14. ABSTRACT

Solid oxide fuel cell (SOFC) technology has been of great interest over many years due to its flexibility in using different fuels for operation; including the fundamental fuel i.e. Hydrogen. Various computational and numerical models have been developed along with experimental work to evaluate the performance as well as to identify and overcome the problems faced in the development of SOFC's. In an attempt to achieve efficient operation with respect to design and combined thermal and electrochemical perspective, the main objective of the proposed study is to present a three-dimensional computational model, which will serve as a framework for the analysis and optimization of SOFC's. A three-dimensional model of a tubular SOFC was developed to study the effect of temperature and electrolyte thickness variations on its performance. A commercial Computational Fluid dynamics (CFD) software ANSYS FLUENT 12.0 was used for the development of the model which incorporates an interactive 3-D electro-thermo-chemical fluid flow analysis. The particular model, after validation against experimental observations for selected benchmark cases, was demonstrated to be compatible for intermediate temperature operations using hydrogen as fuel. The performance of the model was analyzed by varying electrolyte thicknesses from 2-100 μ m. The same model was further evaluated using different fuels such as CH₄ (methane) and CO (carbon monoxide), including the modeling of the reformation and the water-gas shift reactions. The results were compared to other computationally less expensive, analytical and empirical models, thus confirming the given model to be used as a basic model for future research on intermediate temperature solid oxide fuel cells.

ABSTRACT

Solid oxide fuel cell (SOFC) technology has been of great interest over many years due to its flexibility in using different fuels for operation; including the fundamental fuel i.e. Hydrogen. Various computational and numerical models have been developed along with experimental work to evaluate the performance as well as to identify and overcome the problems faced in the development of SOFC's. In an attempt to achieve efficient operation with respect to design and combined thermal and electrochemical perspective, the main objective of the proposed study is to present a three-dimensional computational model, which will serve as a framework for the analysis and optimization of SOFC's.

A three-dimensional model of a tubular SOFC was developed to study the effect of temperature and electrolyte thickness variations on its performance. A commercial Computational Fluid dynamics (CFD) software ANSYS FLUENT 12.0 was used for the development of the model which incorporates an interactive 3-D electro-thermo-chemical fluid flow analysis. The particular model, after validation against experimental observations for selected benchmark cases, was demonstrated to be compatible for intermediate temperature operations using hydrogen as fuel. The performance of the model was analyzed by varying electrolyte thicknesses from 2-100 μm . The same model was further evaluated using different fuels such as CH_4 (methane) and CO (carbon monoxide), including the modeling of the reformation and the water-gas shift reactions. The results were compared to other computationally less expensive, analytical and empirical models, thus confirming the given model to be used as a basic model for future research on intermediate temperature solid oxide fuel cells.

ACKNOWLEDGMENTS

I would like to thank my advisor Dr. Umit O. Koylu for his guidance, encouragement and financial support throughout this research work. I am also thankful to my co-advisors and also graduate committee members, Dr. Serhat Hosder and Dr. Fatih Dogan for extending their help in relevant topics needed for the research and also for serving in the committee, taking time out of their busy schedules. I am grateful to the Energy Research and Development Center at Missouri University of Science and Technology and the Air Force Research Laboratory (AFRL) for funding my research. I am also grateful to all the faculty members of the department who have contributed in my learning of the required skills to finish this work.

I would like to thank all my friends for being with me always in tough times so far away from home. And last, but not the least, I would like to express my gratitude to my parents, my sister and my entire family for their love, affection and support.

jump	voltage Jump condition
ohmic	Related to ohmic losses
ref	Referring to the reference state

1. INTRODUCTION

In recent years, energy has become the most important and challenging aspect of our existence. Tremendous interest and effort have been put into developing new and improved methods of energy generation. Power generation using electrical energy has been of prime importance due to its extensive applications. Various resources, both renewable and non-renewable were introduced into the power industry in the process. Emphasis has been given to alternative sources of energy conversion due to the limitations of the conventional sources. This need gave rise to the concept of fuel cells as an alternative source of energy. Fuel cells coupled with other renewable energy sources like wind, solar etc. can prove to be very useful and clean source of power generation.

1.1. FUEL CELL THEORY

The origin of fuel cell dates back to the late 19th century, when Sir William Grove found out that it was possible to generate electricity by reversing the electrolysis of water [1]. A fuel cell is an electrochemical device consisting of a minimum of two electrodes separated by an electrolyte. As stated in O'Hayre et al. [2], it is like a factory, a *shell*, which converts the chemical energy stored in the fuel into electrical energy. It produces electricity directly from the chemical reactions by harnessing the electrons as they move from high-energy reactant bonds to low-energy product bonds. The electrolyte being used is an ion conducting material, either liquid or solid phase, which separates the fuel and the oxidizer so that the electron transfer needed to complete the bonding reconfiguration occurs over an extended area. The electrolyte used in the fuel cell, plays a very important

role in any fuel cell operation, as it has to be capable of permitting only the appropriate ions through it to generate electricity efficiently. The electrons thus released will move from the fuel species to the oxidant species through an external circuit. This movement of the electrons generates electrical current, which can be used for various applications. Figure 1.1 shows the general architecture of a fuel cell, stating the arrangement of the zones.

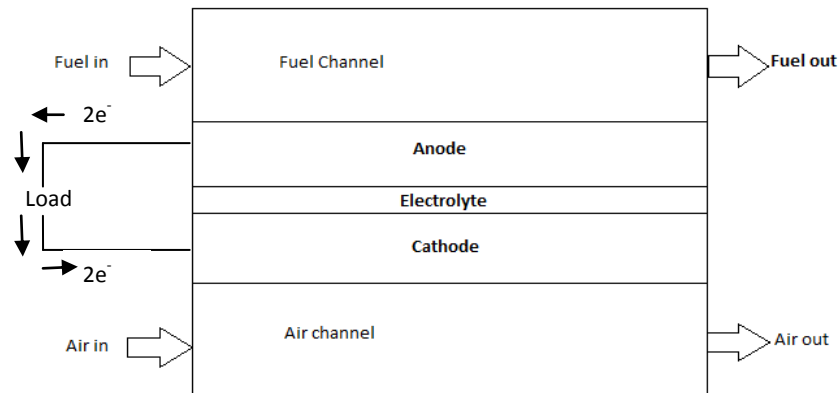

Figure 1.1 General architecture of a fuel cell

The general electrochemical reactions occurring in a basic hydrogen-oxygen fuel cell are shown in the equations 1.1-1 and 1.1-2.

Fuel cells exhibit a potential for highly reliable and long lasting systems with very low emissions because of their capability to directly produce electricity from the chemical energy, without involving any moving parts. They are a clean and almost entirely non-polluting energy source. Also, the elimination of moving parts makes them vibration-free and the associated noise-pollution is also eliminated. The working of fuel cells make them share common characteristics with the conventional combustion engines and primary batteries, combining various advantages of both the types of energy conversion devices. The efficiency obtained by this process is also higher (40%-60%) compared to the conventional devices [3]. The applications of fuel cells are usually based on the type of the fuel cell being used.

Various types of fuel cells have been put to use and are in different stages of their development. The 5 major types of fuel cells in practice are listed below:

- Polymer Electrolyte Membrane Fuel Cell (PEMFC)
- Alkaline Fuel cell (AFC)
- Phosphoric Acid Fuel Cell (PAFC)
- Molten Carbonate Fuel Cell (MCFC)
- Solid Oxide Fuel Cell (SOFC)

This classification in fuel cells broadly depends on the type of the electrolyte being used. The type of the electrolyte lays influence over the other thermo-physical properties such as the operating temperature of the cell and the material properties of the other cell components. A large variation can be found in the operating temperatures of these fuel cell types, ranging approximately from 80 °C to 1000 °C. Usually, in low temperature fuel cells, the fuel used is pure hydrogen wherein all the fuel is required to be converted to

hydrogen before being fed to the low temperature fuel cells. Some high temperature fuel cells possess this advantage over the low temperature one's that CO or other hydrocarbon fuels can be converted to hydrogen internally in the fuel cells or can even be directly oxidized electrochemically to generate electricity. Table 1.1 shows the list of fuel cells along with their types and other properties. The current study is based on the modeling and development of Solid Oxide Fuel Cells.

Table 1.1 Types of fuel cells [2]

Type	Fuel	Electrolyte Material	Operating Temperature (°C)	Efficiency (%)
PEMFC	H ₂ , Methanol, Formic Acid	Hydrated Organic Polymer	< 90	40-50
AFC	Pure H ₂	Aqueous potassium hydroxide	60 – 250	50
PAFC	Pure H ₂	Phosphoric Acid	180 - 210	40
MCFC	H ₂ , CH ₄ , CH ₃ OH	Molten Alkali Carbonate	600 – 700	45-55
SOFC	H ₂ , CH ₄ , CO	Solid Ceramic (YSZ)	600 – 1000	50-60

1.2. SOLID OXIDE FUEL CELL THEORY

Solid Oxide Fuel Cells (SOFC) in particular are considered as promising energy conversion devices due to a number of potential benefits, including high energy efficiency, lower pollutant emissions, possibility of using different fuels and combined heat and power generation applications. SOFC's operate at high temperatures in the range of about 600 °C-1000 °C [2]. This high temperature operation of SOFC's provide multiple co-generation possibilities such as internal reforming of hydrocarbon fuels to generate hydrogen, which is not possible in other types of fuel cells. It also facilitates production of high quality steam, which can be efficiently used for other applications. A number of different designs have been tested in need of optimizing the performance of these cells. The common geometries used are shown in Figure 1.2.

Figure 1.2 Planar and tubular SOFC configuration

Two basic geometries of SOFC's have been studied quite actively in the relevant literature viz. the planar SOFC design and the tubular design. Both types have their own advantages and disadvantages and have been discussed in detail in the cited literature. Figure 1.2 shows the general configuration of the planar and tubular geometry of SOFC's.

The working of a Solid Oxide fuel cell is different to that of other types of fuel cells. The electrolyte material is a ceramic solid which is a very good ion conductor at elevated temperatures. In SOFC operation, the oxygen ions travel through the electrolyte from the cathode to the anode, and reacts with the hydrogen molecules at the Triple phase boundary (TPB) on the anode. This electrochemical reaction produces H_2O and releases electrons in the anode. These electrons travel through the anode and the current collectors and through the external circuit to the cathode to react with the oxygen molecules. This phenomenon generates the electrical current due to the potential developed. The working of the Solid Oxide Fuel cell is well explained in the Figure 1.3.

Figure 1.3. Working of SOFC

1.3. OBJECTIVE

Despite the advantages, there have been certain limitations on the applications of SOFC's, where relatively high operating temperatures are of great concern. It becomes difficult and expensive to acquire materials withstanding such high temperatures. Based on these concerns, efforts are being made to reduce the temperatures involved by developing intermediate temperature SOFC's. This concept is gaining importance to enhance the long term stability prospects of Solid Oxide Fuel cells. Efforts are being made by developing experimental, mathematical and computational models and prototypes to achieve optimum operating conditions for specific target area applications of SOFC's. This calls for a need of fundamental and detailed understanding of the design, transport and electrochemical kinetics involved in the SOFC systems. Mathematical and computational models can prove to be extremely valuable tools for the design and analysis compared to the much expensive experimental evaluation techniques. However a combination of these techniques can be used as a comparably accurate method for the characterization and validation of SOFC systems.

A three-dimensional computational fluid dynamics (CFD) model of a Solid Oxide fuel cell was developed in the work mentioned in this thesis. A single cell cathode-supported, tubular geometry was considered for the design, which is one of the common and most used designs in the fuel cell industry. This model is used to carry out analysis, by varying parameters involved in the operation to optimize the performance of the SOFC for the given set of conditions and design. This model serves as a framework or guideline for setting up successful experimental work for the analysis and optimization of SOFC's. A commercial CFD software, ANSYS FLUENT 12.0 is used for the analysis, which

incorporates a complete electro-thermo-chemical fluid flow analysis. A computational evaluation of this model with the varying parameters will help in the optimization study of the currently installed models based on the current density and the thermal distribution fields generated within a single cell. The results are compared against relevant benchmark SOFC models existing in the literature.

2. LITERATURE REVIEW

The objective of this work is to develop a base model for a tubular Solid Oxide Fuel Cell which can be considered to resemble the actual practical model of a SOFC, taking into account all the conservation principles. As described earlier, a computational model of the desired design will enable a comparatively detailed analysis of the model under consideration. A 3-dimensional model will consider the physics involved in the model in all the significant directions, thus providing us with a detailed analysis of the SOFC model.

Solid Oxide fuel cells have been a subject of extensive study since the 1960's as a promising prospective option for clean energy generation. The first successful demonstration of a Solid Oxide fuel cell was performed in 1962 [1]. Since then, a lot of experimental work has been performed along-with the various numerical and mathematical models to predict the behavior of Solid Oxide Fuel cells to varying conditions. Westinghouse started the concept of long tubular cells (inside air, outside fuel), electrically interconnected by oxides and metallic conductors and accumulated together in tube bundles in 1978 [2, 4]. This design lead to the installation of the first 5 kW SOFC Generator consisting of 324 single cells in 1986 [4-5]. After 12 years, in 1998, a 100 kW SOFC power generator was installed in Netherlands, consisting of 1152 tubular cells[4]. Research work on different SOFC designs has been on its peak over all these years. Majority of the research work are focused on the optimization of the design and the materials used in Solid Oxide fuel cells.

Mathematical and Numerical models along with the experimental analysis have proved to be an extremely useful tool over the years. A mathematical model for

simulation of planar Solid Oxide fuel cells was introduced by Karoliussen and Nisancioglu et al. [6] and by Achenbach et al. in 1994 [7]. Both the studies focused on the effect of different flow structures on the performance of planar SOFC's. But the equations used in these modeling approaches did not account for the heat transfer or conduction through the interconnects [7]. The first mathematical model for a Tubular SOFC was developed by Bessette et al. in 1995 [8-9] which accounted for the electrochemical and thermal factors of the tubular cell resembling the Westinghouse design. The data required for the analysis were obtained from fundamental equations or were independently measured to avoid any discrepancies in the evaluation.

