<b>14. ABSTRACT</b> Vascular disruption agents (VDAs) have been shown to selectively destroy established tumor vasculature, which results in the ischemic death of up to 99% of tumor cells. The weakness of VDA monotherapy is that it often leaves a rim of surviving tumor cells which can then regrow and spread. The overall goal of this study (addressed in Task 2) is to enhance VDA therapy by inducing hyperthermia, targeted to the neovascular endothelium, through the use of superparamagnetic iron oxide nanoparticles (SPIONs), in order to halt, or significantly slow down tumor growth. Therefore, the first aim of this study (Task 1) is to maximize the delivery of SPIONs to the tumor rim, through a combination of neovascular targeting and increased vascular permeability induced by the VDA. Covalent coupling of a primary amine on the antibody to a carboxyl on the SPIONs activated by EDC/Sulfo-NHS resulted in colloiddally-stable particles that showed specific binding to VEGFR-2 expressing cells in vitro. Current in vivo results suggest a synergistic enhancement of SPION delivery to the tumor rim when $\alpha$ VEGFR-2 targeting of PEG-coated particles and 15 min pre-administration of DMXAA (a VDA) are employed. The results suggest that the combination of targeting the neovasculature and increasing vascular permeability through the action of the VDA is an effective SPION delivery strategy. Quantitative chemical analysis of tumor samples are ongoing to obtain statistically-significant iron quantitation. In vitro testing of SPION heating in the presence of an alternating magnetic field has been successful and demonstrates that heating is optimized using 20 nm SPIONs. However, in vivo testing of hyperthermia therapy in mice receiving targeted SPIONs after DMXAA pre-treatment is currently on hold, pending a solution to the problem of poor long-term survival of the mice after DMXAA administration.

# Novel Synergistic Therapy for Metastatic Breast Cancer: Magnetic Nanoparticle Hyperthermia of the Neovasculature Enhanced by a Vascular Disruption Agent

## Introduction

Vascular disruption agents (VDAs) have been shown to selectively destroy established tumor vasculature, which results in the ischemic death of up to 99% of tumor cells<sup>[1]</sup>. The weakness of this therapy alone is that it often leaves a rim of surviving tumor cells which can then regrow and spread<sup>[1]</sup>. *The overall goal of this study (addressed in Task 2) is to enhance VDA therapy by inducing hyperthermia, targeted to the neovascular endothelium, through the use of superparamagnetic iron oxide nanoparticles (SPIONs), in order to halt, or significantly slow down tumor growth. Therefore, the first aim of this study (Task 1) is to maximize the delivery of SPIONs to the tumor rim, through a combination of targeting and increase vascular permeability induced by the VDA.*

Targeted therapy takes advantage of biomarkers that are characteristic of the tumor environment in order to selectively treat tumor cells<sup>[2]</sup>. Angiogenesis, the process by which new blood vessels are formed, plays a crucial role in development, wound repair, and inflammation<sup>[2]</sup>. This process is exploited in cancer, and is essential for tumor growth beyond the size of about 1-2 mm in diameter<sup>[8]</sup>. The integrin receptor  $\alpha\beta3$ , which is over-expressed on the activated endothelium of tumor neovasculature, is a glycoprotein membrane receptor which recognizes ECM proteins expressing an arginine-glycine-aspartic acid (RGD) peptide sequence<sup>[3,10]</sup>. The integrin receptor  $\alpha\beta3$  is a strong potential anti-angiogenic target because it is up-regulated in both cancer cells and tumor associated blood vessels<sup>[9]</sup>. Peptide ligands containing the RGD triad display both a strong affinity, as well as selectivity to the  $\alpha\beta3$  integrin<sup>[11,19]</sup>. However, in our work, SPIONs, when bound directly to the RGD containing peptide c(RGDfK), demonstrated poor specific binding when compared to controls. Though the conjugation was shown to be successful, these results could be due to mis-orientation of c(RGDfK) on the particle surface, or steric hinderance from SPIONs at the active site for  $\alpha\beta3$  integrin. To target  $\alpha\beta3$ , SPIONs were first conjugated to a small molecule ligand, cyclic RGD, c(RGDfK).

Observed functional inactivity of the RGD-conjugated particles led to the replacement of the c(RGDfK) ligand with an antibody against vascular endothelial growth factor receptor 2 ( $\alpha$ VEGFR-2). An antibody against VEGFR-2 was selected to replace the c(RGDfK) conjugate because of the role of VEGFR-2 over-activation in angiogenesis<sup>[2]</sup>. VEGFR-2 is a receptor tyrosine kinase expressed primarily at the surface of endothelial cells, which is auto-phosphorylated through stimulation by circulating VEGF-A to induce endothelial proliferation<sup>[4]</sup>. High levels of tumor VEGF-A production, shown to up-regulate VEGFR-2 gene expression, correlates with the over-expression of VEGFR-2 at the tumor vasculature<sup>[4]</sup>.  $\alpha$ VEGFR-2 targeted contrast agents have been shown to correlate with the relative expression of VEGFR-2 and the vascular phenotype of tumors in mouse models, demonstrating the effectiveness of this modality<sup>[12]</sup>.

The cross-reactivity of  $\alpha$ VEGFR-2 in both mice and humans was also an important intention in our selection of the antibody clone, because the MDA-MB-231 xenograft tumor cells are human derived, whereas the host for the tumor is a NOD SCID mouse. Therefore the tumor will consist of human breast cancer cells, and the vasculature will consist of mouse endothelial cells. Thus a clone that reacts with both mouse and human VEGFR-2 was chosen. Further, the activity of  $\alpha$ VEGFR-2 targeted SPIONs was tested in vitro on human umbilical vein endothelial cells (HUVEC), so the ability to use an antibody with a similar affinity for human and mouse VEGFR-2 simplified the determination of whether the SPION conjugation was successful. The functionalization of  $\alpha$ VEGFR-2-conjugated SPIONs was successfully demonstrated by their specific association with the cell surface of human umbilical vein endothelial cells (HUVEC) when compared to a non-specific Immunoglobulin G (IgG)-conjugated SPION control.

