, and the number of demands occurring in the horizon are assumed to be Poisson with a specified demand mean, then over a large number of replications (or horizons), the percent of replications containing x demands should be equal to the Poisson probability $P(x)$.

The DEM MATLAB code permits the user to select random event-replication assignment in lieu of strict Poisson enforcement; this reduces the run-time of the program dramatically, but will not represent the Poisson distribution as accurately. The event-replication assignment was verified by comparing the output's histograms with the Poisson probability distribution function as shown in Figure 4. The DEM does enforce the Poisson distribution, as expected. Random assignment also approximated the Poisson distribution reasonably well in nearly one-tenth the time; however, precision may be very important to the spares allocation process.

Because there are a predetermined number of micro-replications (number of trials), and there is a constant probability that a single demand is assigned to a replication (the reciprocal of the number of micro-replications), the demands will be distributed binomially when no distribution is enforced. With a large number of micro-replications,

the binomial distribution will approximate the Poisson distribution very closely (Slay, 2007: 4). At this point, it is uncertain how much benefit distribution enforcement can provide relative to its much longer computation time (as employed in this study).

Figure 4. Percent of 1000 Replications Receiving X Events

Because the Distribution Enforcement Method (DEM) was originally described for a single location, the method was modified to subdivide the events by base according to one of two different methods: relative local demand rates via an inverse transform function (randomly), or alternatively, by expectation. The Bernoulli splitting principle permits a Poisson process to be subdivided into lesser Poisson processes.

The inverse transform method builds a cumulative distribution function from the proportion of each base's demand rates relative to the worldwide demand. Random numbers are used to determine which base is assigned any given demand.

The expectation method operates somewhat differently. Because each base has a demand rate and a finite number of demands will be assigned, there is an expected number of demands that will be assigned to each base. The base with the lowest percent of assigned demands already allocated to it will receive the next demand. This process continues until all demands (events) are assigned. Due to the nature of this process, events will be dispersed evenly throughout time at each location.

The two event-base assignment rules were investigated for a single part over one-thousand replications with dissimilar bases; results are shown in Figure 5.

Figure 5. Comparison of Event-Base Assignment Rules

Assignment by expectation performed slightly better than the inverse transform technique. However, in the real world, demands may not always occur at a precise period as the expectation rule dictates. Some randomness may be desirable to enhance the believability of the model. This feature may prove useful in testing model robustness.

Some variation of the DEM technique will be used to generate an event list that contains at a minimum: the part type, event time, failure location, and replication number. This discrete event list provides failure data for the trace-driven simulation. The event list is the primary random feature of the simulation; the only other instances of randomness occur to break ties between minima or maxima when necessary, or to make repair source decisions with respect to the NRTS rate.

At this point, this chapter has discussed how to analytically build stock levels, and construct an event list. All of this will be instrumental in testing portions of simulation code designed to model the USAF supply system and record observed backorders.

Before the simulation begins, the event list only consists of part failure events. As parts fail, base stock is decremented; if the number of failures exceeds the number of parts the base has on hand, a backorder is generated. If a base backorder occurs, or a part is sent to the depot for repair, the base will request a part immediately from the depot. The depot must comply if it is able to do so. If a part is repaired at the base, it can be retained or sent to the depot; this decision will be based on the largest reduction in system EBOs (per METRIC logic). When a depot repairs a part, it will be used to fill an existing backorder at a location with insufficient due-in assets; in the event there are no such backorders, the depot will optimally place the asset to minimize system EBOs using METRIC logic. This process (with key simulation modeling assumptions) is outlined in Figure 6.