Due to the extremely high operating temperatures related to Solid Oxide fuel cells, the materials used in the construction of a cell play a very important role. This has given rise to a lot of active research work in the micro-modeling of SOFC's, which is associated with the micro-level properties of the SOFC materials such as the pore structures, thermal and electrical conductivities, active area etc. for the electrochemical reactions to take place. In 1998, Costamagna et al. [10] developed a micro-model of SOFC electrodes having LSM/YSZ cathodes and Ni/YSZ anodes which helped in understanding a relationship between the electrochemical properties of the materials used, related to the structural parameters. A one-dimensional anode micro-model including the study of the transport of electrons, ions and molecules through the electrode micro-structure were studied by Chan and Xia et al. [11]. Recently, in 2010, Ding et al. [12] studied the anode supported SOFC's in more detail using experimental models for analyzing the performance of the Solid Oxide fuel cells for varying thicknesses. A GDC (Gadolinium doped ceria) electrolyte was used for the study and it was observed that lower electrolyte

thickness was favorable but further reduction of thickness below 5 μm gave rise to electron flux through the electrolyte film, thus degrading the electrical performance of the anode-supported SOFC.

Another advancement in the field of SOFC's included the introduction of the concept of single chamber SOFC's. This concept was considered very promising for reducing the complexity of the SOFC operations. The single chamber concept simplified the design prospects of SOFC's considerably, where the fuel and the oxidizer were premixed and then fed into the fuel cell channel. In 2005, Chung et al.[13] developed a computational model of a single chamber SOFC, modeling the multi-physical phenomena (ionic conduction, fluid dynamics and gas diffusion). The best performance for the micro-single chamber design was observed when the inflow direction was kept perpendicular to the electrode axis. Akhtar et al. [14] developed a 3-dimensional numerical model for a single chamber design in 2009, which used nitrogen diluted hydrogen/oxygen mixture to predict the hydrodynamic and electrochemical performance of the SOFC single cell. Also the porosity of the electrodes played an important role in the electrochemical performance of the cell. Single chamber designs are considered as a promising concept, but their applications are still far-fetched due to the various problems involved with pre-mixing of the fuel and the oxidizer which makes it difficult to control the various reactions that could be initiated, rendering the process out of control.

The basic dual-chambered geometries are the most researched topics recently, which have been already installed and are put to use. Optimization of these basic designs can be considered as more important currently with an application point of view. A lot of researchers have laid focus on modeling of the planar single cells as well as stack designs.

In 2001, Yakabe et al. [15] developed a 3-D mathematical model for a planar single cell SOFC. A finite volume method was employed to solve the conservation equations, taking into account the internal and external reforming reactions, the water shift reaction and the diffusion of the species. It was observed that the reformation reaction induced a steep drop in the temperature of the fuel near the inlet developing stresses, and the co-flow pattern was found to be advantageous to mitigate the steep temperature gradient and to reduce the internal stresses. Even Recknagle et al. [16] (2002) evaluated the planar SOFC design for different flow patterns and found out that the co-flow design had the most uniform temperature distribution and the smallest thermal gradients, thus providing thermo-structural advantages to the model. Murthy and Fedorov [17], in 2003, applied different computational methods to quantify the effect of radiation heat transfer in the SOFC monolith design, which is neglected in most of the modeling cases. They concluded that the radiation heat transfer effect were significant and should be considered for accurate predictions of the temperature distribution in the cell and the cell voltage. Other literature on modeling and optimization of planar SOFC cells involved a numerical model by Lin and Beale [18] in 2003 and 3-D thermo-fluid modeling of anode-supported planar SOFC by Zuopeng Qu et al. [19] which again emphasized on the importance of all the modes of heat transfer in performance prediction of the planar SOFC's.

Although the fabrication and arrangements of planar cells are comparatively easier, tubular cells exhibit better stability against mechanical and thermal stresses and they also provide better sealing between the air and the fuel flow channels [2]. Some significant research work in development of tubular SOFC's are cited. Fang et al. [20] developed a 1-dimensional transient model of a tubular SOFC considering the

thermoelectric properties by recording the dynamic behavior of the electrical characteristics and temperature under variable load conditions. Three transient cases viz. start-up, load resistance decrease and air-flow decrease were employed to capture the dynamic behavior of SOFC stacks. In 2004, Campanari and Iora [21] developed a finite volume model of a tubular SOFC single cell and carried out a sensitivity analysis, considering all the thermal and electrochemical analysis including the heat exchange processes and the internal reforming cases. This paper is cited in most of the research work on tubular SOFC's. Another useful contribution in the tubular SOFC modeling literature is the model described by Suwanwarangkul et al. [22] (2005). A 2-dimensional mechanistic model of a cathode supported tubular SOFC was developed to account for the thermal and electrochemical properties of the SOFC. In 2007, the same model was used to predict the effect of the composition of the biomass derived synthesis gas fuels on the cell performance and behavior [23]. A transient numerical analysis was carried out by Mollayi Barzi [24] in 2009, combining the heat and mass transport effects, which gave more realistic results compared to the 1-dimensional and lumped models due to the consideration of the state variable gradients in the radial direction. It was observed that 82% of the electrical parameter variations take place immediately after the load change and the remaining 18% variations take a very long time to reach a steady state. Stiller et al. [25] developed steady state models for both planar and tubular cells fueled by partially pre-reformed methane to study the hybrid cycle performance of SOFC stacks. It was observed that the air pre-heating internally in case of tubular SOFC was advantageous in improving the effectiveness of the GT cycle. Hybrid system efficiencies of above 65% were achieved using both the planar and tubular geometries.

As mentioned previously, the modeling approach mentioned in this work is based on the 3-dimensional computational analysis of SOFC's using commercial computational softwares. These computational software packages have contributed in the SOFC modeling studies and are also proven to be efficient in saving time required for the analysis. Several commercial CFD software packages such as FLUENT, COMSOL MULTIPHYSICS, CFX, STAR-CD, CFD-ACE etc. have been used for the modeling purposes. The single chamber model by Akhtar et al.[14] mentioned earlier used COMSOL MULTIPHYSICS for the 3-D model, accounting for the hydrodynamic and electrochemical performance of the model. In 2003, Autissier et al. [26] developed a 3-dimensional simulation tool using FLUENT, which also accounted for the radiative heat transfer in the single cell. Other literature work using the FLUENT simulation tool for SOFC modeling include the CFD model developed by Pasaogullari and Wang [27] making use of the UDF (User defined function) developed by FLUENT, taking care of the electrochemical reactions of the SOFC. In 2010, Sleiti et al. [28] analyzed the performance of tubular SOFC at reduced temperatures and cathode porosity using the FLUENT 6.3 SOFC UDF; the model developed resembled the Westinghouse design and is also similar to the model described in the present research mentioned in this thesis. The model was found to demonstrate the capability of SOFC's to operate at intermediate temperatures given that the transport properties of the electrodes and the electrolyte were kept the same. The model mentioned in the current thesis also makes use of the FLUENT 12.0 SOFC UDF to model the electrochemical reactions involved in the SOFC operation, integrated with the other conservation equations.

3. SOFC MODELING

The grid for the three-dimensional SOFC model was generated using GAMBIT 2.3.16. The tubular design was made to resemble the Westinghouse concept, which is already been installed, as mentioned in Section 2. This tubular design was used to set-up a base case using a commercial computational analysis software viz. ANSYS FLUENT, which takes into account all the complex electro-thermo-chemical properties by simulating the complex processes involved in the SOFC operation. FLUENT makes use of computational methods to solve the conservation equations which take care of the parameters involved and help us simulate a near-actual case, thus helping in optimization study of the SOFC operation using different perspectives. The modeling strategy and procedure is described in detail in the following sections.

3.1. GEOMETRIC MODEL

As mentioned earlier, a geometric modeling and meshing software viz. GAMBIT (version 2.3.16) was used for developing the model. GAMBIT is considered as a pre-processor for FLUENT, since the zone definitions and the meshing strategy can be easily imported into the FLUENT solver, for further analysis.

The tubular geometry described in the work is a 130 mm long concentric tube, with layers of the flow channels and the electrodes. The inner tube is the air electrode (cathode) and the fuel flows through the outermost tube adjacent to the fuel electrode (anode). The electrolyte is sandwiched between the two electrodes. Table 3.1 shows the important zones and the dimensions of the model being developed.

Table 3.1. Geometrical properties of the model in study

GEOMETRICAL PARAMETERS	
Zone	Dimension(mm)
Cathode Inner Diameter	4
Cathode Outer Diameter	6
Anode Inner Diameter	6
Anode Outer Diameter	7
Electrolyte Thickness	0.04
Fuel cell Length	130

The design is a co-flow pattern, with the inlets for the fuel and the air channels specified on the same side and the flow is parallel. The inlets are specified at some distance prior to the fuel cell zones, to allow for the initialization of the parameters during the analysis. The electrodes are made thicker i.e. more dominant structurally, which implies an electrode supported design, wherein the cathode is the thickest of all making it a cathode supported structure. The current collectors are solid conducting blocks attached to the two electrodes to maintain electrical contact between them for facilitating the transfer of electrons. The electrolyte material should be a solid, i.e. non-porous, exhibiting a high ionic conductivity. For using it in the FLUENT SOFC module, the electrolyte is modeled as an interface, rather than being used as a zone. The electrodes are porous

ceramic solids while the interlayers are modeled as a pair of wall and wall shadow faces. These surfaces are modeled with species and energy sources and sinks due to electrochemical reactions added to adjacent computational cells. Figure 3.1 shows the cross section of the GAMBIT model of the tubular design. The different zones are labeled to show the architecture of the model.

Figure 3.1. Cross section of tubular SOFC model

The FLUENT solver uses the finite volume method to solve the conservation equations, which makes use of cells as control volumes in the flow field. A hexahedral mesh is generated for the entire volume, where the cells in the zones are hexahedral and face cells are quadrilateral. There are a total of 79680 cells for the entire volume of the

model. The maximum aspect ratio is limited to 20. O-structured mesh is generated on the concentric faces of the model, giving a good mesh quality (skewness). The mesh structure of the model is shown in the Figure 3.2.

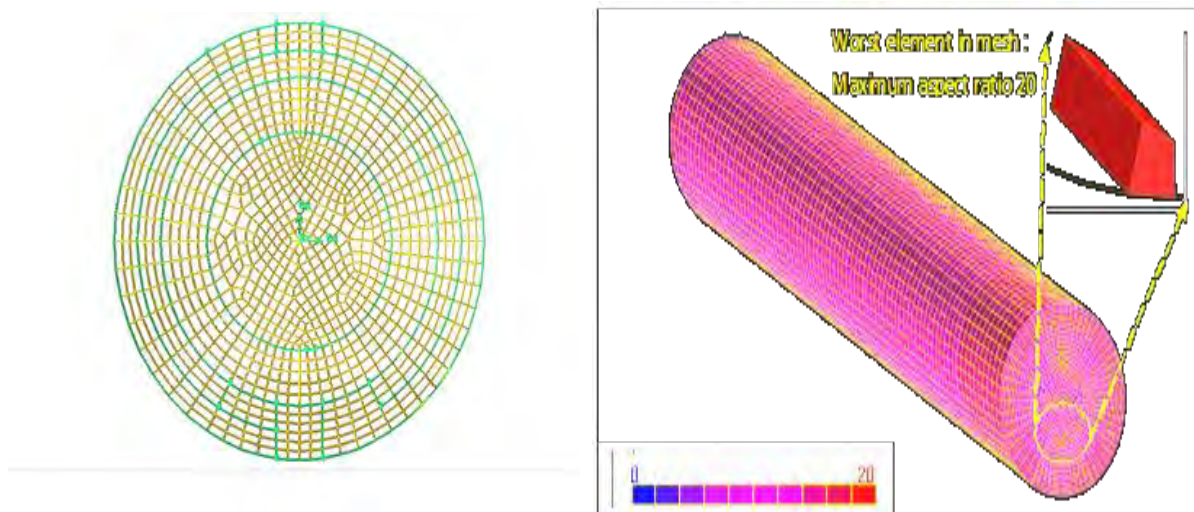

Figure 3.2. Figure showing mesh structure for the model

This model was exported to the FLUENT solver, for further analysis, where the complex conservation equations are solved based on certain different parameters involved. The next section will describe the computational modeling of the prototype.

3.2. COMPUTATIONAL MODEL

The model described in this research work uses ANSYS FLUENT SOFC module (version 12.0). The details of the modeling strategy are explained in the fuel cells module manual by FLUENT [29]. The 3-dimensional tubular SOFC model employs the CFD modeling software to numerically solve the set of partial differential equations involved in the SOFC modeling theory. These partial differential equations describe the heat and mass transfer through the flow channels and the electrodes, the fuel flow and the chemical and electrochemical reactions occurring in the SOFC's. A User Defined Function is employed to model the electrochemical reactions particularly, since they involve some electrical principles which have to be defined in UDF's. The UDF solves for the potential developed in the operation, the current distribution and the different overvoltages (losses) in the fuel cell operation. The electrical model accounts for the potential field in the conductive layers of the cell. The two electrodes in the model are connected using the potential jump feature in the UDF's, for calculating the potential. The mass diffusion model used in the solver, corrects the effect of porosity and tortuosity in the porous media using the multi-component diffusion model.

3.2.1. Computational Model Theory. Computational fluid dynamics modeling of Solid oxide fuel cells requires modeling of the following listed phenomena in the cell.

- *Fluid Flow:* This involves the flow of fuel and air in the flow channels i.e. in the porous and the non-porous media, which can be predicted by solving the conservation of momentum principle.
- *Mass Transfer:* The mass conservation equation and the species conservation equation are solved to account for the diffusion of fuel and air in the porous electrodes.