In addition to targeting, we hypothesize that VDAs may co-facilitate SPION delivery to the tumor rim. The initial changes at the active tumor endothelium which are induced by VDAs include the reorganization of the cytoskeletal network and the alteration of the junctions between endothelial cells<sup>[13]</sup>. This response is generally rapid (within 1 h), and results in the enhanced permeability of the endothelium<sup>[13]</sup>. Downstream

effects triggered by VDAs further lead to the induction of tumor hemorrhagic necrosis[14], and the ischemic death of up to 99% of tumor cells[1]. In order to demonstrate the enhanced endothelial permeability effects on SPION delivery to tumors, subcutaneous xenograft breast tumor-bearing mice were first treated with DMXAA (5,6-dimethylxanthenone-4-acetic acid), a low-molecular-weight VDA. The delay between DMXAA administration and the injection of the  $\alpha$ VEGFR-2 SPIONs that maximizes the SPION concentration in the viable tumor rim was determined by the time variable delivery (15 min, 30 min, or 60 min) of  $\alpha$ VEGFR-2 conjugated SPIONs following VDA administration.

Our current results suggest that VDAs appear to enhance the delivery of  $\alpha$ VEGFR-2-conjugated SPIONs to the tumor rim, by promoting increased permeability of neovascular endothelial cells<sup>[4]</sup>. To demonstrate VDA enhanced delivery, NOD SCID mice were induced with two subcutaneous xenograft MDA-MB-231 breast tumors. The first group of mice was treated with either  $\alpha$ VEGFR-2-conjugated SPIONs, IgG-conjugated SPIONs, or unconjugated SPIONs (PEG only) both without VDA treatment. A second group is currently being assessed under time variable delivery of  $\alpha$ VEGFR-2-conjugated SPIONs, IgG-conjugated SPIONs, or unconjugated SPIONs (PEG only) following VDA treatment. The effects of these treatments are observed qualitatively through Prussian blue histology in order to determine the conditions for maximum SPION delivery to the tumor rim.

Following the determination of optimal SPION tumor delivery, targeted hyperthermia will be induced in tumors by exposing the SPIONs to an alternating magnetic field (AMF). When exposed to an AMF, SPIONs generate heat as a result of hysteresis and relaxational losses, which results in the heating of tissue in which SPIONs accumulate[5]. At high enough concentrations, this heating can be effective at delivering localized hyperthermia to tumor cells [6]. The degree to which magnetic hyperthermia can be applied to cancer then depends on the ability to deliver SPIONs systematically to tumor cells at sufficient amounts of about 1-5 pg per cell, as demonstrated by Marcos-Campos et al[7].

## Body

### Materials and Methods

#### *SPION Surface Functionalization*

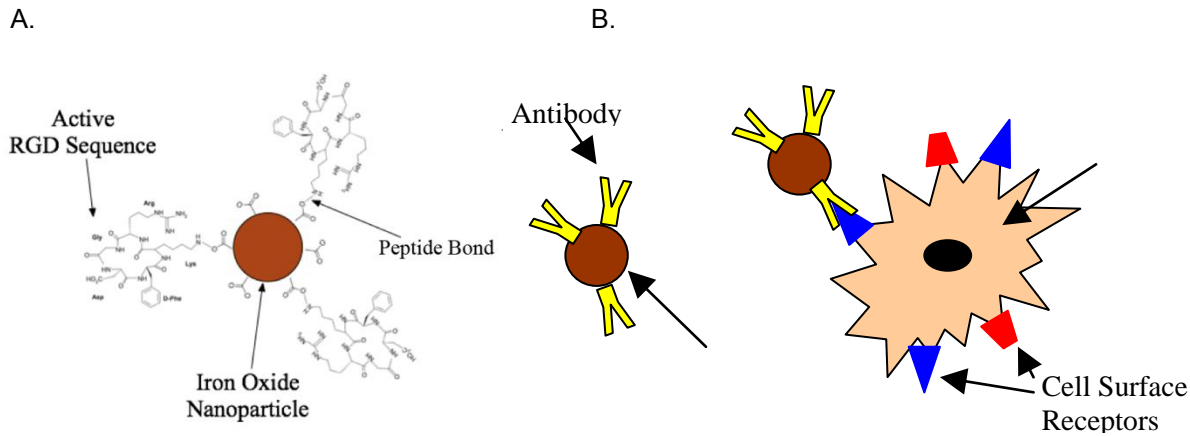

The conjugation of c(RGDfK) peptide to 15 nm carboxyl functionalized SPIONs was performed using a covalent link with the amine group of the peptide and the carboxyl group of the SPIONs using the Ocean NanoTech Carboxyl Magnetic Iron Oxide Nanocrystals Conjugation Kit. First, 0.2 mL of SPIONs (5 mg Fe/mL) were activated by incubating with a molar ratio 2000:1 of sulfo-N-hydroxysuccinimide and 1-ethyl-3, 3-dimethylaminopropyl carbodiimide hydrochloride (EDAC) for 20 min in a borate buffered solution, pH 5.5, after which the pH was adjusted to 8.0. The protein (0.2 mg) was added immediately, mixed well, and incubated for 2 h at room temperature. The resulting nanocrystal conjugates were purified by centrifugation at 18350 RCF (12800 RPM) twice for 1 h each, and stored in 1 mL borate buffered solution, pH 7.4.