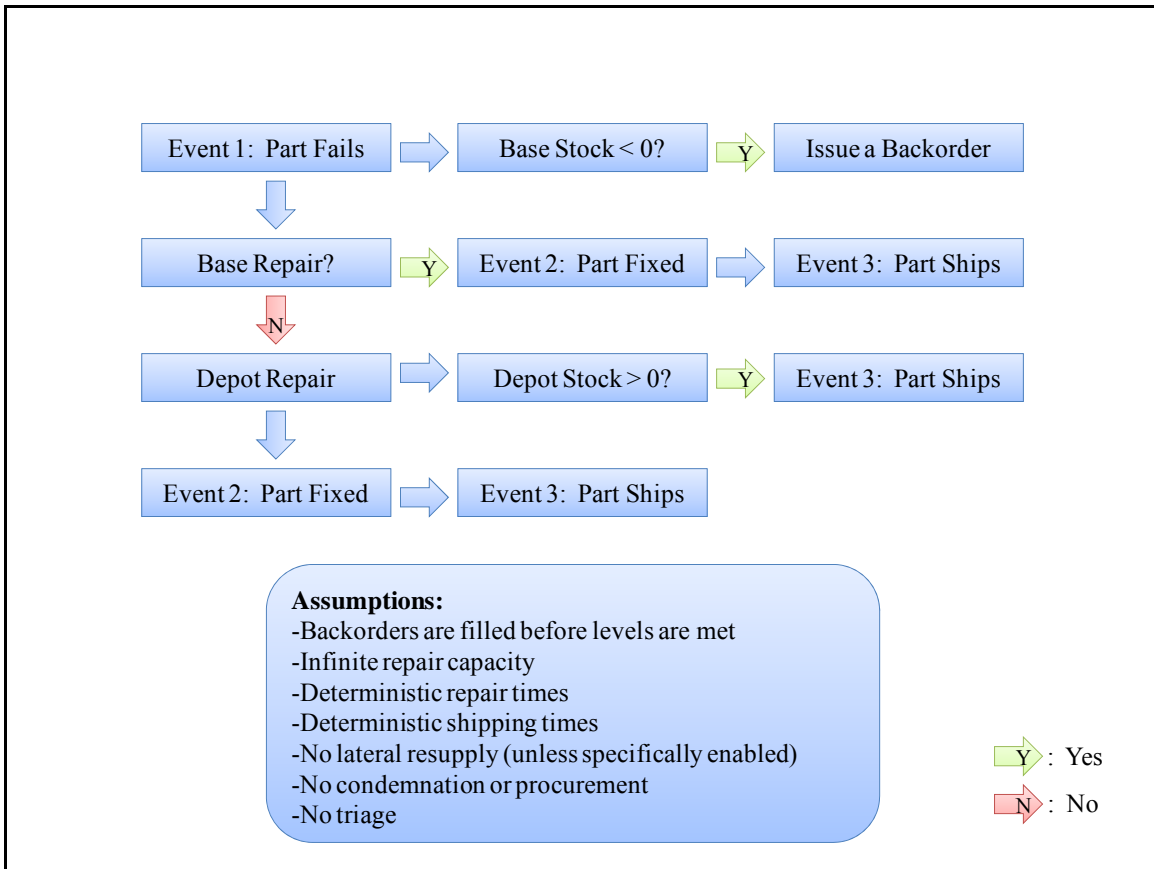

Figure 6. Trace-Driven Simulation Flow Diagram

As the simulation iterates through failures, new events are generated to represent the repair of a part or the arrival of a part at a destination. Naturally, all of these events have times associated with them, so the event list must be resorted after the completion of any event. Stock classifications such as *on hand*, *due in*, *work in process*, and *backorders* are tracked meticulously throughout the simulation. The origination and termination times for all backorders are recorded and tallied for each part type and location.

The verification of model logic for this phase will include analysis for determining steady state conditions, base repair logic, depot repair logic and depot distribution logic. It will also be important to determine appropriate run parameters for the simulation. All of this will be discussed in detail in the Results chapter.

Phase 3 – Simulated Readiness-Based Leveling

The first phase used the analytic model to build levels that minimized EBOs. The second phase took these stock levels and a list of part failures over a time horizon, and simulated the USAF supply pipeline to count the number of backorders occurring at multiple locations. These backorders were shown to correspond to the theoretical values predicted by the analytic model.

The third phase uses the simulation logic from phase 2 without the stock levels supplied in phase 1. Instead, the simulation begins with no stock being assigned to any location and a full budget. It is assumed parts are bought individually.

The simulation manages two types of stock levels: temporary and permanent. Permanent stock levels are those resulting from a *buy* decision. Temporary stock levels are those used to determine which levels should be adjusted permanently. For example, when the simulation begins, the permanent levels for all locations are set to zero. The simulation runs to establish a baseline backorder statistic. The simulation runs again for each part-location combination, temporarily incrementing each location's stock level by one unit for a specific type of part.

After a complete set of simulations (all part-location combinations have been exhausted), the reduction in backorders from the baseline statistic is divided by the appropriate part's cost. The part-location combination with the largest decrease in backorders per dollar spent is selected; one of these parts will be *bought*, and placed at that location. Thus, the permanent level and budget are updated.

Precautions are taken to ensure that a location's stock never exceeds the permanent stock level. This process continues until the budget is expended.

Simulated readiness-based leveling, in this context, cannot be totally independent from METRIC-like logic; there still must be a way for the program to determine which location a repaired asset should be sent to. However, using this approach, the rigid assumptions of METRIC can be bent, if not altogether broken. If necessary, levels can be generated with modeling considerations beyond the capability of an analytic solution such as transportation costs, lateral resupply, finite repair capacity and queuing, and maintenance or scheduling anomalies (such as triage). This capability can greatly influence the quantity of each asset that the AF elects to hold, and can provide insight into answering difficult questions.

An example is the base lateral resupply problem; it is of great interest to know when lateral resupply is beneficial, and how much it affects observed backorders. All previous attempts to model this phenomenon have failed. By adjusting the simulation logic to allow bases to fill their backorders from other bases when the depot has no stock, or by allowing a stock-depleted depot to pull assets from bases with plentiful inventory, the effects on system EBOs can be quantified. With sufficient computing power, levels can be generated with this type of logic.

An easily achievable benefit is to assess the impact of policy or procedural change on the system to enable better business decisions. An equally important benefit, although slightly more difficult to achieve, is to build analytic models assessing the impacts of these changes for use in the requirements computation; this could possibly take the form of modifying the METRIC logic when certain business rules are met, such as a part's parameters falling on a certain side of a threshold. As mentioned previously, even a

small improvement in system EBOs may have enormous financial ramifications. Building such analytic models is possible through use of this type of simulation.

Modeling Assumptions

As shown previously in Figure 6, several assumptions were necessary to manage the discrete event list and are important to consider again before moving on to the Results chapter. The simulation logic used in this research forced the depot to allocate parts to satisfy backorders before providing parts to bases to fulfill their own stock levels. All repair activities were unconstrained, meaning that repairs were independent. The time required for shipping and the repair of a part were assumed to be deterministic. Procurement was assumed to offset condemnation, and thus was not modeled. Triage was assumed to take very little time and was also not considered. Lateral resupply was not permitted in the initial model, but eventually the model was altered to permit the user to enable it. Further discussion of lateral resupply modeling will take place in the following chapter.