- *Heat Transfer*: This accounts for the conduction of heat in the solid regions of the cell and the convective heat transfer in the electrodes and through the layers, by solving the energy conservation equation.
- *Electrochemical Reactions*: The electrochemical reactions occurring at the electrodes are accounted for, with the release of ions and electrons.
- *Current and potential field transport*: This phenomenon accounts for the transfer of ions and electrons and the calculation of the cell potential and the current generated.

These phenomena are modeled by solving the above mentioned conservation equations by adopting the finite volume method, using the implicit discretization scheme.

The modeling assumptions used for solving these equations are as listed below [29]:

- The flow is considered as incompressible and laminar, due to the low velocities and low utilization factors
- Steady state operation
- All components are assumed to have similar thermal expansions
- Radiation heat transfer effects are neglected (single cell model)
- Reactions are assumed to take place in a single step
- Charge transfer reaction is considered as the rate limiting reaction

The conservation of momentum principle to model the flow of fuel and air through different zones in the fuel cell operation is given by Equation 3.2.1-1

$$\frac{\partial}{\partial t} \rho \vec{v} + \nabla \cdot \rho \vec{v} y_i = \nabla \cdot \vec{J}_i + S_{s,i} \quad (3.2.1-1)$$

For the porous electrodes, an effective binary diffusion coefficient is calculated, accounting for the porosity and the tortuosity of the electrode structures. Equation 3.2.1-2 shows the expression for the effective binary diffusion coefficient.

$$D_{ij,eff} = \frac{\varepsilon}{\tau} D_{ij} \quad (3.2.1-2)$$

The conservation of charge principle applied to the conductive regions states that

$$\nabla \cdot i = 0 \quad (3.2.1-3)$$

Where i is,

$$i = -\sigma \nabla \phi \quad (3.2.1-4)$$

The Laplace equation is used as the governing principle for solving the species conservation equation,

$$\nabla \cdot \sigma \nabla \phi = 0 \quad (3.2.1-5)$$

The oxygen in the air flow-channel gets reduced to O^{2-} ions, which diffuses through the porous cathode and the electrolyte to react with the hydrogen atoms at the TPB on the anode side. The electrochemical reaction results in release of electrons which pass through the external circuit connected together by the current collectors. The transfer of electrons generates a current through the circuit, developing a potential difference across the two electrodes. The output voltage of the cell is calculated using the Nernst Equation [29](Equation 3.2.1-6) while the current density and the activation overpotentials are calculated using the Butler-Volmer relations [29](Equation 3.2.1-9).

At equilibrium, the reversible cell voltage (Nernst Voltage) is given by Equation 3.2.1-6,

$$\phi_{ideal} = \phi^0 + \frac{RT}{4F} \ln \left(\frac{P_{H_2} P_{O_2}^{\frac{1}{2}}}{P_{H_2O}} \right) \quad (3.2.1-6)$$

The actual cell potential is lower than the Nernst voltage by reduction due to activation, Ohmic losses due to resistivity of the electrolyte, and a linearized for voltage reduction due to activation,

$$\phi_{cell} = \phi_{jump} - \eta \quad (3.2.1-7)$$

Where,

$$\phi_{jump} = \phi_{ideal} - \eta_{ele} - \eta_{act,a} - \eta_{act,c} \quad (3.2.1-8)$$

The current density on the interface can be calculated using the Butler-Volmer equation where the reaction rates are written in terms of the exchange current density.

$$i = i_{0,eff} \left[e^{\frac{\alpha_a n \eta_{act,a} F}{RT}} - e^{\frac{-\alpha_c n \eta_{act,c} F}{RT}} \right] \quad (3.2.1-9)$$

Where,

$$i_{0,eff} = i_{0,ref} \left(\frac{\chi_j}{\chi_{j,ref}} \right)^{\gamma_j} \quad (3.2.1-10)$$

More specifically, the effective exchange current density can be calculated for the anode side and the cathode side; for the anode side:

$$i_{0,eff}^{anode} = i_{0,ref}^{anode} \left(\frac{\chi_{H_2}}{\chi_{H_2,ref}} \right)^{\gamma_{H_2}} \left(\frac{\chi_{H_2O}}{\chi_{H_2O,ref}} \right)^{\gamma_{H_2O}} \quad (3.2.1-11)$$

and for the cathode side,

$$i_{0,eff}^{cathode} = i_{0,ref}^{cathode} \left(\frac{\chi_{O_2}}{\chi_{O_2,ref}} \right)^{\gamma_{O_2}} \quad (3.2.1-12)$$

The Butler-Volmer equation can be solved using the Newton's method after the initial input values for the model are provided. The activation overpotentials for the cathode and the anode are calculated using this equation.

The temperature distribution in the single cell structure i.e. the heat transfer phenomenon is modeled using the energy conservation equation given by equation 3.2.1-13.

$$\frac{\partial}{\partial t} \rho E + \nabla \cdot \bar{v} \rho E + p = \nabla \cdot \left(k_{eff} \nabla T - \sum_j h_j \bar{J}_j + \bar{\tau}_{eff} \cdot \bar{v} \right) + S_h \quad (3.2.1-13)$$

where S_h is the volumetric source or sink of energy and,

$$E = h - \frac{p}{\rho} + \frac{v^2}{2} \quad (3.2.1-14)$$

and

$$h = \sum_j Y_j h_j \quad (3.2.1-15)$$

All the zones in the SOFC model apart from the electrolyte are electrical conductors, which needs a source term in the energy equation given by,

$$S_h = i^2 * R_{ohmic} \quad (3.2.1-16)$$

Equation 3.2.1-16 accounts for the ohmic heating in the cell zones due to the electrical conduction, but the model also needs to take into account the heat generated or lost due to the electrochemical reactions and due to the overpotentials (losses) in the fuel cell operation. The enthalpy flux terms are introduced into the energy equation to take care of the electrochemistry, Equation 3.2.1-17 and Equation 3.2.1-18 show a general energy balance for hydrogen reaction and the enthalpy of formation for the same, respectively.

$$\dot{Q}'' = h_{H_2}'' + h_{O_2}'' - h_{H_2O}'' - i\nabla V \quad (3.2.1-17)$$

$$h_{H_2} = \dot{m}_{H_2} \left[\int_{T_{ref}}^T C_p dT + h_0 \right] \quad (3.2.1-18)$$

The last term in Equation 3.2.1-17 is the work done by the system which is calculated as a product of the local voltage jump and the local current density. The effects of all overpotentials are taken into account by the introduction of the work term for each electrode into the energy equation.

The ohmic resistance in the conducting regions is calculated as:

$$\eta_{ohmic} = i.R \quad (3.2.1-19)$$

The electrochemical reactions are modeled by calculating the rate of species production and destruction, thus calculating the dependence of the concentration of species on the current-voltage characteristics of the cell,

$$S = -\frac{ai}{nF} \quad (3.2.1-20)$$

By convention the current density i is considered positive when it flows from electrode into the electrolyte solution, i.e. the current densities are positive at the anodes and negative at the cathodes. Equation 3.2.1-20 can be used with the conventions to quantify the source terms for the calculations, depending on the electrochemistry involved.

3.2.2. Case Setup. The flow is defined as a viscous laminar flow through both tubes. The fuel and air flow rates are 2.5×10^{-7} kg/s and 1.35×10^{-5} kg/s respectively [2, 28]. The fuel flows through the outer tube diffusing through the porous anode to reach the Triple Phase Boundary (TPB). The air flows through the inner tube at the given flow rate. The inlet temperature for fuel and air is considered to be 973 K to facilitate for faster reaction rates, increasing the effective time of the SOFC operation. Materials are specified for each component using the available materials and also defining new materials in the FLUENT database. The material properties for the components are listed in Table 3.2.

The SOFC Module developed by FLUENT takes the material properties which are defined by the user, along with the electrical parameters which can also be specified by the user as per the required case. The electrical properties used for this case are shown in Table 3.3. Since, not all the electrical and electrochemical parameters needed for the specifications are mentioned in the literature, some of these values have to be calculated approximations, used to try and match the results to the referred case. The values mentioned in Table 3.2. and Table 3.3. were extracted from the FLUENT UDF Manual examples.[29]

Table 3.2. Material specifications for model

MATERIAL PROPERTIES				
Property	Zones			
	Anode	Cathode	Current Collector	Electrolyte
Material	Ni-Doped YSZ	LSM	Ferritic Chromium steel	YSZ
Density(ρ) kg/m ³	3030	4375	8900	5371
Thermal conductivity (k) W/mK	595.1	Temperature Dependent	446	585.2
Specific heat (c_p) J/kg K	6.23	1.15	72	2.2
Porosity (ϵ) %	30	30	Impermeable	Impermeable
Tortuosity (τ)	3	3	-	-

Table 3.3. Electrical properties in the SOFC model

ELECTRICAL PROPERTIES	
Property	Value
Total system current (Amp)	8
Electrolyte resistivity (ohm - m)	0.1
Current under relaxation factor	0.3
Anode exchange current density (Amps)	1.00e+20
Cathode exchange current density (Amps)	512
- Anodic transfer coefficient	0.5
- Cathodic transfer coefficient	0.5
- Anode Conductivity (1/ohm-m)	333330
- Cathode Conductivity (1/ohm-m)	7937
- Current collectors conductivity (1/ohm-m)	1.50e+07
- Anodic contact resistance (ohm-m ²)	1.00E-07
- Cathodic contact resistance (ohm-m ²)	1.00E-08

As discussed earlier, the electrochemical modeling makes use of a User Defined Module (UDF) for the calculation of the current and potential characteristics. This requires definition of basic initial parameters as inputs to the governing equations. The FLUENT module allows us to specify an initial system current or to converge to a specific output voltage. The present simulation makes use of the initial specified current through

the system to find out the developed voltage. The module also provides us with the flexibility of specifying the thickness of the electrolyte used, since the electrolyte was modeled as an interface rather than as a thick zone. The electrical input parameters to the model are specified in Table 3.3.

Although, it is difficult to replicate the behavior of all the materials that are in practical use, because the properties of materials at such high temperatures vary indefinitely, but care had been taken to set these parameters to nearest possible behavior of those materials to obtain an accurate comparison. The UDF gives the flexibility of setting up the electrical and thermal conductivities for the given materials as per the predictions. Also the contact resistances can be varied according to the case. After the initial setup of the case by defining the basic input parameters, the model needs to be validated against a benchmark case to test for the reliability and accuracy of the model, for the given set of boundary conditions.

1. MODEL VALIDATION

First step after developing any model based on mathematical and computational principles is its verification and validation. A few basic questions is needed to be answered about the model i.e. 1) are the equations taking care of all the processes involved, and 2) Is the solution accurate enough to represent the real life case. The validation is usually done by comparing the results to either experimental observations or another independent model for the given set of operating conditions. For a successful verification and validation of the model, it is necessary to match the independent parameters as much as possible to have a comparison, although sometimes there is less chance of an exact match of the parameters with the experimental values due to the various limitations imposed on the model based on the assumptions.

The validation of a computational SOFC model is an extremely challenging task. Small size of the cells coupled with high temperatures make it difficult to probe and measure parameters in SOFC's. However, before implementation, any computational model needs to be validated against some experimental analysis i.e. against some benchmark case for similar geometry. Validation of the model will signify the relevance and reliability of the model to match the actual conditions using computational analysis. In general, fuel cell performance is evaluated using the basic polarization curve, which exhibits the current-voltage characteristics of the fuel cell under consideration. In this section, results from the computational FLUENT SOFC model are compared against experimental work mentioned in Barzi et al. [24] as well as against 2 other computational models.

4.1. BOUNDARY CONDITION SETUP

For the comparison of the present model with the cases in the literature mentioned, the initial and boundary conditions needs to be matched with the cases. As was discussed in the modeling theory in section 3, it is quite difficult to obtain all the required parameters for setting up an exact replica of the base case, the modeling is done with the available conditions and then try to setup approximate values for the other parameters. Table 4.1. gives a detailed description of the boundary conditions for the present model.

Table 4.1. Cell zone conditions and boundary conditions applied to the present model

OPERATING AND BOUNDARY CONDITIONS	
Property	Value
Viscous resistance for porous zone (1/m ²)	1.00e+13
Fuel flow rate (kg/s)	2.49e-07
Air flow rate (kg/s)	1.37e-05
Fuel inlet temperature (K)	9.73e+02
Air inlet temperature (K)	9.73e+02
Inlet mass fractions :	
- H ₂ O	0.525
- H ₂	0.475
- O ₂	0.292
Operating pressure (Pa)	101325

The flow rates for the tubular fuel cell model are calculated as per the length of the cell and the fuel utilization for the given total current through the circuit. The operation is carried out at atmospheric pressure but at a higher initial temperature for the fuel as well as air. The model was simulated for these operating and boundary conditions.

4.2. RESULTS AND ANALYSIS

After setting up the boundary conditions for the model according to the specifications mentioned in the literature, the model was simulated using the FLUENT interface and also using the UDF. Figure 4.1. shows the results obtained from Barzi et al. [24] which includes a compilation and comparison of results from three different sources. The plot shows the output voltage of the system plotted against the localized current density. Also, included is the plot obtained using the experimental observations of Hagiwara et al. [30]. The results obtained from the simulation performed on the present model are imposed onto the same plot for comparison with the relevant cases. The output voltage is plotted against an area-weighted average (Equation 4.2-1.) of the current density.

$$\frac{1}{A} \int \phi dA = \frac{1}{A} \sum_{i=1}^n \phi_i |A_i| \quad (4.2-1)$$

Averaging is done by dividing the summation of the product of the selected field variable and the facet area by the total area of the surface [29]. The results are in close accordance for all the 4 cases.