This method was repeated using 0.2 mg c(RADfK) peptide as a negative control. In order to separate the RGD binding sequence further from the particle surface as a way to overcome steric hinderance, this method was repeated for 0.2 mg c(RGDfK)(PEG-PEG) peptide. This RGD analog contains two PEG derivatives (8-amino-3,6-dioxaoctanoic acids) that act as spacers between ligand and lipid head groups, to allow for more efficient binding[20]. For these experiments c(RADfK(PEG-PEG)) was conjugated by the same methods as a negative control.

For antibody conjugated SPIONs, these methods were repeated using 0.02 mg polyclonal  $\alpha$ VEGFR-2. As a negative control, 0.02 mg of polyclonal normal mouse immunoglobulin G (IgG) was conjugated to SPIONs, also by the same methods.

In order to improve SPION circulation time for more effective tumor delivery in vivo, these methods were repeated for 0.02 mg polyclonal  $\alpha$ VEGFR-2, as well as 0.02 mg IgG using particles which were functionalized with a PEG-Carboxyl coating. The polymeric PEG coating acts to further stabilize the particles, and has been shown to increase the blood half-life of particles in vivo by up to 5 fold [15].

### Conjugated SPION Quantification

Stock 15 nm carboxyl functionalized SPIONs were diluted from a concentration of 5 mg Fe/mL to three individual cuvettes at 0.04 mg/mL, 0.02 mg/mL, and 0.01 mg/mL in di-H<sub>2</sub>O. A full spectrum absorbance of each solution was generated using a Beckman Coulter DU 800 UV/Vis Spectrophotometer. To generate a standard curve, the absorbances at 350 nm for these particle solutions were plotted as a function of SPION concentration. Conjugated SPIONs (with unknown concentrations) were each diluted 1:500 in di-H<sub>2</sub>O, and their concentrations were determined by plotting individual absorbances at 350 nm on the standard curve.

Because the carboxylic acid functional groups of SPIONs are strongly anionic when free, compared to when conjugated to protein, they freely form carboxylate salts with metal cations. If the surface charge is providing colloidal stabilization (i.e., the repulsion of like surface charges prevents the particles from aggregating), this shielding of the surface charge by ions can lead to aggregation and the precipitation of SPIONs in ionic solutions. To determine successful conjugation, 0.1 mg of SPIONs were mixed with 0.4 mL of serum free Dulbecco's Modified Eagle Medium:Nutrient Mixture F-12 (DMEM/F-12), which contains divalent cations for the purpose of cell culture. Visual inspection of the solution to look for particle stability was then compared 1 h after mixing in order to determine successful conjugation. Differences in this form of colloidal stability between un-conjugated and conjugated SPIONs imply that the surface modification was successful.

### Cell Culture Conditions

HUVEC line was cultured at 37° C under a humidified atmosphere of 5% CO<sub>2</sub> and 95% air in MCDB-131 complete medium with fetal bovine serum and antibiotics (VEC Technologies) on gelatin coated surface. SK-OV-3 ovarian adenocarcinoma cell line was cultured at 37° C under a humidified atmosphere of 5% CO<sub>2</sub> and 95% air in McCoy's 5A medium supplemented with 10% fetal bovine serum (FBS), 1% glutamax, and 1% penicillin:streptomycin. MDA-MB-231 and MDA-MB-435 mammary gland adenocarcinoma cell lines were cultured at 37° C under a humidified atmosphere of 5% CO<sub>2</sub> and 95% air in DMEM/F-12 supplemented with 10% fetal bovine serum (FBS), 1% glutamax, and 1% penicillin:streptomycin.

### Conjugated SPION Cell Targeting

Cultured cells were divided into 4x6 well plates over poly-L-lysine coated cover slips at a concentration of 1x10<sup>5</sup> cells per well, and cultured overnight. The optimum SPION concentration for short-term cell targeting in culture was determined by preparing 2.5 mM incremental solutions within the range of 0 mM to 15 mM of c(RGDfK) conjugated SPIONs in serum free DMEM/F-12 media. Time dependence for the receptor mediated

endocytosis of particles was then determined by incubating cultured cells with each solution in 15 min increments up to an hour at 37° C. All SPION incubations which followed were carried out with a 10mM solution of conjugated SPIONs in serum free culture media for 30 min. Adherent cells were washed with PBS, and fixed using 4% paraformaldehyde (PFA) in PBS buffer solution for 15 min. Fixed cells were then washed twice with PBS.

These conditions were repeated for  $\alpha$ V $\beta$ 3 targeting using c(RADfK) conjugated SPIONs as a control. Conditions were also repeated using c(RGDfK)(PEG-PEG) conjugated SPIONs and c(RADfK)(PEG-PEG) conjugated SPIONs as a negative control. Finally, for VEGFR-2 targeting, these conditions were repeated using  $\alpha$ VEGFR-2 conjugated SPIONs and IgG conjugated SPIONs as a control.

### *SPION Staining*

Prussian blue is produced by mineral acid hydrolysis to release ferric ions, which then form a dark blue precipitate in the presence of ferrocyanide ions by the following reactions[21]:

This staining method was performed on fixed cells by incubating with equal parts 10% potassium ferrocyanide and 20% hydrochloric acid for 20 min. Cells were washed 3 times with di-H<sub>2</sub>O and counterstained with nuclear fast red for 5 min. Stained cells were washed again 2 times with di-H<sub>2</sub>O and mounted using VECTASHIELD mounting medium with DAPI.