Results

Chapter Overview

The Methodology chapter provided descriptions of the project plan for research and verification. This chapter will build upon it by showing analysis results of the verification process and providing appropriate interpretations. Additionally, results pertaining to investigative questions will also be presented, where appropriate. The format will be similar to that of the previous chapter.

Phase 1 – Analytic RBL Model

A multi-echelon optimization example for the METRIC algorithm is provided in the literature and is shown in Figure 7 (Sherbrooke, 2004: 49-53). The corresponding MATLAB output is provided in Figure 8.

Inputs		Annual Demand Rates					
		Depot	Base 1	Base 2	Base 3	Base 4	Base 5

Figure 8. MATLAB Output for Analytic Model Example

According to Figure 8, the MATLAB version of the analytic model determined that the total budget was best spent purchasing eight units of a certain type of part (although there were no alternatives in this example). These eight parts were then spread across locations using the marginal analysis procedure. To guard against the *flushout* phenomena, a sub-routine verified that the RBS allocation was optimal. In this case no adjustments needed to be made, and base expected backorders (BEBOs), and total system EBOs (SEBOs) were reported. The function executed in slightly over one-tenth of a second. Results matched Sherbrooke's example exactly.

This type of verification procedure was repeated for multiple parts, differing bases, and various item characteristics. No evidence was discovered to suggest that it was dissimilar to the METRIC model proposed by Dr. Sherbrooke, being used in USAF models today.

Phase 2 – Trace-Driven Simulated Backorders

The first phase of model verification was to determine an approximate steady-state run-length. A small scenario was created assuming five identical bases, and three parts with differing demand rates: fifteen, ten, and five parts per year at each base, respectively. The NRTS rate for all parts at all locations was set to 0.5. Repair times and shipping times were all identical. The DEM function was set to use random demand-replication and demand-base assignment with one-hundred replications per simulation. The simulation was run for between one and one-hundred eighty days using intervals of one day. The average observed backorders for each trial (Figure 9) were plotted against the constant theoretical EBOs from the analytic model (Figure 10).

Figure 10. Analytic Model Output for Steady State Determination

As shown in Figure 9, the steady state conditions for this experiment seemed to occur around ninety days. The average observed backorders converged to the theoretical EBO values predicted by the analytic model, as expected. The selection of ninety days as the appropriate run-length may need to be reevaluated as parts with larger demand rates are incorporated into the model, but it serves as a valuable set point for continued verification experimentation.

In the previous experiment, the NRTS rate was set to 0.5, providing an equal balance between base and depot workload. To ensure the base logic and depot logic were working correctly (independently), the NRTS rate was set to its extreme values for runs of ninety days; this was replicated five times to form 90% confidence intervals about the means. Because each simulation consisted of one-hundred micro-replications, and the

event list was refreshed five times, there were a total of five-hundred possible futures evaluated (more discussion regarding micro-replications will take place later in this chapter).

The first trial used a NRTS rate of zero for all parts at all bases; this implies that all parts are repaired at the base (Figure 11). The second trial was for a NRTS rate of one for all parts at all bases, mandating the depot as the sole source of repair; this results in higher EBOs because inventory is unable to be used while being transported (Figure 12). This effect becomes more pronounced for parts with higher demand rates.

Figure 11. Average Expected Backorders for Base Repair Only

Figure 12. Average Expected Backorders for Depot Repair Only

In both figures (11 & 12), the confidence intervals for average observed backorders for all parts contained the expected backorder value from the analytic model; these experiments offer evidence that the model’s base and depot repair logic is operating correctly. Furthermore, as shown in the steady state experiment (Figure 9), the interplay between the model’s two repair processes seems to be correct.

So far, all verification experiments have been conducted using identical bases. Subsequently, the annual demand rates were altered to create dissimilar bases (Table 1). The model was run for five replications of ninety days with the NRTS rate set to 0.5 for all parts to generate 90% confidence intervals around the average observed backorders (Figure 13). No problems were detected.

Table 1. Annual Demand Rates for Dissimilar Bases

	Base 1	Base 2	Base 3	Base 4	Base 5
Part 1	15	16	17	18	19
Part 2	10	9	8	7	6
Part 3	7	3	7	3	5

Figure 13. Average Expected Backorders for Dissimilar Bases

The simulation model was also built with several other adjustable parameters that may influence the output. These parameters are micro-replications, random *demand-base* assignment, random *demand-replication* assignment, and the option of *owner bases*.

Micro-replications refer to the number of potential futures that are tested in each run of the simulation; each future will result in a specific number of backorder-days, but over all micro-replications, an average backorder statistic can be calculated for a given run-length. Because the average backorder statistic is the number-of-interest, many

simulations (macro-replications) are necessary to construct means and confidence intervals about the statistic.

Random demand-base assignment permits the use of random numbers to be used in an inverse transform technique to allocate a demand to a base in proportion to that base's demand rate. If unselected, demands will be placed at the base with the highest expectation of receiving it. The total number of demands assigned to each base is divided by that base's expected number of demands. The base with the lowest percent of demands assigned will receive the next demand.

Random demand-replication assignment refers to the action of enforcing a demand distribution rigidly, as the DEM does (Poisson), or permitting demands to be allocated randomly amongst micro-replications (binomially).

The final parameter-of-interest is the option of using *owner-bases*. If this feature is used, a broken part that is sent to the depot for repair can only be returned to the base at which it originally failed. This concept is sometimes used for specialized engine components, but is generally not used and is unsupported by legacy systems.