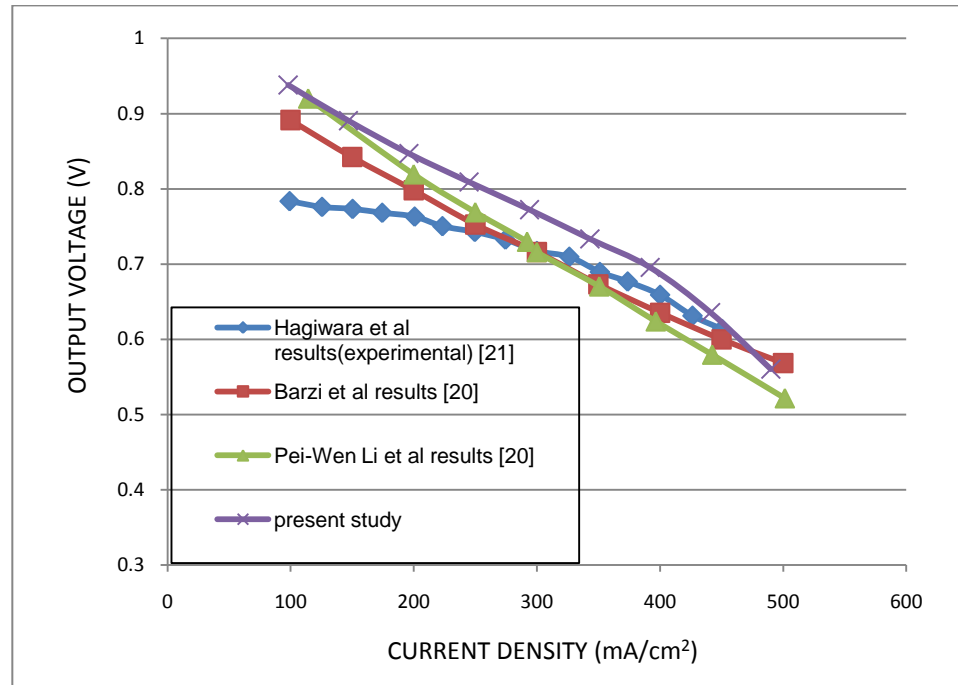

Figure 4.1. Comparison plot with experimental results from Barzi et al. [24]

It can be observed from Figure 4.1 and Figure 4.2. that the plots for the voltage for the given computational model and the mathematical model show an average deviation of 5% for current densities above 250 mA/cm^2 , whereas below 250 mA/cm^2 the deviation is 15% from experimental. Variation in the voltage is observed in the low current density region, whereas in the intermediate and high current density values, the model shows close acceptance to the base case. This can be explained by considering the unknown losses due to the material properties as well as the environmental factors, which are difficult to account for in the mathematical and the computational models, due to their non-quantitative nature. These unknown factors impart some losses to the voltage developed in

the experimental i.e. practical situations, which ultimately results in a lower total voltage, especially at low current densities, where the resistances become dominant.

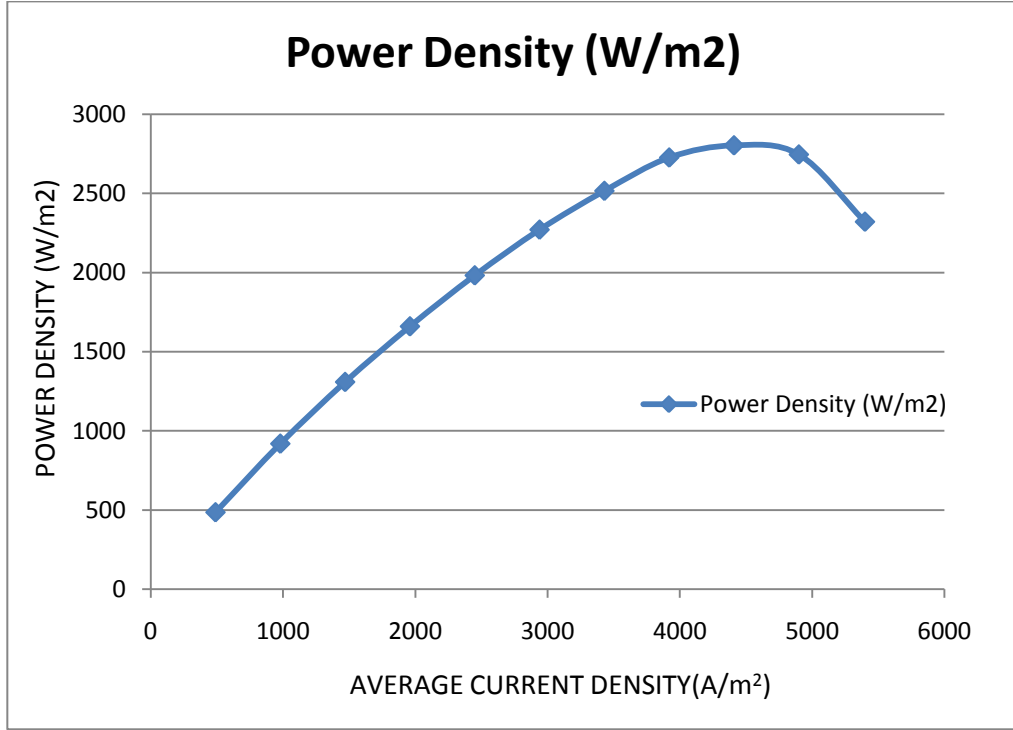

Figure 4.2. Plot of power density vs. the current density for present model

Figure 4.2. shows the power density developed by the current model plotted against the average current density for the given set of conditions. This characteristic plot is also important to measure the fuel cells performance for certain load variation. It helps to identify the optimum operating current density for the fuel cell corresponding to the

maximum current density, considering all other important factors. The optimum operating current density for the given model is found to be in the range of 400-500 mA/cm².

The current model was validated for the mentioned case using the experimental data. The same model was then used for its performance analysis by varying the conditions and parameters. The response of the computational model to different conditions is analyzed and discussed in detail in the next section.

5. PARAMETRIC ANALYSIS

After the successful verification and validation of the SOFC model, several parametric studies were performed on the model. The material covered in this section deals with tracking and analyzing the response of the model, to change in various important parameters involved. The effect of change in operating temperature, cathode porosities and the electrolyte thickness are being noted on the model to evaluate its performance and to find the optimum conditions for SOFC operation. Basic characteristics, involving the geometry, mesh, material properties and the operating conditions are kept the same as in the previous section, unless mentioned specifically.

5.1. TEMPERATURE DEPENDENCE & EFFECT OF POROSITY

As mentioned earlier, the model was developed to evaluate the response of SOFC cells to varying parameters. Temperature dependence of the same model was checked by simulating it for three different temperatures, keeping all other parameters constant. This evaluation technique was adopted by Sleiti et.al [28] for the similar cathode supported tubular model. Simulations were performed for initial temperatures of 500 °C, 600 °C and 700 °C and all the response parameter variations were noted. Figure 5.1. shows the plot of the total voltage for all the three cases, two more cases are added to check for the effect of cathode porosity variation for a specified inlet temperature. The cathode porosity is varied from 30 % - 10 % for a fixed inlet temperature of 700 °C. The two plots for porosity values of 20 % and 10 % are also added onto the same figure for a comparison.

Figure 5.1. Plot of total voltage vs. average current density for different cases with variation in temperature (T) and cathode porosity (p)

The operating temperature is of utmost importance in case of Solid Oxide fuel cells, since the electrolyte material exhibits high ionic conductivity at higher temperatures. It can be observed, though, in Figure 5.1. that the SOFC model under study performs better at a lower temperature when compared to the other two temperature cases. The lowest total voltage is attained for the higher temperatures from the observation obtained. It can also be seen that small variations in the porosity of the cathode does not impose a significant effect on the performance of the cell. The plots for the three different porosity values at 973 K look superimposed with very slight variation in values in the Figure 5.1. It is implied from the 5 plots that the case with inlet temperature of 773 K shows the best

performance in case of the total output voltage among the compared cases. Figure 5.2. shows the power density plot for all the five cases to support the observation.

Figure 5.2. Power density plotted against average current density for temperature dependence study

It can be observed from the Figure 5.2. that the highest power density is attained for the case with initial temperature of 773 K. It can be concluded from the observations

that the model can be used as an intermediate temperature SOFC model provided that the basic conditions are kept the same. The present model can be simulated and analyzed for different operating conditions as a prototype for an intermediate temperature SOFC operation.

Other characteristic plots were also studied for the same model for further analysis.

Figure 5.3-a to c. shows the contour plots of the cell voltage, the current density distribution and the temperature distribution over the length of the model.

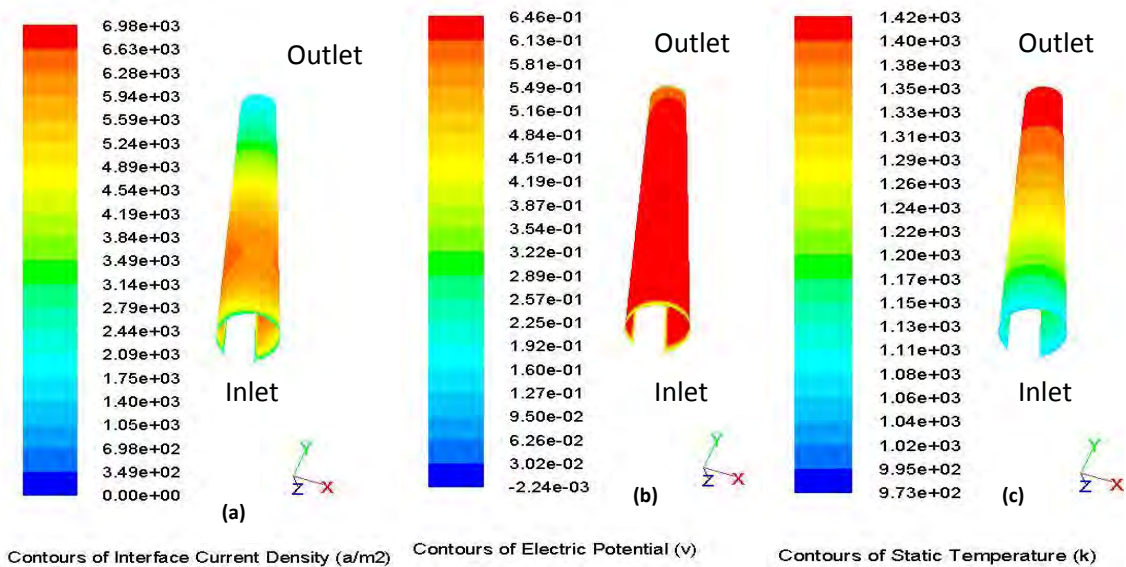

Figure 5.3. Contour plots of current density, voltage & temperature distribution

Figure 5.3. shows the distribution of the important parameters on the electrolyte interface on the anode side in the SOFC architecture described in Section 3. The contour

plots are obtained for the case with inlet temperature of 973 K and cathode porosity of 30 %. It can be seen from the figure that the current density distribution varies along the length of the cell from the inlet to the outlet along with the variation in the temperature. As can be seen, the maximum current density is observed very close to the inlet as compared to the other areas on the surface. The current density decreases along the length thus decreasing the power output of the single cell. The cell voltage is however constant over the length, because it defines the potential difference developed across the two electrodes. This characteristic along with other factors can be considered as an important observation for determining the optimum length of the single cells in a fuel cell stack system. Another indication for restricting the length of the cell in this case can be the sudden increase in temperature towards the outlet of the cell. As illustrated in the Figure 5.3-c, the temperature rises considerably towards the outlet end of the cell, where even the current density is lower. Also Figure 5.4. and Figure 5.5. shows the distribution of mole fractions of the reacting species in the anode side for all the 5 different cases mentioned earlier.

The concentration of H_2 in the anode side goes on decreasing from the inlet to the outlet of the tube. The variation is a result of the electrochemical reaction taking place along the length of the cell. Figure 5.4. shows the decrease in the H_2 mole fraction whereas Figure 5.5. indicates the increase in the H_2O mole fraction which is the product of the electrochemistry. It is evident from the plots that the H_2 concentration reduces to a very low value near the outlet for the given model, which is another indication for reducing the length of the single cells in this case for optimization of resources.

Figure 5.4. Plot of H₂ mole fraction over length of cell for all 5 cases

Figure 5.5. Plot of H₂O mole fraction over length of cell for all 5 cases

The temperature dependence study of the model for the different cases mentioned above indicates that the model can be used as an intermediate temperature SOFC model. This model can be simulated and analyzed for different operating conditions as a prototype for an intermediate temperature SOFC operation, which can prove to be a useful and important guiding tool for successful experimental setups. Further parametric analysis was performed on the model to enhance the geometrical and material properties for the model.

5.2. EFFECT OF ELECTROLYTE THICKNESS

Low SOFC operating temperatures have various advantages such as broadening the material selection prospects, reducing the sealing problems and enhancing the commercialization of SOFC's. However, lower operating temperatures also result in increase of electrolyte resistance and higher electrode overpotentials which might reduce the electrochemical performance of the cell. One of the methods of reducing the operating temperature of the SOFC's while retaining its electrochemical performance is to reduce the electrolyte thickness to attainable values.

The thickness of the electrolyte plays a very important role in the overall SOFC operation. Electrolytes are important to carry out the ion transport process in the operation, which is the initial step for the electrochemical reaction to take place at the anode-electrolyte interface. Theoretically, reducing the thickness of the electrolyte implies providing less resistance to the flow of oxygen ions from the cathode side to the anode side. Figure 5.6. shows the effect of the variation in the electrolyte thickness in the present model.