The presence of antibody conjugated SPIONs was also detected using a secondary, fluorescent antibody. This was performed by first incubating fixed cells with blocking serum (3% normal goat serum) for 30 min with continuous mixing. Cells were then washed twice with PBS and incubated with a 1:250 solution of secondary antibody (rabbit  $\alpha$  mouse 488) in PBS for 30 min with continuous mixing. Labeled cells were washed with PBS and mounted using VECTASHIELD mounting medium with DAPI. For each secondary antibody labeled experiment, a negative control was used which did not receive particle or antibody treatment.

### *Conjugated SPION Murine Tumor Delivery*

Female NOD-SCID mice were bred at the University of New Mexico Animal Resource Facility. All mouse procedures were performed according to a protocol approved by the University of New Mexico Health Sciences IACUC. Prior to injection, MDA-MB 231 cells were collected and suspended with 50% MatriGel in DMEM/F-12 media and kept on ice. Two million cells were injected into each of the inguinal mammary fat pads of the NOD-SCID mice at 6-8 weeks of age. Tumor development was monitored weekly until the outer diameter reached about 10 mm in size.

On the day of injection, a total of 0.250 mg of SPIONs were re-suspended in 0.1 ml PBS and given to mice retro-orbitally. Tumors were collected either 2 or 5 h following the injection. Tissues were then fixed in 4% paraformaldehyde in PBS buffer solution overnight, and embedded in paraffin for sections. Tissue sections were deparaffinized and hydrated to water, stained using Prussian blue histology, dehydrated, cleared in xylene, and mounted in Permount.

For VDA treated mice, DMXAA was dissolved in 10% DMSO/PBS and given to mice by intraperitoneal injection at a dose of 25 mg/kg, which is typical for other mouse studies[22].

Mice were initially given a treatment of  $\alpha$ VEGFR-2 or IgG conjugated to 15 nm Carboxyl SPIONs (no PEG) without VDA. A second group was treated with  $\alpha$ VEGFR-2 or IgG conjugated to 15 nm PEG-Carboxyl SPIONs without VDA. A third group was treated with  $\alpha$ VEGFR-2 or IgG conjugated to 15 nm PEG-Carboxyl SPIONs at 15 min, 30 min or 60 min following VDA.

Table 1. Mouse experiments performed to date.

SPION prep	No VDA	Vehicle	15m	30m	60m
VEGFR-2	7	4	4	2	-
IgG	7	-	4	-	-
PEG	5	-	3	2	-
PEG-Carboxyl	1	-	-	2	2
PBS - None	4	-	-	-	-
		Total	47		

Figure 2:

(A) Un-conjugated carboxyl-SPIONs in serum free DMEM/F-12 show significant aggregation after 1 h. Because the carboxylic acid functional groups of SPIONs are strongly anionic when un-conjugated to protein, they freely form carboxylate salts with metal cations. This shielding reduces repulsive electrostatic interactions and leads to the precipitation of un-conjugated SPIONs in culture media, which contains divalent cations for the purpose of cell culture.

(B)  $\alpha$ VEGFR-2 conjugated SPIONs in serum free DMEM/F-12 show reduced aggregation after 1 h. The peptide bond which is formed by the conjugation reaction replaces free carboxylic acid groups with a protein, which sterically stabilize the particles in solutions containing divalent cations. This result indicates that the SPION surface was successfully modified. This image is representative of each conjugation of antibody/peptide with carboxyl-SPIONs.

## Results

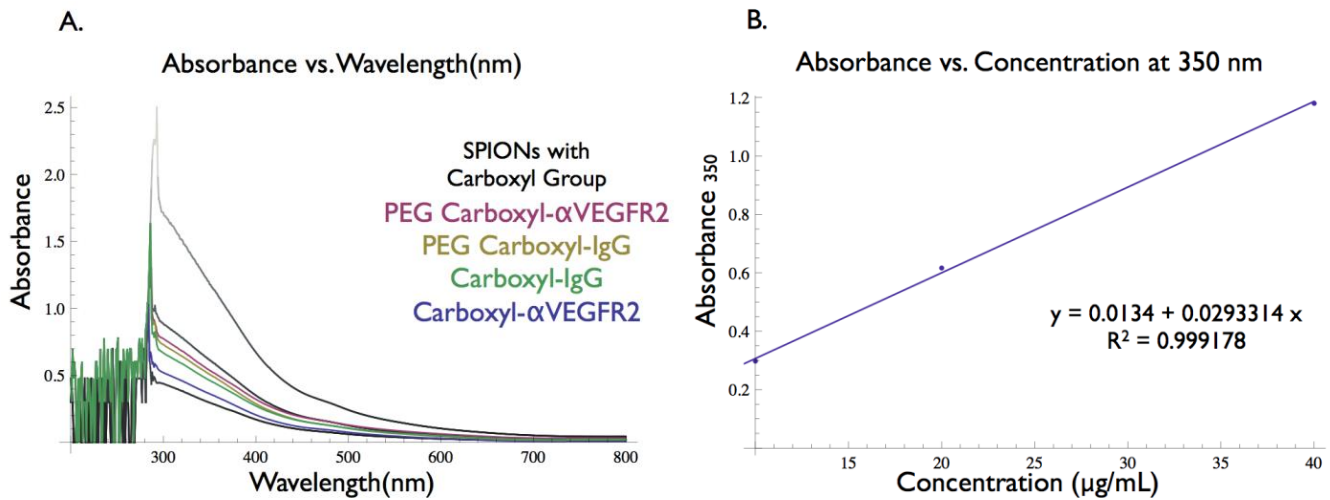

### *SPION Surface Conjugation*

A cross-linking reaction with carboxyl functionalized SPIONs using EDAC as an activating agent to couple the carboxyl groups on particles to amino-terminal groups on the antibody or peptides yielded particles with functional biocompatibility. Carboxyl-SPIONs conjugated with protein exhibited greater colloidal stability at biological pH, salinity, and temperature conditions compared to un-conjugated SPIONs, which formed a precipitate in culture medium (Figure 2). The addition of protein apparently provided steric stabilization, i.e. the protein provided a spacer that prevented particles from getting close enough together to aggregate due to attractive VanderWaals interactions. Because PEG-Carboxyl particles show native stability in biological pH, salinity, and temperature conditions prior to conjugation, no difference in solubility was observed following conjugation for PEG-Carboxyl particles. The PEG molecules provided steric stabilization, such that further