To investigate the parameters' effects, a 2^4 full-factorial experimental design was used on the steady state example. Each run consisted of five macro-replications with parameter settings as shown in Table 2. The response was the sum of the absolute differences between the average observed backorders and the theoretical optima from the analytic model. The design matrix, responses and runtimes are shown in Table 3.

Table 2. Factor Labels and Experimental Levels

Parameter	Factor Label	Low	High
Micro-Replications	A	50	100
Random Demand-Base Assignment	B	on	off
Random Demand-Replication Assignment	C	on	off
Send Repairs back to Origin	D	on	off

Table 3. Factor Labels and Experimental Levels

Run	A	B	C	D	Response ($\times 10^2$)	Time (min)
1	1	1	1	1	1.1380	3.583
2	-1	1	1	1	0.9609	1.833
3	1	-1	1	1	0.5227	3.458
4	-1	-1	1	1	0.4249	1.725
5	1	1	-1	1	0.5212	0.583
6	-1	1	-1	1	0.9696	0.292
7	1	-1	-1	1	0.2985	0.542
8	-1	-1	-1	1	0.4195	0.250
9	1	1	1	-1	8.0290	3.333
10	-1	1	1	-1	7.8570	1.667
11	1	-1	1	-1	9.4811	3.208
12	-1	-1	1	-1	7.7469	1.625
13	1	1	-1	-1	7.8816	0.333
14	-1	1	-1	-1	8.3099	0.158
15	1	-1	-1	-1	8.3982	0.258
16	-1	-1	-1	-1	9.2381	0.117

The regression coefficient statistics for this model (Table 4) indicate that the intercept and factor D are statistically significant for an alpha of 0.05. Base ownership dramatically increases the absolute deviation from the optimal EBOs; because the objective is to minimize the response, and the coefficient for factor D is negative, it is desirable to set factor D to the high setting (or off).

It is also worth noting that the seemingly small regression coefficients are in part due to the relatively small response values.

Table 4. Regression Coefficient Statistics for the 2⁴ Experimental Design

	Coef.	Standard Error	Tstat	Tcrit	p-value
Intercept	0.0451	0.0011	42.4811	2.5706	0.0000
A	0.0002	0.0011	0.2022	2.5706	0.8477
B	-0.0005	0.0011	-0.5076	2.5706	0.6333
C	0.0001	0.0011	0.0728	2.5706	0.9448
D	-0.0386	0.0011	-36.2967	2.5706	0.0000
AB	-0.0009	0.0011	-0.8231	2.5706	0.4479
AC	0.0025	0.0011	2.3647	2.5706	0.0644
AD	-0.0006	0.0011	-0.5488	2.5706	0.6067
BC	0.0003	0.0011	0.2833	2.5706	0.7883
BD	0.0029	0.0011	2.7719	2.5706	0.0393
CD	0.0010	0.0011	0.9129	2.5706	0.4032

For completeness, a regression model was fit to the statistically significant factors: the intercept, D and BD. About 99% of this data's variability was explained by this selection of terms. The regression summary statistics are provided in Table 5.

Table 5. Regression Summary Statistics for the 2⁴ Experimental Design

	SS	dof	MS	Fstat	F p-value

Residual	0.0002	13	0.0000		
Total	0.0242	15			
R ²	0.9904				
R ² adj	0.9890				

SS: Sum of Squares

dof: Degrees of Freedom

MS: Mean Square

There are several takeaways from this exercise that will be useful in the progression of this project. For the types of experiments that have been completed so far, run-time can be reduced by using fifty micro-replications in lieu of one-hundred without sacrificing much model accuracy. Statistically, it does not matter whether demands are assigned to bases by expectation or randomly, or if demands are assigned to micro-

replications randomly or by the DEM. Because random demand-base assignment and random demand-replication assignment execute faster on a computer, these settings will be used unless otherwise specified. Finally, optimal allocation of spares shows great benefit over an *owner-base* policy as reflected by factor D.

These parameter settings will be tentatively used in Phase 3, but may need to be verified again when new part data is used or when substantial changes to the model are implemented.

Phase 3 – Simulated Readiness-Based Leveling

As mentioned previously, the objective of this phase was to replicate the output of the METRIC model using observed backorders from a simulation. By doing so, the simulation's logic can be altered in such a way as to reflect USAF operating conditions or policies that have been assumed non-existent in the METRIC model. This has the effect of eliminating bias that was previously built into the model that can improve the way the USAF allocates levels.

In phase 2, the primary thrust was equating the system observed backorders for each part type to the analytic solution's EBO estimates for model verification. Because the system backorders are the sum of the base backorders, if some base estimates were biased low, and others high, the errors would offset, and the SEBO estimate would be approximately correct. This effect aided model robustness and permitted relatively fast model run-times.

In phase 3, levels were incremented greedily one part-location combination at a time. Because decisions can never be re-evaluated, and the problem resolution has been

refined from the system level to the base level, base EBO estimation accuracy becomes more important.

Using the example resulting in the analytic model output shown in Figure 10, the run parameters found in phase 2 were used to perform simulated RBS. The results of this exercise are shown in Figure 14. As funding diminishes, the levels for each part (rows) are allocated to each location (columns), with the first column representing the depot, and each successive column representing a base. After each level is allocated, the system average observed backorders are shown.