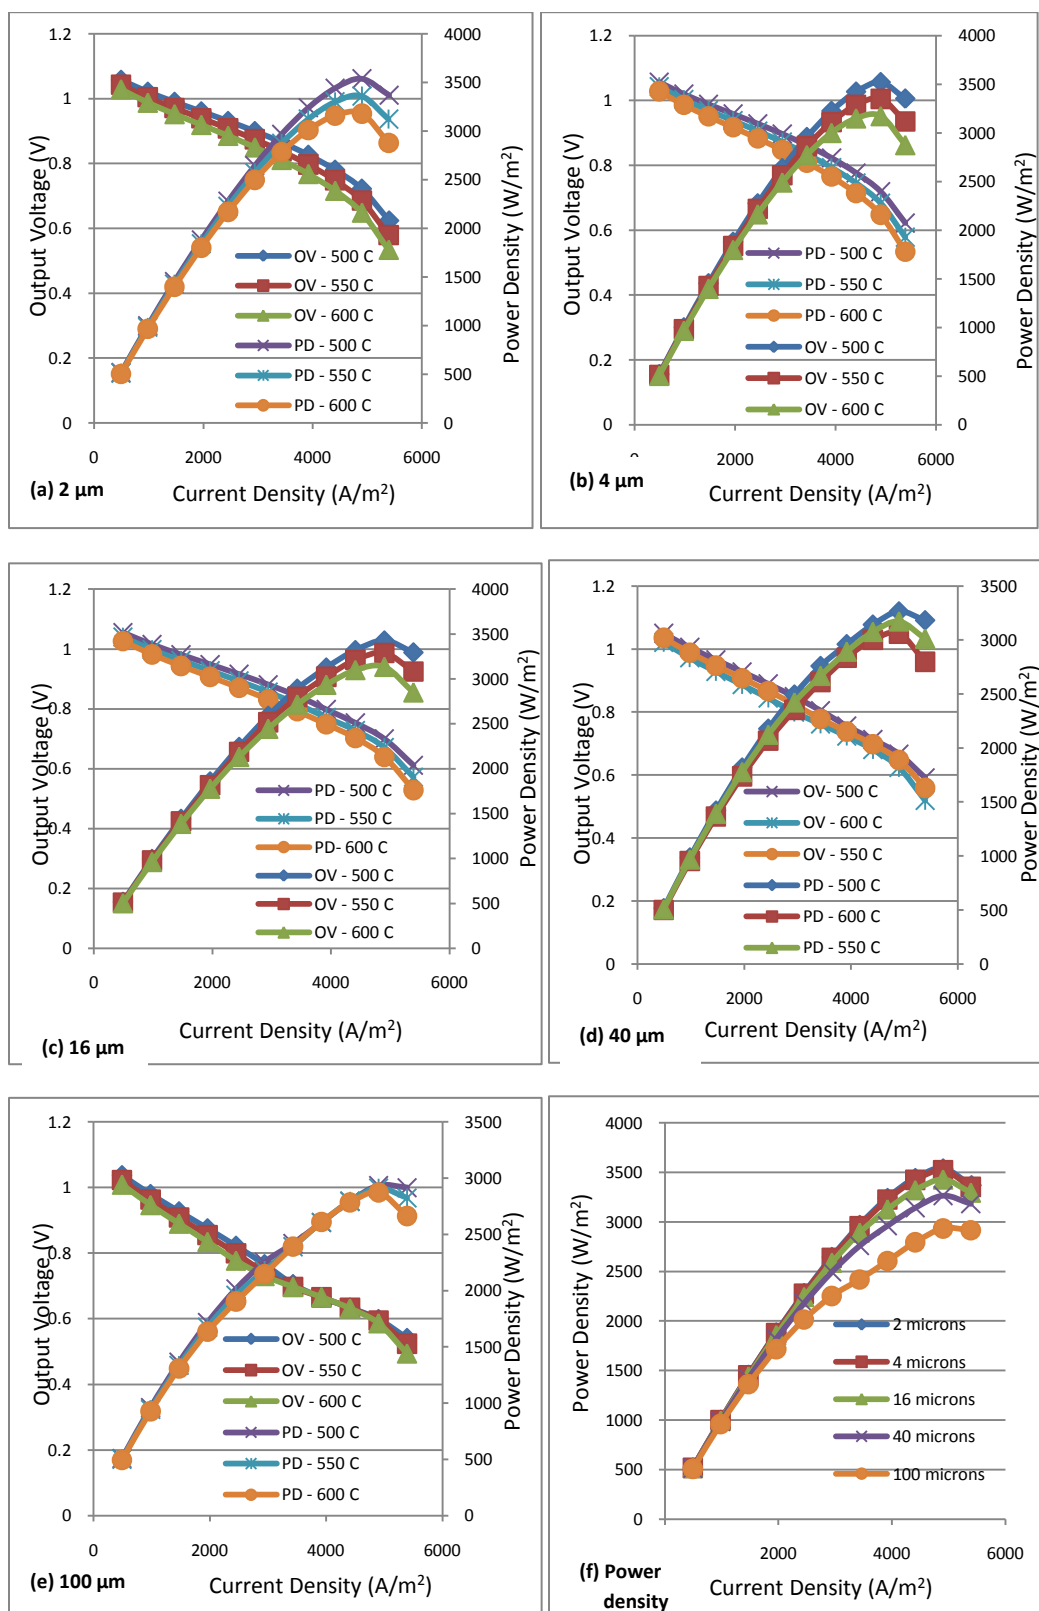

Figure 5.6. Plots to study the electrolyte thickness variation effects

The present model was tested and evaluated for different cases, by changing the electrolyte thickness to certain values. The thickness was varied from 2-100 μm and the output voltage for each system was noted as the response variable. The simulations were performed at three different operating temperatures to find the optimum operating thickness for the present model. Also, variation in temperature would help in understanding the inter-relation between both the parameters. The model was simulated for these cases and the simulation results i.e. the plots for the variation of output voltage against the current density and also the power density curves are shown in Figures 5.6-a to 5.6-e.

The variation of the output voltage for different thicknesses, considering the same parameters for all the cases are shown in the above mentioned figures. It is clearly evident from the plots that lower electrolyte thicknesses exhibit better performance. The maximum power density values for the cell, obtained by varying the electrolyte layer thickness are 0.354 W/cm^2 , 0.352 W/cm^2 , 0.343 W/cm^2 , 0.326 W/cm^2 and 0.29 W/cm^2 for the electrolyte thicknesses of $2 \mu\text{m}$, $4 \mu\text{m}$, $16 \mu\text{m}$, $40 \mu\text{m}$ and $100 \mu\text{m}$ respectively.

It can be observed from Figure 5.6-f. that there is not much change in the power density as the thickness is reduced from $4 \mu\text{m}$ to $2 \mu\text{m}$. An optimum thickness can be established for this model based on this observation; however, the computational model does not account for the electron leakage which can occur through the electrolyte due to very low thickness. This electron leakage can result in a reversal of current, reducing the overall output voltage and consequently the power provided by the cell. Also, lower electrolyte thicknesses are more difficult to manufacture, making the process expensive [12]. Based on the electrical limitations of the computational model, compared to the

actual experimental work, an optimum thickness of the given model can be considered to be between 4-16 μm .

The temperature variation also shows a considerable effect on the performance of this cell as shown in the Figure 5.6. It is observed that the model is at its peak performance at 500 $^{\circ}\text{C}$ compared to the higher temperatures. A very low operating temperature can again impart some voltage losses due to the activation barrier for the electrochemical reactions to take place, which can lower the overall performance of the fuel cell. Thus an operating temperature of 500 $^{\circ}\text{C}$ along with an electrolyte thickness of 4-16 μm can be considered as the most favorable operating parameters based on the present computations. The model can be used for the evaluation of intermediate temperature SOFC operations.

5.3. ANALYSIS USING DIFFERENT FUELS

From the study based on the parameter variations on the model, it was observed that this model can serve as a base model for study of intermediate temperature fuel cells for the given set of conditions. For further exploring the advantages of SOFC systems over other fuel cell types i.e. checking for its compatibility with fuels other than hydrogen, the model was simulated using fuels like CO and then using a hydrocarbon fuel CH_4 for simulating other processes involved. The following section makes use of the CO electrochemistry feature of the FLUENT SOFC module.

5.3.1. CO Electrochemistry Model. The model was evaluated for different cases using H_2 as the fuel and air as the oxidizer for all the previous tests. SOFC systems possess the flexibility of working with fuels other than hydrogen. To explore and analyze these characteristics of the SOFC systems, H_2 in the fuel channel was replaced by CO. The

difference will be in the electrochemistry part of the operation, where CO will react with the O_2 ions electrochemically to generate CO_2 as the by-product of the process. The electrochemical reaction is as mentioned below,

All the basic parameters for the model are kept the same for the CO electrochemistry model, with the same total current through the circuit as mentioned in the previous section. This approach is adopted to obtain a comparison of the output parameters for both the cases with H_2 and with CO as the primary fuel. The comparison is done using the same contour plots as mentioned in Figure 5.3. and Figure 5.7.

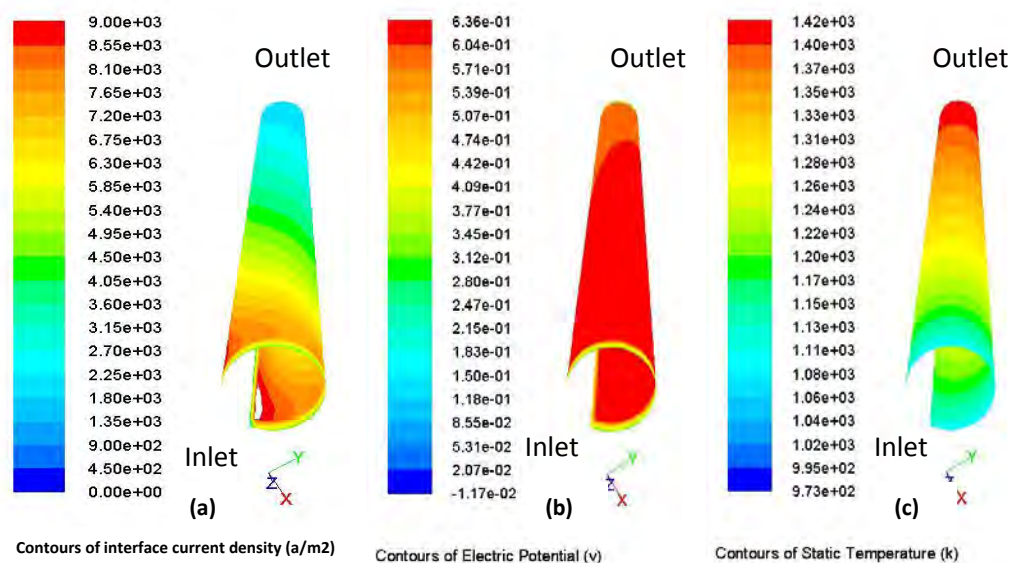

Figure 5.7. Contour plots of current density, voltage and temperature for CO electrochemistry model

Figure 5.7-a. to c. compared to Figure 5.3. shows a small difference in the voltage developed by the cell for both the cases. The cell voltage differs by just 0.1 V, with greater value achieved using H₂ as the fuel. It can still be considered that H₂ contributes greater to the electrochemistry when H₂ and CO both are present in the fuel mixture, because of the consumption of CO in the shift reaction, associated with the SOFC operation. The shift reaction was not considered in the CO electrochemistry case and will be discussed in the further section.

5.3.2. Modeling the Reformation and Water–gas Shift Reaction using CH₄ as Fuel. After checking the model for the CO electrochemistry case and the comparison of the results for H₂ and CO as the fuel, the same design was used to model the reformation reactions and the water-gas shift reaction using hydrocarbon fuel methane (CH₄). As discussed in Section 1, solid oxide fuel cells possess this characteristic of using fuels other than H₂ for generating electricity. This model involves the integration of the chemical reaction modeling with the other transport and conservation principles discussed earlier, along with the UDF defined for the electrochemistry.

Humidified methane can be fed directly at the anode inlet of the SOFC model and due to its high operating temperatures; methane reacts with the steam in the presence of nickel which acts as the catalyst to generate CO and H₂. This reaction is called as the methane reformation reaction which is endothermic in nature. The reformation reaction is shown in Equation (5.3.2-1),

The CO generated in the reformation reaction further reacts with the steam in the mixture to produce more hydrogen and carbon dioxide as the by-product. In this case, both the CO and H₂ generated in the process take part in the electrochemical reactions and contribute to the power produced. Equation (5.3.2-2) shows the Water-Gas shift reaction mechanism.

The electrochemical reactions for hydrogen and CO are shown in Equations (1.1-1) in Section 1 and (5.3.1-1), respectively.

Usually, for practical applications, methane is pre-reformed to a certain extent before being fed at the inlet to the fuel cell. The high operating temperature of solid oxide fuel cells provides the necessary heat energy for the initiation of the reformation reaction. But the highly endothermic nature of this reaction generates large thermal gradients along the path. This could result in high thermal stresses being induced in the materials used, consequently affecting the life of the cell. To control and eliminate this problem, care is taken to have a uniform distribution of the necessary species at the inlet to balance out the thermal requirements of the processes involved. This is attained by having a partial reformation process carried out prior to the fuel cell operation.

Stiller et al. [25] worked on a mathematical model for a tubular SOFC for the partially pre-reformed methane case, for different operating conditions. The present model

was simulated using the same conditions for better comparison amongst different operating parameters.

Table 5.1 shows the simulation parameters and results for the Stiller [25] model and the present model for two different operating pressures.

Table 5.1. Comparison of results for the model with Stiller et al. [25]

	Stiller (atm)	Model (atm)	Stiller (press.)	Model (press.)
Pressure (bar)	1.05	1.05	3.5	3.5
Inlet fuel temperature (K)	823	823	860	860
Inlet Air temperature (K)	1104	1104	1048	1048
Fuel utilization (%)	69	69	69	69
Inlet Fuel Composition :				
H ₂	0.258	0.258	0.226	0.226
H ₂ O	0.284	0.284	0.334	0.334
CH ₄	0.11	0.11	0.131	0.131
CO	0.057	0.057	0.057	0.057
CO ₂	0.228	0.228	0.241	0.241
N ₂	0.063	0.063	0.011	0.011
Voltage (V)	0.695	0.762	0.564	0.709
Average Current density (A/m ²)		5000		7000

As mentioned earlier, the products obtained in the fuel stream after the partial pre-reformation process is fed at the model inlet with the composition shown in Table 5.1. It can be observed from the table that the current model performs better than the Stiller model for similar set of operating and boundary conditions, considering the overall voltage developed. This variation in the results can be due to various undeterminable parametric differences in both the models. The total voltage is found to be lower for the pressurized case, also needing a higher overall current through the circuit thus increasing the average current density for the pressurized case. However, the results are found to be very sensitive to the inlet temperature and the fuel composition.