addition of protein does not increase the stability. SPIONs conjugated with  $\alpha$ VEGFR-2 antibody were effectively labeled with a secondary fluorescent antibody (rabbit  $\alpha$  mouse 488). Furthermore,  $\alpha$ VEGFR-2 conjugated showed a high level of binding to HUVECs (which express high levels of VEGFR-2) compared to an IgG conjugated SPION control, which showed a low level of binding (Figure 6). The absorbances of known concentrations of a standard (stock carboxyl-SPIONs) were measured at 350 nm, which was used to determine the concentrations of conjugated SPION solutions (Figure 3).

Figure 3:

C.

Particle Type	Estimated Concentration	Measured Concentration	Percent Yield
C-VEGFR2	1 mg/ml	0.595 mg/ml	59.5%
PC-VEGFR2	1 mg/ml	0.896 mg/ml	89.6%
C-IgG	1 mg/ml	0.843 mg/ml	84.3%
PC-IgG	1 mg/ml	0.767 mg/ml	76.7%

(A) Full Spectrum absorption for each stock SPION dilution (black), as well as for each conjugated-SPION dilution.

(B) Standard best fit of absorbances at 350 nm for stock SPION dilutions, used to determine (C) yield from each conjugation.

### $\beta$ 3 Immunohistochemistry (IHC)

IHC was carried out to show the relative expression of  $\alpha$ V $\beta$ 3 integrin in cells. HUVEC, MDA-MB-231, and MDA-MB-435 cell lines were also included along with SK-OV-3 cells as a positive control, as well as to correlate the relative presence of  $\alpha$ V $\beta$ 3 with c(RGDfK) conjugated SPION activity. For this experiment, adherent cells were first lifted using EDTA, and suspended during incubations in order to view  $\alpha$ V $\beta$ 3 presence on all sides, including adherent portions of the cell surface. A polyclonal  $\beta$ 3 antibody containing an RGD sequence was used to label cells. This staining was successful in all cell types, with the greatest overall presence of  $\alpha$ V $\beta$ 3 integrin shown in SK-OV-3 (Figure 4A) and MDA-MB-231 (Figure 4B) cell lines.

Figure 4:

A.

(A)  $\beta 3$  - IHC for SK-OV-3 Cells 64x

B.

(B)  $\beta 3$  - IHC for MDA-MB-231 Cells 64x

Figure 5:

A.

(A) SK-OV-3 cells 32x.  
SPIONs covalently conjugated to c(RGDfK),  
which selectively binds to  $\alpha V\beta 3$ .

B.

(B) SK-OV-3 Cells 32x.  
SPIONs covalently conjugated to c(RADfK),  
which does not bind  $\alpha V\beta 3$  as a negative control.

Particles are visible in blue, and Nuclei in red following prussian blue histology. The lack of difference between the c(RGDfK) conjugated, and c(RADfK) conjugated control SPIONs suggests that only non-specific binding occurs.

#### *c(RGDfK)(PEG-PEG)-SPION Incubation*

Accounting for possible steric hindrance from particles being too closely associated with RGD peptide, SPIONs were conjugated with c(RGDfK)(PEG-PEG) peptide. This analog contains two mini-PEG derivatives (8-amino-3,6-dioxaoctanoic acids) that act as spacers between the ligand and the particle surface to allow for more efficient binding<sup>[20]</sup>. For this experiment, HUVEC, MDA-MB-231, and MDA-MB-435 cell lines were included along with SK-OV-3 cells to correlate the relative presence of  $\alpha V\beta 3$  with functionalized SPION activity. Particle internalization was again generally minimal, with no observable difference between cell types or conjugates. This again suggests that only non-specific binding occurs for c(RGDfK)(PEG-PEG) conjugated SPIONs.

#### *$\alpha$ VEGFR-2 Conjugated SPIONs*

HUVECs, having the highest confirmed expression of VEGFR-2 from IHC, were used for particle incubations with  $\alpha$ VEGFR-2 conjugated SPIONs, and with IgG conjugated SPIONs as a negative control. After incubations, cells were fixed, incubated with a blocking agent, and lastly incubated with secondary antibody to reveal

labeled particles attached at the cells surface.  $\alpha$ VEGFR-2 conjugated SPIONs (Figure 5A) demonstrated effective functionalization, binding around the cell surface at high concentrations, while IgG conjugated SPIONs (Figure 5B) were only found minimally associated with cells.

Figure 6:

A.

(A) HUVEC cells 64x.  
 $\alpha$ VEGFR-2 Conjugated SPIONs demonstrated specific binding at high concentrations.

B.

(B) HUVEC cells 64x.  
IgG Conjugated SPIONs showed some association with the cell surface, representative of non-specific binding.

SPIONs are visible in green (2° AB - 488 nm), and nuclei in blue (DAPI - 358 nm).

Figure 7:

A.