As Figure 14 is examined, the reader note three takeaways. First, this system involves only three parts, five bases, and a single depot; nearly six minutes were required to perform each level allocation. Second, the final EBOs, shown at the bottom of the figure do not match the expected 0.1026 (from the summation of the part-specific EBOs), forecasted by the analytic model. Last, the final stock levels exactly match those shown in Figure 10.

Figure 14. Simulated Readiness-Based Sparing Model Output

Clearly, the time required to perform this exercise with real USAF data consisting of over 100,000 parts at hundreds of bases makes this problem infeasible on a personal computer at this time. However, this does not diminish its importance; this technique can still be used to characterize how levels would change under a hypothetical policy for different classes of parts.

Although the levels shown in Figures 10 & 14 match, coincidence is partly responsible. The accuracy of the EBO estimation was not sufficient to make this repeatable in all cases. By increasing the number of macro-replications from five to thirty, and increasing the length of the simulation from ninety to nine-hundred days, the analytic model's EBO estimate could be achieved to within 0.0003 with 95% confidence (further refinements could be possible with Slay's DEM if time were not an issue); this is a dramatic improvement over the error shown in Figure 14 that can be measured in tenths. The time to perform this technique with these new set points and current technology is prohibitive.

One could also argue that getting the right mixture of parts in the system, regardless of location is what is most important, or that differences in part-mixture in the single digits are negligible over the whole inventory system. These philosophical arguments will not be discussed further in this document.

Lateral Resupply

The simulation code used in phase 2 was modified to include lateral resupply. As the model runs, when depot stock is fully depleted and a base backorder occurs for a part

with an empty base pipeline, that base can access the on-hand stock of other bases. This process uses two steps to determine if a lateral resupply is worthwhile.

The first step is determining the base that can most afford to release the asset. Of all the bases that have at least one unit on-hand, the sum of the on-hand, due in and work in process is divided by the local demand rate. This is roughly proportional to the probability that the base will be able to fill a local demand in the near future. The base with the highest ratio will be selected as the candidate donor.

The second step is making a decision on whether it is better to wait on the depot to fill the backorder from its pipeline. The depot is checked to determine if there is a broken part currently being repaired. Because the depot has a demand rate, and the system is assumed to be in steady state, one could expect the repair rate to be equal to the demand rate. If at least one part is currently in repair, the expectation of the repair date is just half of the repair rate into the future. If half of the repair rate plus the depot-to-base shipping time is less than the base-to-base shipping time, it is not worth performing the lateral resupply.

A key reason that USAF lateral resupply research has lagged is the complex mathematics required to model this phenomena in a multi-echelon system. There are numerous inputs that may have confounding or unclear effects; it can be difficult to determine when lateral resupply is beneficial, or in some cases if it can be detrimental.

The large number of input factors and levels makes a design of experiment approach cumbersome. Instead, a two-hundred run screening experiment was performed using combinations of uniformly disturbed random settings between low and high settings. The ranges for the screening experiment are shown in Table 6.

Table 6. Lateral Resupply Factor Screening Experiment Ranges

	Low (-1)	High (1)
Annual Demand Rate	1	52
NRTS	0	1
Depot Repair Time	15 days	90 days
Base Repair Time	3 days	45 days
Order and Ship Time (base-base)	3 days	45 days
Order and Ship Time (depot-base)	3 days	45 days
Part Cost	0.5	2

It is worth noting that the verification portion of this project did not assess all values falling in these ranges, and because of certain non-linear behavior, doing so would not be an efficient use of time. Instead, it is assumed that the model may give biased EBO estimates at some values; to compensate, the response from this experiment was the percent reduction in EBOs when lateral resupply was enabled.

For each random combination of inputs, the model was run with and without lateral resupply for 730 days and twenty macro-replications subject to a budget of eight units. Other simulation set points were as described in the results at the end of phase 2. This simulation took two weeks on a recent-model laptop with a 1.8 GHz processor.

Multiple linear regression was experimented with, but no noteworthy results were found; despite numerous transformation attempts, the highest coefficient of determination found was 0.35. This is somewhat expected given the non-linear nature of the problem.

The largest observed reduction in backorders was 6.88%, and the lowest was -0.83%. Four parts had a backorder reduction greater than 2%; these parts seemed to be notably affected by lateral resupply. A two-sample t-test was performed to determine if a difference exists between the two populations; results are shown in Table 7.

Table 7. Two-Sample T-Test for Parts Affected by Lateral Resupply

	Sample Size	Mean (% EBO Reduction)	Standard Deviation	Test Data
Unaffected	196	0.06518	0.33134	
Affected	4	4.55756	1.92058	
T Statistic				-4.68
Test Statistic ($\alpha=.05$)				2.35

Interesting results from the two-hundred trials are shown in Figures 15-22. The four parts with a backorder reduction exceeding 2% are labeled A-D. The horizontal axes of the graphs range from the lowest to highest observed values, and correlate to the factor settings (some factors, such as Depot Demand Rate, are functions of other factors and were not specified in terms of low and high settings).

Figure 15. Percent EBO Reduction vs. Order & Ship Time (Base-Base)

The base-to-base OST seemed to have an effect. There seemed to be a reduction in backorders when bases could resupply each other quickly.

Figure 16. Percent EBO Reduction vs. Order & Ship Time (Depot-Base)

Similarly, a low depot-to-base OST may have led to a reduction of EBOs with lateral resupply enabled. Perhaps donor bases were generally replenished before backorders could occur.