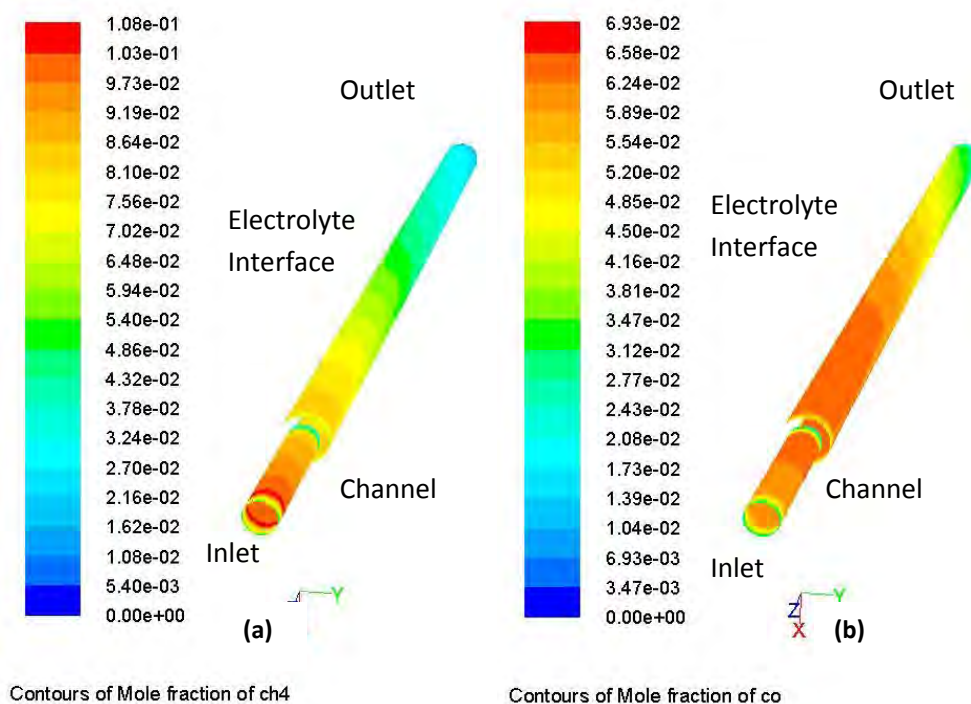

Figure 5.8. Contour plots of the distribution of fuel species in the flow channel and on the electrolyte surface

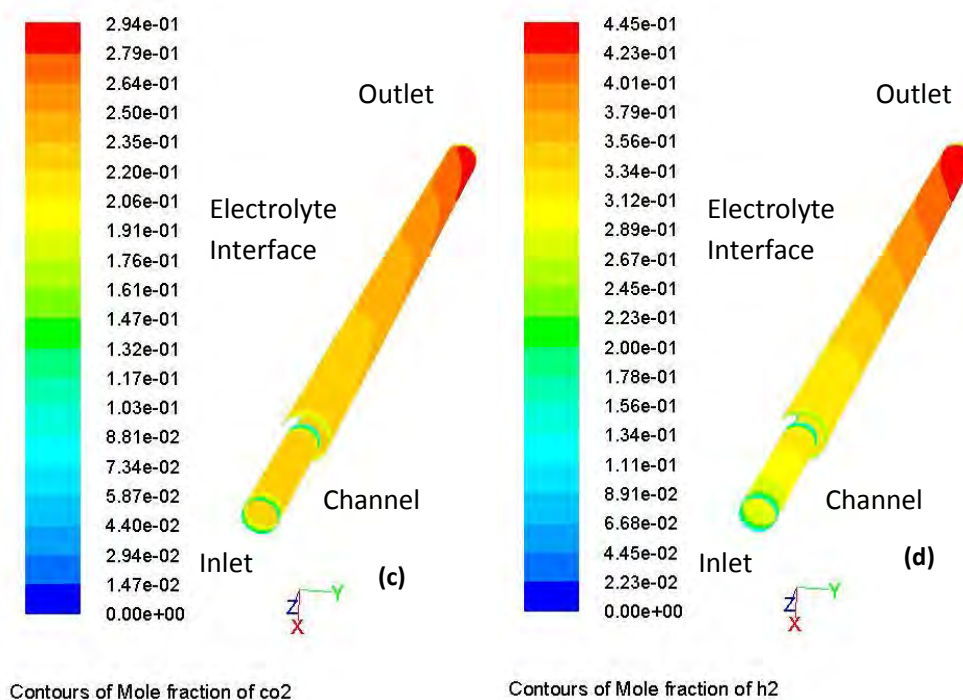

Figure 5.8. Contour plots of the distribution of fuel species in the flow channel and on the electrolyte surface (cont.)

Figure 5.8-(a-d). shows the contour plots of the distribution of the fuel species, as it flows from the inlet to the outlet of the fuel cell. Figure 5.9. shows the variation of the H₂O mole fraction over the length of the cell. The distribution is analyzed in the anode flow channel wall and the electrolyte surface on the anode side. Figure 5.8-a. shows the distribution of CH₄ over the length of the cell; it can be seen that the concentration gradually goes on decreasing with a good overall distribution along the length for the given set of conditions. The reformation reaction taking place (Equation 5.3.2-1) uses up a portion of the steam contained in the mixture and produces CO and H₂ which can be seen in Figure 5.8-b and 5.8-d. There is an increase in the CO fraction at the start of the

electrolyte interface, which is further consumed in the electrochemistry and also for the shift reaction. It is noted that the shift reaction is more dominant further down the line i.e. closer to the outlet, producing more CO_2 and H_2 closer to the outlet as seen in Figure 5.8-c and 5.8-d.

Figure 5.9. Plot showing distribution of H_2O along length of the cell

Figure 5.9. shows the distribution of H_2O along the fuel cell length. The decrease in the concentration is due to the consumption of H_2O in both the reformation and the shift reactions, but the electrochemical reaction involving H_2 prevents the H_2O concentration from falling considerably over the cell length.

The chemical reactions are modeled using the finite rate model in the FLUENT solver. The activation energies for the reactions are specified approximately, based on the values mentioned in the literature. The activation energy for the reformation reaction is considered in the range of 60-230 kJ/mol [31] and for the shift reaction it's considered to be 100-300 kJ/mol [31-32]. Figure 5.10-(a-b). shows the contour plots for the kinetic rates of reaction for the reformation reaction (reaction 1) and the shift reaction (reaction 2) respectively.

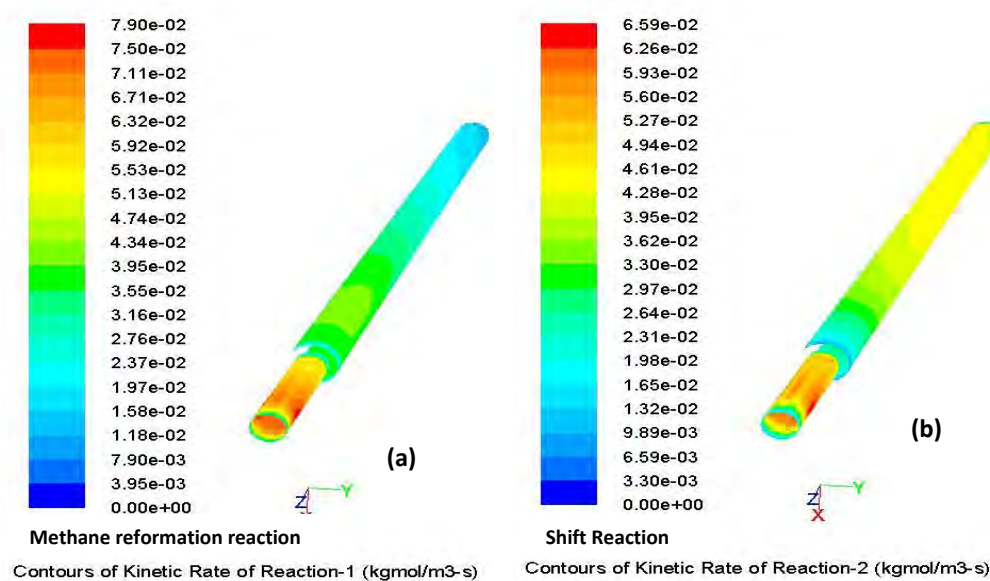

Figure 5.10. Contour plots for kinetic rates of reaction

Figure 5.10. indicates that both the reactions were dominant in the flow channel where there was enough concentration of the reactants and the high temperature to carry out the reactions. Figure 5.10-b. shows that the shift reaction becomes dominant along the

length of the cell when there is more CO and H₂O produced from the reformation reaction and the electrochemical reaction down the line. As mentioned earlier, the strongly endothermic nature of the reformation reaction makes the temperature fall considerably in the channel and then increases again due to the exothermic electrochemical reaction and the shift reaction.

Thus, the computational model used in this study, helps understand and analyze the processes involved in the SOFC operation much more descriptively as compared to other modeling approaches. Lowering the initial temperatures in this case can prove to be helpful to reduce the high thermal gradients generated due to the reactions and also catalysts can be used to control the activation requirements i.e. ultimately the kinetics involved in the reactions.

6. CONCLUSIONS AND FUTURE WORK

This thesis work included a detailed computational fluid dynamics modeling, simulation and analysis of a tubular solid oxide fuel cell. A cathode supported structure was developed using a FLUENT pre-processor software GAMBIT 2.3.16. The meshed structure was then modeled for fluid flow, mass transport and electro-thermo-chemical analysis using the FLUENT 12.0 interface including the SOFC UDF developed by FLUENT for modeling the electrochemical reactions occurring in the SOFC's. Some important discussions based on the analyses of the model for the different conditions are mentioned in the following sections.

6.1. CONCLUSIONS AND DISCUSSIONS

The results obtained from the analyses performed on the model for the different conditions mentioned in the previous sections show that the computational model developed is much more advantageous for understanding the complex processes involved in the SOFC operation. The plots and results obtained are much more descriptive in terms of the distribution of various important parameters in a three dimensional perspective.

A parametric analysis was performed on the model, to analyze its response and performance to varying parameters. By the temperature effect study, it was discovered that the model showed a greater overall operating potential at a lower temperature compared to the other cases for the specific set of basic properties defined. This characteristic of the model makes it suitable to be used as a prototype for an intermediate temperature SOFC

for further analysis. An optimum operating temperature combined with suitable electrolyte thickness was observed for the given model [33].

For further exploring the advantages of solid oxide fuel cells, the model was simulated for cases using fuels other than hydrogen, to analyze the performance. The simulation was carried out successfully, describing the reformation reaction and the shift reaction for methane as the fuel. The simulation results were studied for a single case, evaluating the effect of the specified parameters. Since, no complete set of input parameters and experimental results are found in the literature for tubular fuel cells, the obtained correspondence can be considered sufficient for the validation. Based on all the analyses, the model could be used as a base model or a prototype of a cathode supported tubular SOFC, to carry out a faster and cheaper analysis prior to a successful experimental setup.

6.2. FUTURE WORK SUGGESTIONS

The SOFC model mentioned in this work was evaluated considering a few assumptions mentioned in Section 3. The steady state models used in these analyses can be replaced by adopting a transient analyses approach. FLUENT itself provides the option of setting-up a transient case using its implicit solver. A complete transient analysis can be very helpful in analyzing the kinetics of each reaction and also the flow duration for different composition and flow rates of the fuel and oxidizer. Also, as discussed in Section 2, a radiation model can be included to account for the effect of radiation heat transfer on the final operating temperature of the cell, which was neglected in the present model. The integration of the chemical reactions with the electrochemical model can be studied in

detail, by considering different rate limiting reactions, and also by modifying the catalytic effect on the reactions involved.

This single cell model can be further modified to be used as an appropriate pre-evaluation tool by upgrading it to a complete fuel cell stack, with all necessary parts involved in the operation. A complete stack model, will evaluate the performance most accurately compared to any other single cell models.

These important additions to the model can help considerably in this research area of solid oxide fuel cell modeling. These computational setups can be simulated for different parameters and conditions and the results can be analyzed and used for optimizing the performance of the fuel cell systems.

APPENDIX

FLUENT TUTORIAL FOR SETTING UP THE TUBULAR SOFC MODEL

The Solid Oxide Fuel Cell Unresolved electrolyte module was developed by FLUENT for modeling and simulating 3-D SOFC designs. A license for this module is needed to be bought separately for the unresolved electrolyte. The steps mentioned below will help in complete setup and modeling of a SOFC design using FLUENT.

Step 1: Importing the mesh and starting up the SOFC module

- Start FLUENT 12.0 using the 3-D double precision model.
- Read the mesh file for the model from the location.

(FILE → READ → MESH)

- Scale the mesh according to the case requirement

(Problem setup → General → Mesh → Scale)

- The Solid Oxide Fuel Cell (SOFC) With Unresolved Electrolyte Model is loaded into ANSYS FLUENT through the text user interface (TUI). The module can only be loaded after a valid ANSYS FLUENT mesh or case file has been set or read. The text command to load the addon module is

define models → addon-modules

A list of FLUENT addon modules is displayed as shown below:

FLUENT Addon Modules:

0. None

1. MHD Model

2. Fiber Model

3. Fuel Cell and Electrolysis Model

4. SOFC Model with Unresolved Electrolyte

5. Population Balance Model

Enter Module Number: [0] 4

Select the SOFC Model with Unresolved Electrolyte by entering number 4, which will load the SOFC module for the selected model.