(A) HUVEC cells 64x.  
 $\alpha$ VEGFR-2 Conjugated to PEG-Carboxyl SPIONs demonstrated specific binding. This overall binding was reduced however when compared to carboxyl-SPIONs conjugated to  $\alpha$ VEGFR-2 (Figure 6A).

B.

(B) HUVEC cells 64x.  
IgG Conjugated to PEG-Carboxyl SPIONs showed very minimal association with the cell surface, representative of a very low level of non-specific binding.

SPIONs are visible in green (2° AB - 488 nm), and nuclei in blue (DAPI - 358 nm).

#### *Conjugated SPION Murine Tumor Delivery*

When injected with carboxyl-SPIONs which were conjugated to  $\alpha$ VEGFR-2, particles were apparently quickly cleared, with no tumor delivery observed. Carboxyl-SPIONs were then replaced by particles with a PEG-Carboxyl surface functionalization. The polymeric PEG coating acts to improve the stability of particles, and has been shown to increase the blood half-life of particles in vivo by up to 5 fold<sup>[15]</sup>. These particles show

sustained stability in biological conditions, but also demonstrate reduced binding to HUVECs (Figure 7A) compared to VEGFR-2 conjugated particles without PEG (Figure 6A). However, the addition of PEG has the benefit of reducing non-specific binding of IgG-conjugated particles (the negative control condition) to HUVECs (comparing Figure 6B to Figure 7B). When injected alone, a small degree of  $\alpha$ VEGFR-2-SPION localization at the tumor rim was observed (Figure 8B). Delivery was qualitatively increased when the particles were injected at 15 min following VDA treatment (Figure 8A). Tumor delivery was reduced however when  $\alpha$ VEGFR-2-SPIONs were injected 30 min following VDA treatment.

Figure 8:

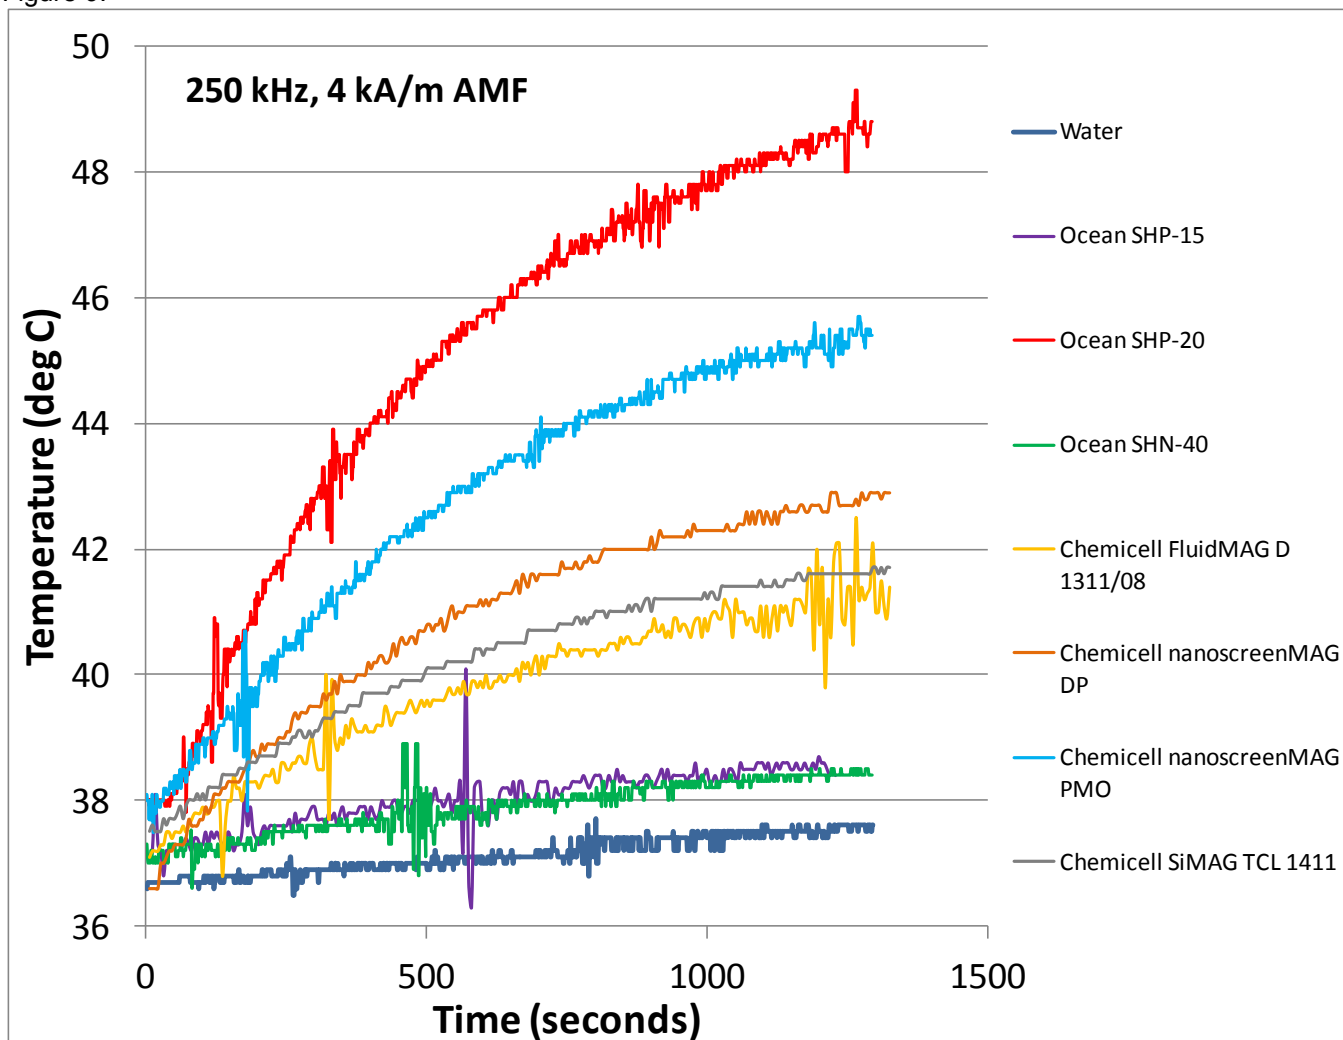

(A) Mouse tumor section at 20x.  $\alpha$ VEGFR-2 conjugated SPIONs 15 min following VDA treatment show enhanced particle delivery to the tumor rim.

(B) Mouse tumor section at 20x.  $\alpha$ VEGFR-2 conjugated SPIONs without VDA treatment show some particle delivery to the tumor rim when given alone.

### SPION heating under Alternating Magnetic Field Conditions

In preparation for in vivo testing of hyperthermia therapy (Task 2), SPIONs in aqueous solution were exposed to a biocompatible alternating magnetic field (AMF), i.e. using a field strength and frequency safe for normal tissue. The sample chamber was maintained at a background temperature of 37 deg. C, suitable for future in vivo testing. A sample containing only water (no nanoparticles) showed a temperature rise <1 deg C after 20 minutes, which demonstrates that the AMF conditions are safe for normal tissues. Ocean SHP-20 SPIONs yielded the greatest heating capacity and will be used in future in vivo studies of hyperthermia therapy.

Figure 9:

Sample temperature (deg C) vs. Time (seconds) for various types of SPIONs in water. The AMF conditions (frequency = 250 kHz, field amplitude = 4 kA/m) are safe for normal tissue, but produce significant heating in the presence of Ocean SHP-20 SPIONs.

### Discussion

When compared to unconjugated carboxyl functionalized SPIONs, c(RGDfK)-conjugated carboxyl SPIONs show greater colloidal stability at physiological pH and salinity, indicating a successful conjugation. In vitro, these SPION conjugates were, however, ineffective at targeting cell types shown by IHC to highly express the receptor for the RGD ligand ( $\alpha v \beta 3$  integrin). This could be due to the misorientation of c(RGDfK) following the conjugation, steric hindrance from the overcrowding of peptide on the particle surface, or possibly due to the steric hindrance of ligand/receptor interaction from particles themselves. Attempts to reduce steric hindrance using a c(RGDfK) peptide with a PEG linker (to extend the distance between the RGD and the nanoparticle surface) were also unsuccessful.

When conjugated to  $\alpha$ VEGFR-2 antibody, SPIONs demonstrated effective in vitro targeting of VEGFR-2 expressing human epithelial cells. The antibody clone chosen has also been shown to react with mouse VEGFR-2. While this model was effective for cell targeting under culture conditions, tumor models provide additional obstacles to overcome for SPION delivery. Initial injections of SPIONs in tumor bearing mice resulted in the apparently rapid clearance of particles (particles observed in liver, spleen, and to a small extent, lung), with no tumor delivery. In order to improve SPION circulation time for more effective tumor delivery, carboxyl-SPIONs were replaced by particles which were functionalized with both a PEG and carboxyl coating. The added stability of including PEG on the surface of  $\alpha$ VEGFR-2-SPIONs coincided with a reduction in binding to HUVECs in vitro, but also a desirable reduction in non-specific binding of IgG-SPIONs to HUVECs. The reduced binding of  $\alpha$ VEGFR-2-SPIONs to HUVECs is presumed to be due to a reduction of the conjugation efficiency of  $\alpha$ VEGFR-2 to SPIONs, because the presence of PEG reduces the number of carboxyl sites on the particle surface. These particles did, however, demonstrate a modest level of delivery to the tumor rim when injected alone into mice (i.e. without the addition of VDA). Thus the addition of PEG appears to be beneficial for in vivo delivery of these particles.

The initial VDA response, which results in the alteration of the junctions between endothelial cells,<sup>[13]</sup> appears to increase the delivery of  $\alpha$ VEGFR-2-conjugated SPIONs to the tumor rim when the particles were injected 15 min after DMXAA. A lower level of delivery was observed from IgG-conjugated SPIONs under the same VDA conditions. Overall, the combination of VEGFR-2 targeting and 15 min. pre-administration of VDA appears to act synergistically to increase SPION delivery to the tumor rim. These results, which have been assessed qualitatively using Prussian blue histology, are currently being assessed quantitatively using inductively-coupled plasma mass spectroscopy of tumor.

Further changes in neovascular permeability in response to VDAs, which include the induction of endothelial apoptosis<sup>[16]</sup>, blood vessel rupture, and a boost of  $N_2O$ <sup>[17]</sup> all occur after about 12-24 h. These events could potentially have similar benefits to the delivery of SPIONs, and will be investigated in ongoing studies. The heating which can be achieved by exposing SPIONs to an AMF is shown to be linearly proportional to particle concentration<sup>[6]</sup>, indicating that effectiveness is directly proportional to delivery. Thus our demonstration that combining the targeted  $\alpha$ VEGFR-2 conjugated SPIONs with VDA mediated vascular permeability increases particle delivery is an important first step in developing this therapy.