Figure 17. Percent EBO Reduction vs. Average Base Repair Time

A low average base repair time permits donor bases to recover serviceable stock quickly, contributing to backorder reduction.

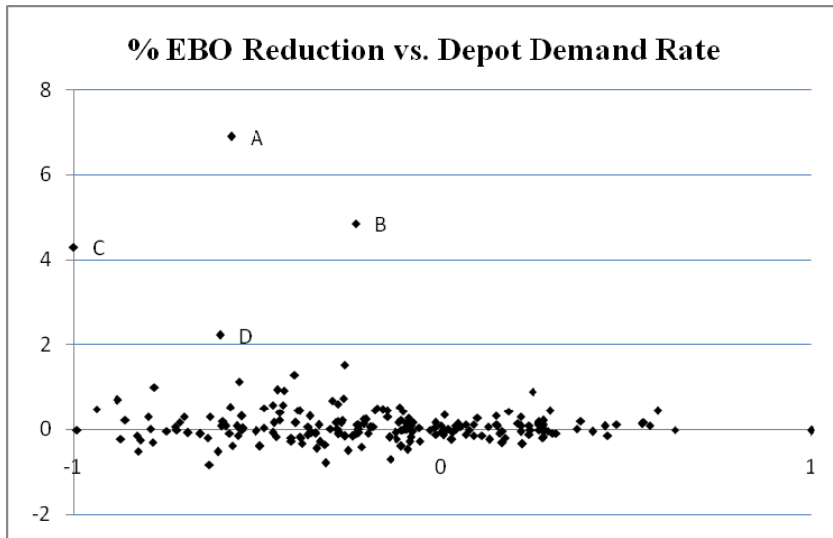

Figure 18. Percent EBO Reduction vs. Depot Demand Rate

A low depot demand rate means that more assets are housed at the bases; this may aid the donor bases in avoiding backorders. It also increases the likelihood that a base exists with on-hand assets to share with other bases.

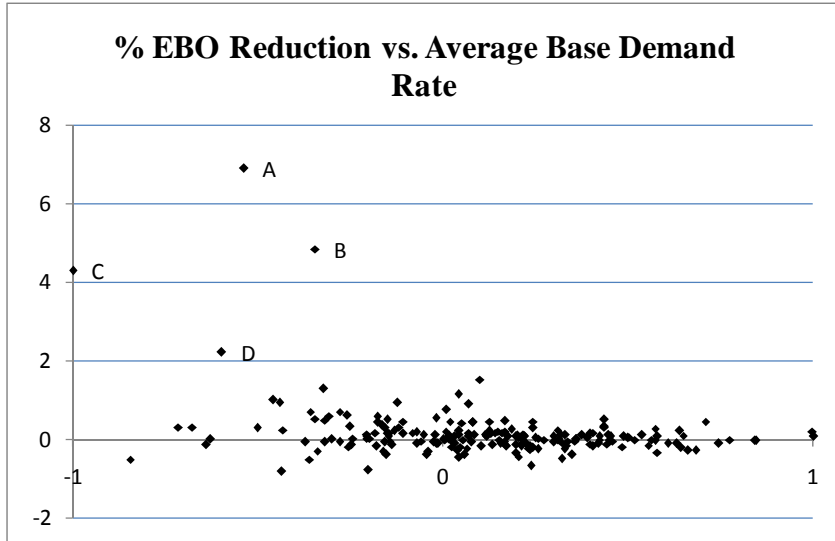

Figure 19. Percent EBO Reduction vs. Average Base Demand Rate

A low average base demand rate could impact the backorders observed at bases because demands are not able to deplete inventory.

Figure 20. Percent EBO Reduction vs. Average NRTS Rate

The NRTS rate is the percent of repairs outsourced to the depot. A moderately high rate could mean that depots are filling levels at donor bases before backorders can accrue.

Figure 21. Percent EBO Reduction vs. Interaction of Average Base Demand Rate and Average Base Repair Time

Interaction effects were also observed. The interaction of average base demand rate and average base repair time was interesting. It appears that when parts are not

demanded frequently and can be repaired quickly, lateral resupply provides backorder reduction.

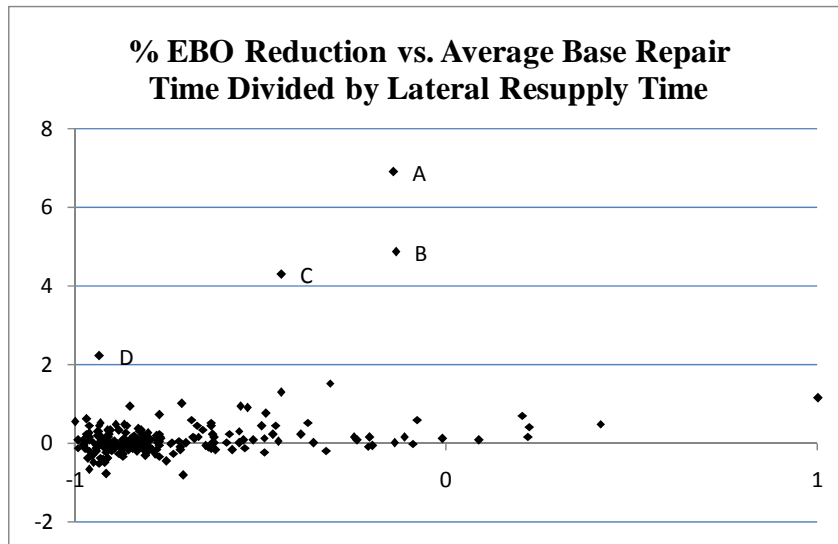

Figure 22. Percent EBO Reduction vs. Average Base Repair Time Divided by the Order & Ship Time (base-base)

Sherbrooke postulates that lateral resupply is only beneficial when the OST (base-base) is less than one-fourth of the base repair time (Sherbrooke, 2004: 258). He offers no evidence to support this claim, but may be conceptually correct; the result shown in Figure 22 seems to agree with his assertion. Lateral resupply may be beneficial if the base repair time is excessive.