Step 2: Case setup for the fluid flow, species transport and the heat transfer

- For simplicity in recognizing the zones in the tubular model, rename the electrolyte zone to electrolyte-cathode and the electrolyte shadow zone to electrolyte-anode.
- Check the display and the grid (correct the mesh if any discrepancies observed in the quality of the mesh)
- Retain the solver settings with a pressure-based and steady state solver.

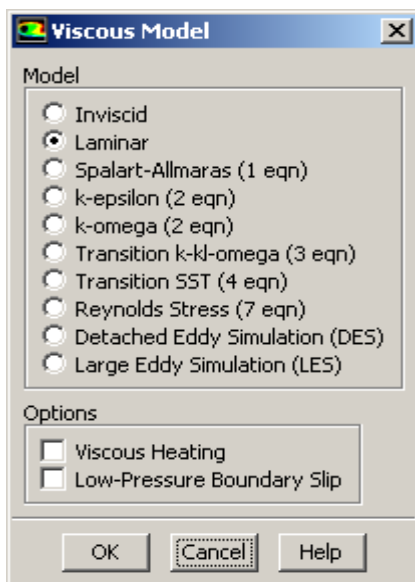

- Turn on the heat transfer analysis tool by enabling the energy equation

Problem setup → Models → Energy

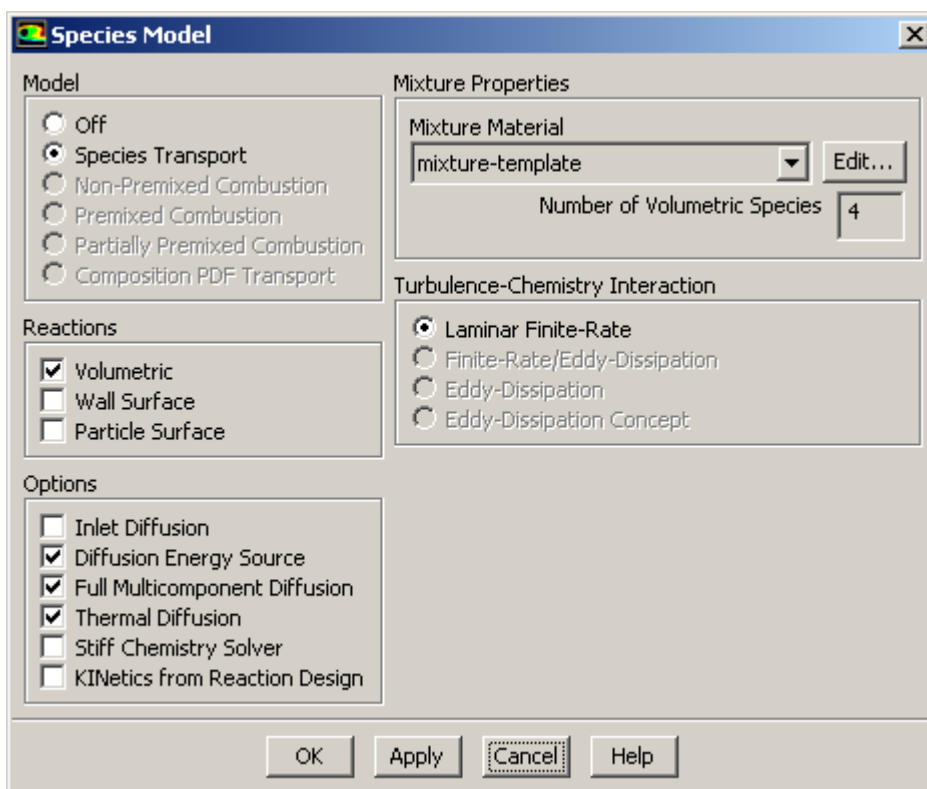

- Enable laminar flow simulation, ensuring that the viscous heating is disabled.

Problem setup → Models → Viscous

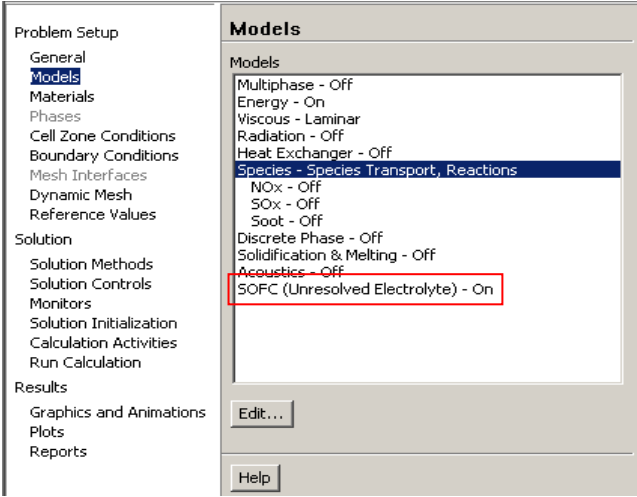

- Define the species transport and reaction models.

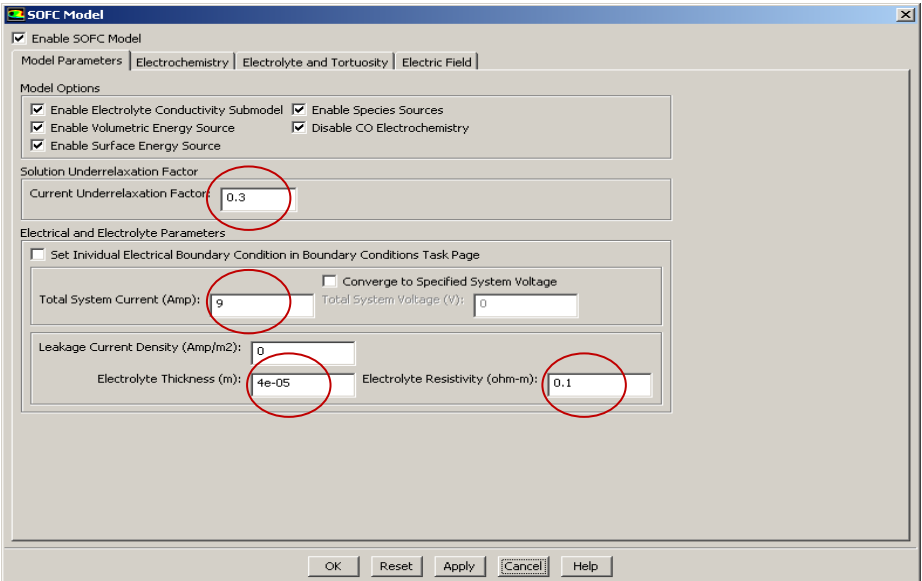

Enable the species transport model for volumetric reactions and also enable the Diffusion Energy Source, Full Multicomponent Diffusion and the Thermal Diffusion models.

Step 3: Setting up the electrochemical model using the FLUENT UDF (the values mentioned in the brackets are an example for the present tubular model)

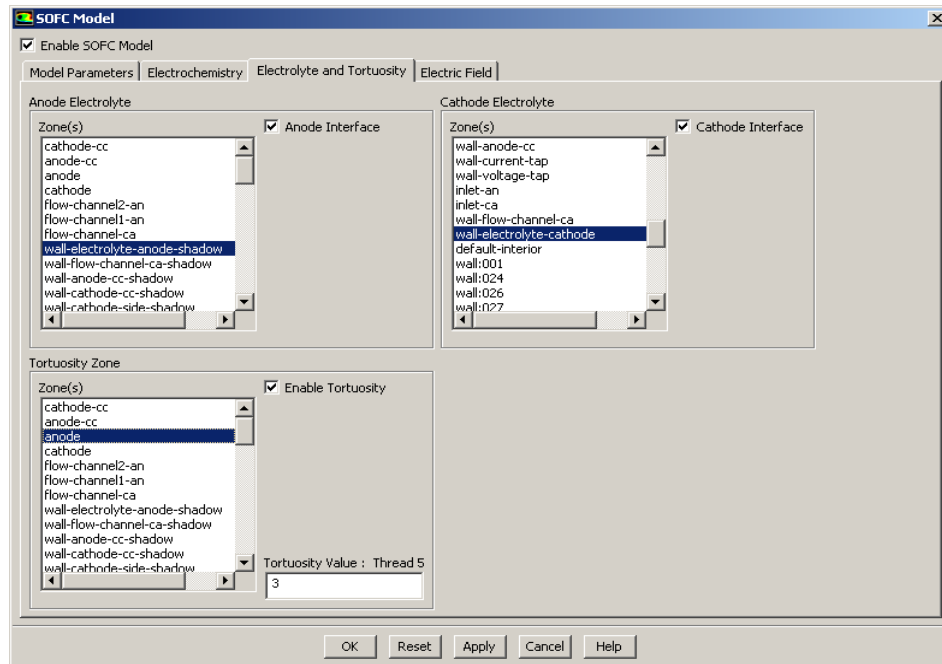

Problem Setup → Models → SOFC (Unresolved Electrolyte) → Edit

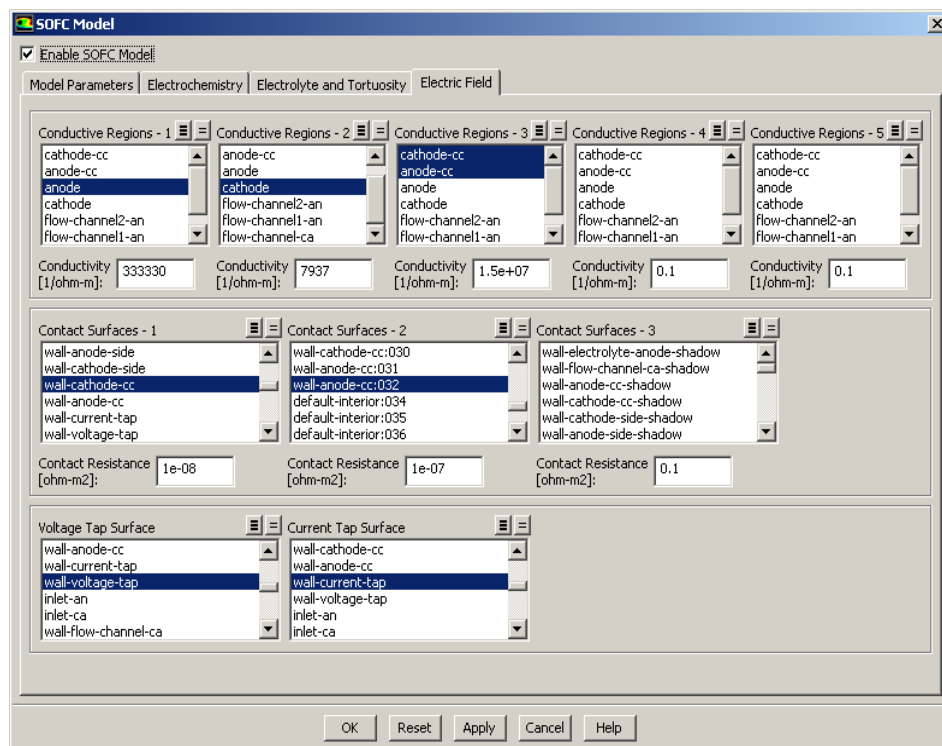

- Specify the Current Underrelaxation Factor for the solver for the given case
- Set the Total System Current or the Specified System Voltage, as per the output requirement
- Set the Leakage Current Density, Electrolyte Resistivity and the Electrolyte Thickness as per the case requirement.
- Enable the Electrolyte Conductivity Submodel, Volumetric Energy Source, Surface Energy Source, Species Sources and disable the CO Electrochemistry (for H₂ as the fuel) models in the Model Options section.

The screenshot shows the 'SOFC Model' dialog box with the 'Electrochemistry' tab selected. The 'Enable SOFC Model' checkbox is checked. The 'Constant Exchange Current Densities (Amp/m²)' section has 'Anode Exchange Current Density' set to 1e+20 and 'Cathode Exchange Current Density' set to 512. The 'Mole Fraction Reference Values (moles/moles)' section has 'H2 Reference Value' set to 1, 'H2O Reference Value' set to 1, and 'O2 Reference Value' set to 1. The 'Concentration Exponents' section has 'H2 Exponent' set to 0.5, 'H2O Exponent' set to 0.5, and 'O2 Exponent' set to 0.5. The 'Butler-Volmer Transfer Coefficients' section has 'Anodic Transfer Coefficient' and 'Cathodic Transfer Coefficient' both set to 0.5 for both the 'Anode Reaction' and 'Cathode Reaction'. The 'Temperature Dependent Exchange Current Density' section has the 'Enable Temperature Dependent I₀' checkbox unchecked, with 'A' and 'B' both set to 0. The bottom of the dialog box contains 'OK', 'Reset', 'Apply', 'Cancel', and 'Help' buttons.

- In the Electrochemistry tab, define the Exchange Current Densities, Concentration Exponents (obtained from the electrochemical reaction) and the Butler Volmer Coefficients

- Define the zones having the anode and the cathode interface and also the tortuosity values can be set for specific zones in the Electrolyte and Tortuosity tab.