## Problems Encountered

### Task 1.

- The preparation of neovascular-targeted SPIONs proceeded more slowly than initially anticipated, but the initial problems with lack of neovascular binding specificity were eventually solved.
- SQUID magnetorelaxometry, although sufficiently sensitive to detect intratumorally injected SPIONs [23], has not been able to achieve the sensitivity required to monitor targeted SPION uptake in tumors after systemic i.v. delivery. We had hoped that the SPION concentrations after VDA therapy might be high enough to enable in vivo monitoring by SQUID magnetorelaxometry, but so far the concentration is too low. Thus, in vivo SQUID magnetorelaxometry was not pursued for these studies, and instead inductively-coupled plasma mass spectrometry (ICP-MS) of iron, which is a much more sensitive technique, is being used to quantitatively assess tumor iron content in fixed tissue samples.
- In vivo testing has been slowed by an as yet undiagnosed illness in the mouse colony, resulting in the death of some mice after DMXAA treatment several hours after DMXAA administration. The deaths are difficult to understand in light of the fact that this drug has been successfully administered to mice in many previous experiments,[24-28] and we are using a dose typical of previous studies, and much less than the maximum tolerable doses reported previously. Recently 6 of our NOD SCID tumor-bearing mice were administered DMXAA, and 2 died within 3 hours – the mice that died were observed to have grossly enlarged spleens, indicating an underlying illness that was not obvious during routine daily

observation. The mice from that group that survived DMXAA treatment were observed to have normalized spleens. A previous attempt at administering DMXAA and waiting 12 hrs to administer SPIONs resulted in both mice dying prior to nanoparticle administration. We are currently in the process of diagnosing this problem.

## **Task 2.**

- Until the problem with the long-term survival of mice receiving DMXAA is solved (through diagnosis of the pathology leading to the enlarged spleens, and/ or adjustment of the dose or vehicle, and/or breeding a new mouse colony), the in vivo testing described in Aim 2, which requires long term survival after DMXAA administration, is on hold. Determining the cause of poor survival after DMXAA administration is currently our top priority to enable progress on Task 2.

## **Key Research Accomplishments**

- production of functional  $\alpha$ VEGFR-2-conjugated PEG-coated iron oxide nanoparticles, with binding specificity verified in vitro
- synergistic enhancement of SPION delivery when  $\alpha$ VEGFR-2-conjugated PEG-coated SPIONs are administered following 15 min. DMXAA pre-treatment, demonstrated by:
  - greater in vivo delivery of  $\alpha$ VEGFR-2-conjugated PEG-coated SPIONs relative to  $\alpha$ VEGFR-2-conjugated SPIONs (no PEG)
  - greater in vivo delivery of  $\alpha$ VEGFR-2-conjugated PEG-coated SPIONs when administered 15 min. after VDA injection, relative to  $\alpha$ VEGFR-2-conjugated PEG-coated SPIONs alone (no DMXAA)
  - greater in vivo delivery of  $\alpha$ VEGFR-2-conjugated PEG-coated SPIONs administered 15 min. after DMXAA injection, relative to IgG-conjugated PEG-coated SPIONs or PEG-coated SPIONs (no antibody)

## **Reportable Outcomes**

- Eric Joseph, an undergraduate Biochemistry Honors student, presented the work he did on this project at Biochemistry Research Day (April 28, 2012, University of New Mexico). Upon graduation in May 2012, Eric received a Bachelors of Science with Magna Cum Laude Honors in Biochemistry and received the Lofffield Research Award, the most prestigious student research prize awarded by our department.
- Based on his experience working on this project, Eric Joseph, B.S., was hired in June 2012 as a Research Technician II at the Oregon Health Sciences University (from a pool of more than 100 applicants). This fall, Eric plans to apply to the Ph.D. program at OHSU. Eric has indicated that he would not have considered a career as a scientific researcher prior to working on this project.
- Natalie Adolphi (PI) applied for and received a UNM Cancer Center pilot award (\$5k) to pursue radioimaging of monocyte infiltration of tumors, based in part on micrographs showing infiltration of monocytes that had ingested SPIONs in vivo, obtained during these studies. Additionally, Helen Hathaway (Co-I) applied for and received UNM Research Allocation committee funds (\$25k) to study delivery of SPIONs to tumors using monocyte adoptive transfer.

## Conclusions

### Task 1.

- Significant progress on Task 1 has been achieved, with current in vivo results suggesting synergistic enhancement of SPION delivery to the tumor rim when  $\alpha$ VEGFR-2 targeting of PEG-coated particles and 15 min pre-administration of DMXAA are employed. Thus the combination of targeting the neovasculature and increasing vascular permeability through the action of the VDA appears to be an effective SPION delivery strategy. Additional in vivo experiments (to improve statistics) and quantitative chemical analysis of existing tissue samples are ongoing with the goal of bolstering these conclusions with statistically-significant iron quantitation.
- We note that the conjugation chemistry that proved successful was covalent coupling of a primary amine on the antibody to a carboxyl on the SPIONs activated by EDC/Sulfo-NHS. Strategies that were attempted but abandoned included SATA coupling of RGD to SPIONs (originally proposed in Task 1), carboxyl/EDC coupling of RGD to SPIONs, carboxyl/EDC coupling of RGD with a PEG spacer to SPIONs – these strategies were deemed unsuccessful because they did not result in specific binding of SPIONs to appropriate cell types in vitro. The successful conjugation resulted in colloiddally-stable particles that showed specific binding to VEGFR-2 expressing cells in vitro.

### Task 2.

- Preliminary in vitro testing of the ability of the SPIONs to generate heat in the presence of an alternating magnetic field has been successful, but in vivo testing of hyperthermia therapy in mice receiving targeted SPIONs after DMXAA pre-treatment is temporarily on hold, pending a solution to the problem of poor long-term survival of the mice after DMXAA administration.