Factors that failed to show a relationship in the screening experiment were the depot repair time, cost per part, and various other two-factor interactions. The data characterizing parts A-D is displayed in Table 8.

Table 8. Specific Data Characterizing Parts A-D

	A	B	C	D
Demand Rate at Base 1	17.871	9.277	8.402	26.375
Demand Rate at Base 2	11.533	40.664	3.381	24.094
Demand Rate at Base 3	19.609	28.289	3.496	1.801
Demand Rate at Base 4	3.051	3.155	5.191	4.686
Demand Rate at Base 5	19.209	9.078	5.065	8.475
Average Base Demand Rate	14.255	18.093	5.107	13.086
Standard Deviation of Base Demand	7.057	15.776	2.027	11.368
NRTS Rate at Base 1	0.766	0.275	0.267	0.460
NRTS Rate at Base 2	0.897	0.964	0.671	0.681
NRTS Rate at Base 3	0.114	0.511	0.897	0.483
NRTS Rate at Base 4	0.131	0.843	0.387	0.581
NRTS Rate at Base 5	0.762	0.526	0.705	0.856
Average NRTS Rate	0.534	0.624	0.585	0.612
Standard Deviation of NRTS Rates	0.380	0.277	0.255	0.162
Base 1 Repair Time	8.645	8.932	19.790	23.135
Base 2 Repair Time	7.873	28.808	42.052	20.386
Base 3 Repair Time	29.202	13.849	41.248	3.369
Base 4 Repair Time	3.973	13.642	21.741	6.145
Base 5 Repair Time	15.083	40.001	8.059	20.144
Average Base Repair Time	12.955	21.046	26.578	14.636
Standard Deviation of Base Repair Time	9.919	12.970	14.723	9.147
Depot Demand Rate	41.330	63.657	13.229	39.381
Depot Repair Time	42.986	34.413	88.069	75.532
Cost	0.970	1.449	0.642	1.482
Order & Ship Time (base-base)	3.095	4.991	9.424	24.565
Order & Ship Time (depot-base)	9.920	7.067	5.094	27.118
% EBO Reduction with Lateral Resupply	6.884	4.841	4.293	2.212

Using knowledge gained from the screening experiment, the factor ranges were adjusted as shown in Table 9. An additional one-hundred runs were performed to determine if a difference in response was detectable from that of the initial screening runs.

Table 9. Lateral Resupply Alternate Factor Ranges

	Low (-1)	High (1)
Annual Demand Rate	1	26 (reduced from 52)
NRTS	0.5 (increased from 0)	1
Depot Repair Time	15 days	90 days
Base Repair Time	3 days	30 days (reduced from 45)
Order and Ship Time (base-base)	3 days	24 days (reduced from 45)
Order and Ship Time (depot-base)	3 days	24 days (reduced from 45)
Part Cost	0.5	2

Upon analyzing the data, the mean benefit (reduction in EBOs) from the alternative random settings (1.33%) was found to be significantly different ($\alpha=.05$) than the mean benefit from the initial random settings (0.16%). Seventeen parts (of 100) showed an EBO reduction of greater than 2%, whereas in the initial set only four parts (of 200) showed such benefit. Statistics for this experiment are shown in Table 10.

Table 10. Two-Sample T-Test for Experiments of Initial and Alt. Factor Ranges

	Sample Size	Mean (% EBO Reduction)	Standard Deviation	Test Data
Initial Ranges	200	0.15646	0.74833	
Alternate Ranges	100	1.32812	2.71995	
T Statistic				-4.23
Test Statistic ($\alpha=.05$)				1.65

A more detailed examination of the contributing factors for the benefits of lateral resupply was attempted through a grant of computer time from the DoD High Performance Computing Modernization Program at Wright Patterson AFB. However, time did not permit restructuring the MATLAB code to take full advantage of parallel processing; the computing time could only be reduced by approximately 50% using serial

processing on the supercomputer. Code alteration to support the use of parallel processing could be immensely beneficial, and is left for future research.

The key takeaway from this portion of research was that lateral resupply was modeled and tested; this has never been accomplished or documented in the literature previously, despite efforts of mathematicians and logisticians over the past fifty years. Although the computer code executed slowly, future research can almost certainly increase the computational efficiency and continue the documentation of the circumstances required to observe benefits of lateral resupply. This will enable refinements of the requirements computations that will guide better allocation of Air Force sustainment funding.

Conclusion

Chapter Overview

This chapter summarizes the contributions of this research and discusses potential avenues of future research.

Summary

As stated previously, the goal of this research was to provide a flexible model of the repairable asset supply chain processes that could be modified to investigate research topics that were previously inaccessible due to mathematical complexity.