- In the Electric Field tab,
 - ◆ Define upto 5 conductive zones with their conductivities
 - ◆ Define upto 3 contact surfaces with the surface resistance values
 - ◆ Specify the voltage and the current tap surfaces

Step 4: Specify the Material Properties

- Define a User-defined scalar, by changing the number of user-defined scalars to 1

Define → User-defined → Scalars

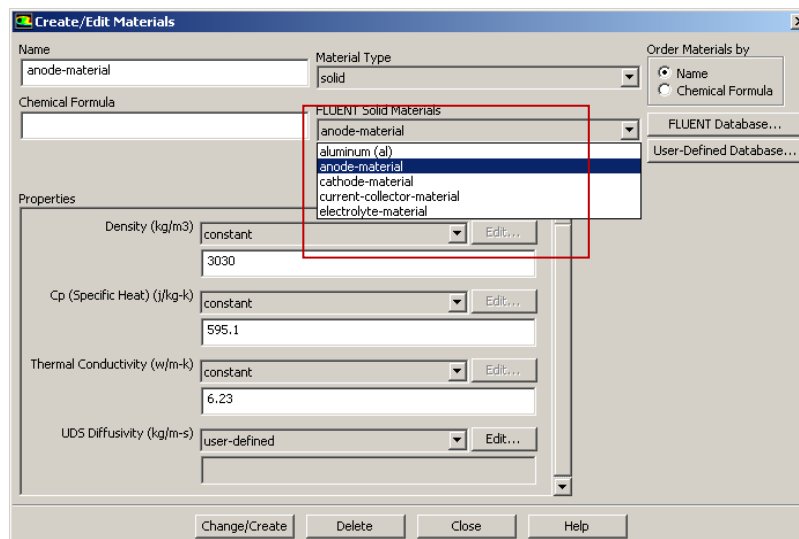

- Define 14 user-defined memory locations for storing the user-defined parameter values

Define → User-defined → Memory

- Define user-defined function hooks by changing the Adjust function to adjust_function

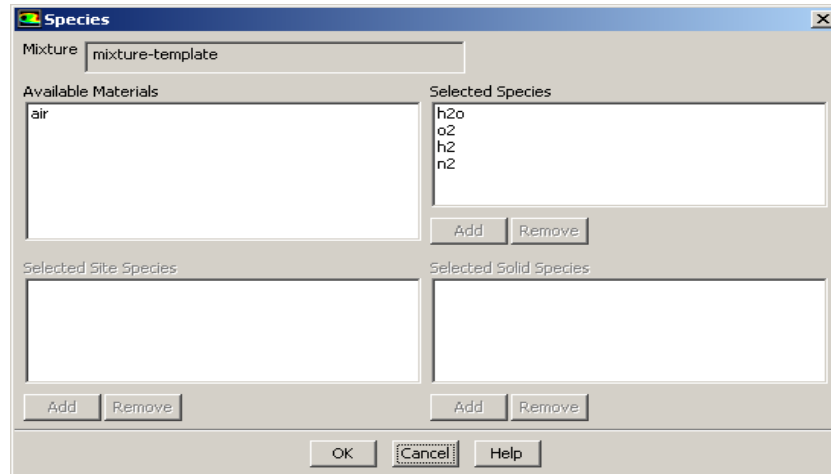

Define → User-defined → Function hooks

- Create or re-define new solid materials as appropriate for the electrodes and the electrolyte according to the problem specifications.

- Edit the mixture template by specifying the mixture species as per the case setup

1. Using H₂ as the fuel:

In the Species dialog, arrange the materials under Selected Species in the following order: h₂o, o₂, h₂, and n₂.

Materials → *Create/Edit materials* → *Mixture Species*

(Copy the properties for H₂ from the fluent database)

2. Using partially pre-reformed CH₄ as fuel:

Arrange the species in the increasing order of their specified compositions in the mixture species box.

CH₄, when used as the fuel also involves chemical reactions along with the electrochemical part. The reactions are modeled using the FLUENT solver, which needs the user to feed in the values of the parameters needed for the reaction such as the activation energies and the pre-exponential factor, which are needed for the calculation of the reaction rates.

Materials → Create/Edit → Mixture template → Reaction

The screenshot shows the 'Reactions' dialog box in FLUENT. The 'Mixture' is set to 'mixture-template' and the 'Total Number of Reactions' is 2. The reaction name is 'reaction-1' with ID 1. The reaction type is 'Volumetric'. The number of reactants is 2 and the number of products is 2. The reactants are CH₄ and H₂O, both with a stoichiometric coefficient of 1 and a rate exponent of 1. The products are CO and H₂, both with a rate exponent of 0. The Arrhenius rate parameters are: Pre-Exponential Factor = 3.6e+08, Activation Energy (j/kgmol) = 8e+07, and Temperature Exponent = 0. The Mixing Rate parameters are A = 4 and B = 0.5. There are checkboxes for 'Include Backward Reaction', 'Third-Body Efficiencies', 'Pressure-Dependent Reaction', and 'Coverage-Dependent Reaction', all of which are currently unchecked. The 'Specify...' buttons are visible next to the unchecked options. The dialog has OK, Cancel, and Help buttons at the bottom.

Change the Thermal conductivity and Viscosity to ideal-gas mixing law.

Change the Mass Diffusivity to user-defined and select diffusivity::SOFC as the user-defined function.

Change the UDS Diffusivity to user-defined and select E_Conductivity::SOFC as the user defined function.

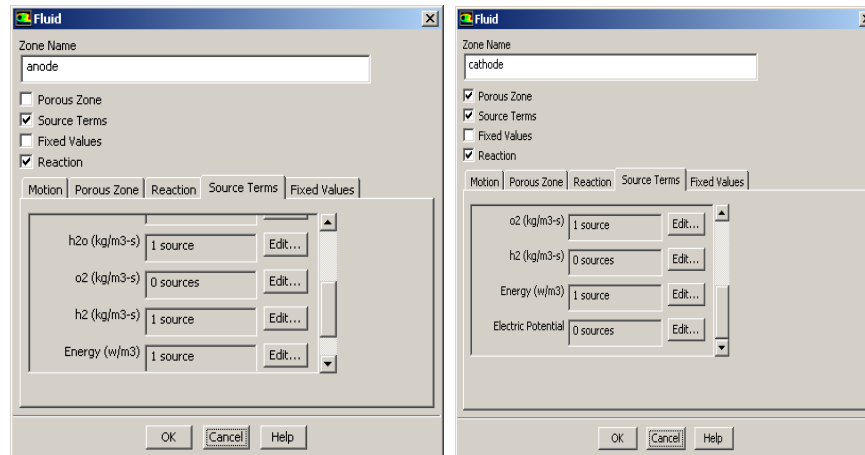

Step 5: Setting up the Operating and Boundary Conditions

- *Problem Setup* → *Cell-zone conditions* → *Operating Conditions*

- Boundary Condition specifications

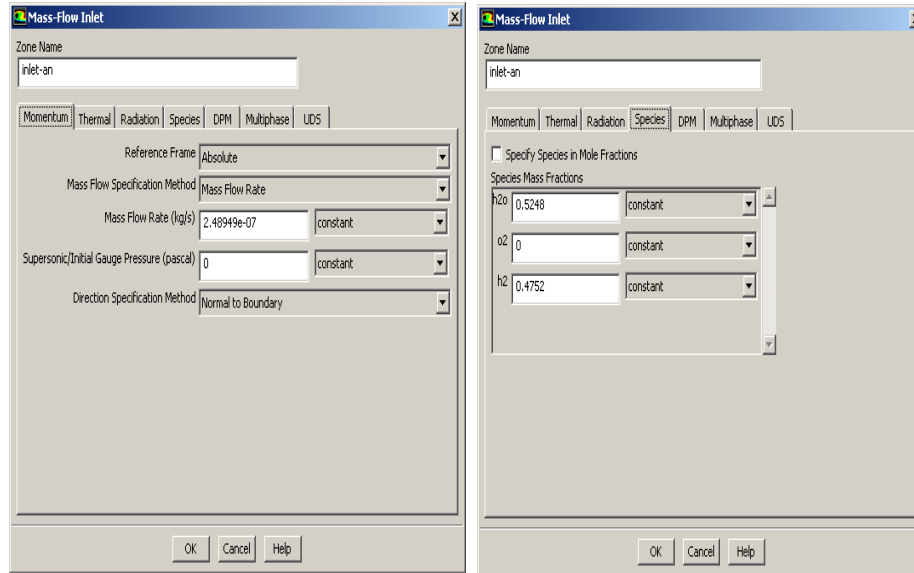

1. Using H₂ as the fuel:

The anode and the cathode properties are set as shown in the screenshot above.

The source terms are decided as per the case setup and the electrochemical reactions. The electrodes are modeled as porous zones by specifying the percent porosity of the zones.

Change the material for the current collectors to current-collector-material.

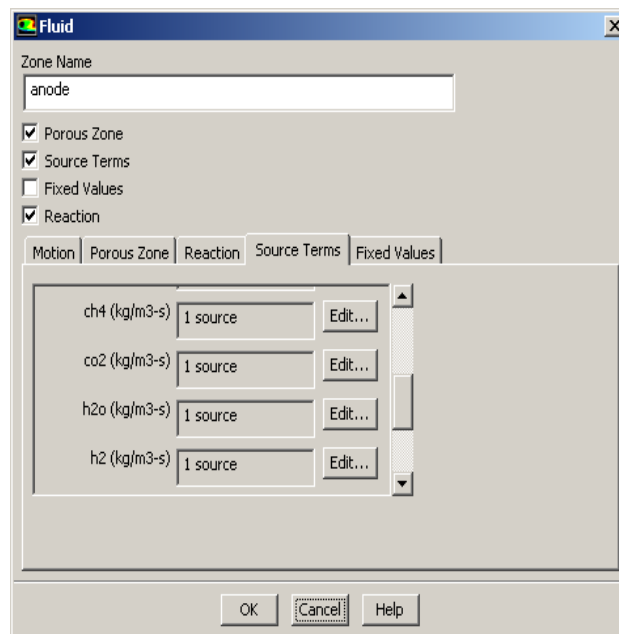

Problem Setup → *Boundary Conditions* → *inlet*

The inlet properties for the anode are specified, flow rate is calculated as per the case setup. Species composition and distribution is specified in the Species tab. Similarly the cathode inlet properties are specified.

The operating temperature can be specified in the Thermal tab.\

3. Using partially pre-reformed CH₄ as fuel:

The source terms in this case are specified for the anode and the cathode zones in a similar manner.

The inlet conditions for the anode and the cathode in this case is specified in a manner similar to the H₂ case. The mole fractions of the species at the inlet are fed in the Species tab.

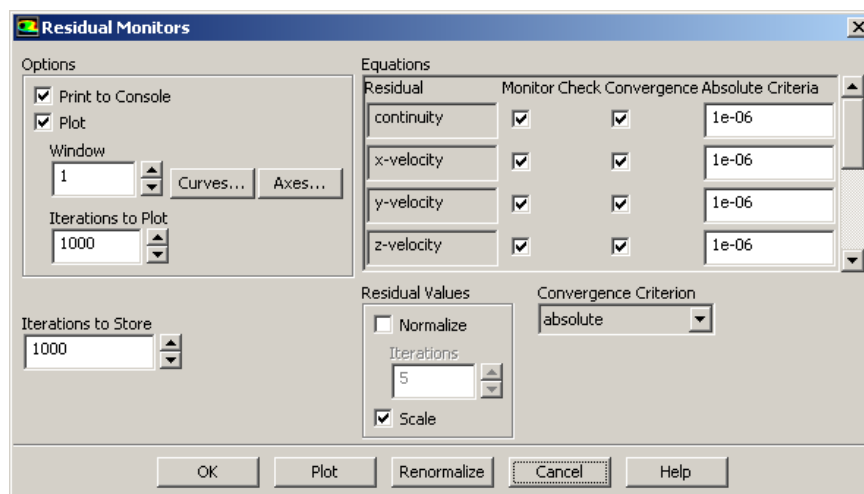

Step 6: Solution Methods and controls

Problem Setup → *Solution Methods*

- Select the SIMPLE pressure-velocity coupling scheme with a Green-Gauss Cell Based discretization method.
- Select Standard for pressure and First Order Upwind scheme for momentum, Energy and all the species for the case.
- Use the default under-relaxation factors for all parameters, unless required to be changed to rectify errors

Problem Setup → *Monitors*

- Turn on the residual monitors and set the convergence criteria as shown or as per requirement

Step 7: Initialization and simulating the model

- Initialize the flow field for all the zones.

Problem Setup → Solution Initialization → Initialize

- Run the simulation until the residuals converge.

Problem Setup → Run Calculation

Step 8: Postprocessing

- Carry out the postprocessing of the electrochemical parameters as per the chart mentioned below [29]:

UDM-0	Interface Current Density (A/m^2)
UDM-1	Nernst Potential (Volts)
UDM-2	Activation Overpotential (Volts)
UDM-3	Volumetric Ohmic Source (W/m^3)
UDM-4	x Component of the Current Density (A/m^2)
UDM-5	y Component of the Current Density (A/m^2)
UDM-6	z Component of the Current Density (A/m^2)
UDM-7	Electrolyte Voltage Jump
UDM-8	Electrolyte Resistivity (Ohm-m)
UDM-9	Effective Electric Resistance
UDM-10	Anode Activation
UDM-11	Cathode Activation
UDM-12	Electrochemical Source (W/m^3)
UDM-13	Magnitude of Current Density (A/m^2)

VITA

Sachin Laxman Puthran received his B. Tech in Mechanical Engineering from Vidyavardhini's College of Engineering and Technology affiliated to the Mumbai University, India in May 2007. Soon after that, in July 2007, he joined Jindal Drilling and Industries Ltd. as a MWD (Measurement While Drilling) Engineer. Duties included working on-field at oil drilling rigs, operating an electro-magnetic depth and direction measurement tool in directional drilling services. Later worked as an instructor at JTG Classes, teaching mathematics to secondary and higher secondary level students from November 2008 to July 2009. In August 2009, he joined the Mechanical and Aerospace Engineering Department at Missouri University of Science and Technology for the Master's in Mechanical Engineering program. He completed his M.S in Mechanical Engineering in August 2011.

He has presented a conference paper at the 5th International Energy Sustainability and Fuel Cell Conference by ASME, 2011, Washington DC. His graduate research included Computational Fluid Dynamics (CFD), simulation softwares, modeling and analysis of Solid Oxide fuel cells. Other interests include fuel cell applications, renewable energy research and fluid dynamic applications. Sachin has been a student member of ASME.