This research has produced a simulation model and documented business rules that capture the interactions resulting in the statistics predicted by Dr. Sherbrooke's METRIC model. It incorporated and tested the Distribution Enforcement Method, a novel technique for bias and variance reduction; although constrained by run time, the DEM did produce very accurate demand-replication assignments. A simulation model was used to perform the readiness-based sparing technique reserved previously only to analytic models such as METRIC. Finally, this research began to document the characterization of parts benefiting from lateral resupply.

The lateral resupply investigation was a substantial achievement. All prior attempts to model this phenomenon over the past fifty years have either failed or gone

undocumented. More research will be necessary to adequately describe the circumstances under which this policy is beneficial.

This approach to supply chain modeling does provide opportunities to improve the USAF supply chain. With appropriate time, computer resources and further research, the current requirements computation can be modified to provide better warfighter support.

Further Research

The investigative questions posed previously are only a small fraction of the breadth of questions that can be addressed with the appropriate simulation model. Simulation-based leveling will enable research of many more topics than is possible with legacy models. Future research topics are left for other students' undertaking. All MATLAB code written for this project has been included in the appendix.

Future Investigative Questions

- 1.) How else can lateral resupply be implemented in a simulation model? What are the benefits and detriments of doing so?
- 2.) Using the simulation approach provided in this document, can a detailed assessment of the conditions under which lateral resupply is beneficial be generated?
- 3.) How can the requirements computation be modified to make use of lateral resupply information?
- 4.) How can this simulation and DEM code be modified to maximize computational speed on 64-bit clusters?

- 5.) What are the additional effects, if any, of lateral resupply on multi-indentured parts, or those undergoing cannibalization?
- 6.) How can lateral resupply modeling affect post-legacy USAF supply systems?
- 7.) Was Slay's assertion that traditional methods of variance reduction are too slow and insufficient correct? Can other methods of variance reduction be postulated?
- 8.) Can a simulation model be enhanced to consider transportation options, costs and business rules for prioritization of repair and distribution?
- 9.) What is the impact of often-ignored supply chain characteristics such as repair capacity, cannibalization, throughput, flight line maintenance time and transportation time between bases?
- 10.) Can simulated Readiness-Based Sparing be performed in a more computationally efficient manner?
- 11.) How can a model be built to evaluate levels and effects of CIRFs?
- 12.) Does modeling of CIRFs and cannibalization enable more realistic projections of system availability and improved inventory solutions?
- 13.) Owner-bases were shown to be detrimental; how appropriate is this policy for engine components?

List of Symbols, Abbreviations and Acronyms

0	a context dependent index used to denote LRU or depot
A	aircraft availability
AAM	Aircraft Availability Model
B_i	backorder for a particular type of LRU
BEBO	base expected backorder
BO	backorder
BRT	base repair time
c	cost
CIRF	centralized intermediate repair facility
$D^{\#}$	number of non-operational planes
D_c	number of aircraft being cannibalized
D_{nc}	planes disabled that cannot be fixed through cannibalization
DDT	depot delay time
DEM	Distribution Enforcement Method
DI	due-in inventory
DoD	Department of Defense
Dof	degrees of freedom
DRIVE	Distribution and Repair in Variable Environments
E()	expectation operator

f	fraction of SRU demand
EBO	expected backorder
GAO	Government Accountability Office
$g(t)$	resupply time probability distribution
i	part type index
j	location number index
k	the most aircraft that can be down if cannibalization is performed to maximum extent
λ	mean demand rate
l	number of specific part types used per weapon system
LRU	line replaceable unit
n	number of types of LRUs on a weapon system
N	fleet size
NMCS	not mission capable supply
NRTS	not reparable this station
μ	pipeline quantity
m	average annual demand
METRIC	Multi-Echelon Technique for Recoverable Item Control
MS	mean square
O	average order and ship time
OH	on-hand inventory
OST	order and ship time
q_i	number of LRUs of a particular type installed on a weapon system

q_{ij}	conditional probability that a SRU i is responsible for failure of a LRU at base j
QPA	quantity per application
r	RTS rate
RBL	Readiness-Based Levels
RBS	Readiness-Based Sparing
RTS	reparable this station
s	stock
\underline{s}	a vector of stock levels for a type of plane
SEBO	system expected backorder
SRU	shop replaceable unit
SS	sum of squares
sv	sort value
τ	the mean of the resupply distribution
t	mean repair time
USAF	United States Air Force
$V()$	variance operator
VBO	variance of backorders
X	random variable for pipeline quantity
Z	number of parts in weapon system

OMB No. 074-0188

The public reporting burden for this collection of information is estimated to average 1 hour per response, including the time for reviewing instructions, searching existing data sources, gathering and maintaining the data needed, and completing and reviewing the collection of information. Send comments regarding this burden estimate or any other aspect of the collection of information, including suggestions for reducing this burden to Department of Defense, Washington Headquarters Services, Directorate for Information Operations and Reports (0704-0188), 1215 Jefferson Davis Highway, Suite 1204, Arlington, VA 22202-4302. Respondents should be aware that notwithstanding any other provision of law, no person shall be subject to a penalty for failing to comply with a collection of information if it does not display a currently valid OMB control number.

13. SUPPLEMENTARY NOTES					
14. ABSTRACT For the past fifty years, U.S. Air Force reparable inventory has been allocated based on an analytic model developed by Dr. Craig C. Sherbrooke. Although versions of his model can be implemented easily with the help of a computer, the analytic approach fundamentally lacks the flexibility to address numerous logistics issues. This body of research will offer a novel alternative approach that will enable researchers to investigate currently unsolved logistics problems such as quantifying the benefits of lateral resupply.
