**Scientific Progress** 

The project during the first year was focusing on (1) deriving the maximum entropy (MaxEnt) distributions of Type I and II multi-scaling processes and establish the links between the multi-scaling distributions and the aggregated properties of the corresponding field variables; (2) developing a model of evapotranspiration (ET) over the land surfaces using the Principle of Maximum Entropy Production (MEP).

#### 1. Derivation and validation of MaxEnt distributions of Type I multi-scaling processes

Following the MaxEnt formalism, the probability distribution of a Type I multi-scaling process (i.e. self-similar process with constant parameters), z, has been derived under the constraints of given multi-scaling moments and geometric mean of the incremental process |z1 - z2|,

where Z is the partition function (normalization factor), ?0 is determined from the constraint of given geometric mean, M the highest order of multi-scaling moment of the incremental process and ?q the Lagrangian multipliers corresponding to the given multi-scaling moments. Figure 1 The MaxEnt distributions have been validated against empirical histograms of soil moisture and topographic fields (not shown). The findings have been published in Physical Review Letters.

### 2. Derivation and validation of MaxEnt distributions of Type II multi-scaling processes

The probability distribution of the more general case of Type II multi-scaling (i.e. multi-fractal) process, similar to that of Type I, where the parameters are described by probability distributions has also been derived following the MaxEnt formalism where an additional constraint of multi-fractal condition to those of multi-scaling moments and geometric mean was imposed. The MaxEnt distributions have been validated against empirical histograms of topographical fields. The findings has been published in Geophysical Review Letters.

function in terms of the surface fluxes (latent, sensible and ground); and (3) solve numerically the heat fluxes as functions of input variables of net radiation, temperature and humidity at/near the surface. A key component of the MEP model is the concept of "thermal inertia" for latent heat flux, which was postulated according to three heuristic arguments: (1) the turbulent mixing responsible for the transport of heat in the ABL is also responsible for the transport of water vapor, (2) evaporation/transpiration may be expressed in terms of surface soil/leaf surface temperature and humidity according to the maximum principle of evaporation so that the thermal inertia should be expressed in terms of these two surface variables as well, and (3) water vapor within an infinitesimal layer next to the evaporating (soil/leaf) surface is presumably in equilibrium with the liquid water within the soil/leaf-tissues. The model for the case of bare soil is expressed as follows, with

where Rn is the net radiation, Ts the surface temperature, qs the surface specific humidity, Is the thermal inertia of the soil, I0 is the "apparent thermal inertia of the air"? is the latent heat of vaporization of liquid water, Cp the heat capacity of air at constant pressure, and Rv the gas constant of water vapor. E, H and G can be solved from the three nonlinear algebraic equations for given input of Rn, Ts, and qs, referred to as the MEP model of ET over non-vegetated land surfaces. Figure 2 shows a test of the MEP model using field observations.

The MEP model of ET over vegetated surfaces can be obtained through setting G=0 in the above equations,

where all variables are the same as those defined for the case of non-vegetated surfaces. Figure 3 shows an example of the MEP model predicted vs observed E and H.

The findings have been published in Water Resources Research (see below), which was one of the most popular papers (in terms of number of downloads).

# Final Report of ARO W911NF-10-1-0236 (UCI)

Using the Maximum Entropy Principle as a Unifying Theory for Characterization and Sampling of Multi-scaling Processes in Hydrometeorology

> Co-PIs: Rafael L. Bras and Jingfeng Wang with Dr. Veronica Nieves

## 25 January 2012

This document summarizes the first year work of the project during 21 June 2010 to 31 July 2011 conducted at University of California at Irvine (UCI) before the PIs moved to Georgia Institute of Technology (GaTech). This final report is a replica of the technical report as part of the first annual report submitted earlier.

## **Activities and Findings**

The project during the first year was focusing on (1) deriving the maximum entropy (MaxEnt) distributions of Type I and II multi-scaling processes and establish the links between the multi-scaling distributions and the aggregated properties of the corresponding field variables; (2) developing a model of evapotranspiration (ET) over the land surfaces using the Principle of Maximum Entropy Production (MEP).

## 1. Derivation and validation of MaxEnt distributions of Type I multi-scaling processes

Following the MaxEnt formalism, the probability distribution of a Type I multi-scaling process (i.e. self-similar process with constant parameters), z, has been derived under the constraints of given multi-scaling moments and geometric mean of the incremental process  $|z_1 - z_2|$ ,

$$p(z_1, z_2) = \frac{1}{Z} |z_1 - z_2|^{-\mu_0} \exp\left(\sum_{q=1}^M \mu_q |z_1 - z_2|^q\right),$$

where Z is the partition function (normalization factor),  $\mu_0$  is determined from the constraint of given geometric mean, M the highest order of multi-scaling moment of the incremental process and  $\mu_q$  the Lagrangian multipliers corresponding to the given multi-scaling moments. **Figure 1** The MaxEnt distributions have been validated against empirical histograms of soil moisture and topographic fields (not shown). The findings have been published in *Physical Review Letters*.

## 2. Derivation and validation of MaxEnt distributions of Type II multi-scaling processes

The probability distribution of the more general case of Type II multi-scaling (i.e. multifractal) process, similar to that of Type I, where the parameters are described by probability distributions has also been derived following the MaxEnt formalism where an additional constraint of multi-fractal condition to those of multi-scaling moments and geometric mean was imposed. The MaxEnt distributions have been validated against empirical histograms of topographical fields. The findings will be published in *Geophysical Review Letters* (in press).

Figure 1. From top to bottom. Left panels: AMSR-E soil map moisture for October 18, 2009 and region R1SSM. empirical associated  $(p_e)$  and the MaxEnt distributions  $(p_t)$ for M=1.2  $(p_{t:M=1})$ and  $p_{t;M=2}$ ). Right panels: for region R2SSM. Maps are represented in longitude and latitude. All probabilities are plotted versus the absolute value of the increments  $\Delta z = |z(x_1)|$  different for separation distances r = $|x_1 - x_2|$  where  $x_1$  and  $x_2$ are two locations over a two-dimensional domain.

## 3. Development and test of a MEP model of ET over the land surfaces

Built on the case of dry soil, a MEP model of ET has been formulated following the MEP formalism. The formulation has three steps: (1) formulate the dissipation function including latent heat flux (evaporation/transpiration) term; (2) find the stationary point of the dissipation

function in terms of the surface fluxes (latent, sensible and ground); and (3) solve numerically the heat fluxes as functions of input variables of net radiation, temperature and humidity at/near the surface. A key component of the MEP model is the concept of "thermal inertia" for latent heat flux, which was postulated according to three heuristic arguments: (1) the turbulent mixing responsible for the transport of heat in the ABL is also responsible for the transport of water vapor, (2) evaporation/transpiration may be expressed in terms of surface soil/leaf surface temperature and humidity according to the maximum principle of evaporation so that the thermal inertia should be expressed in terms of these two surface variables as well, and (3) water vapor within an infinitesimal layer next to the evaporating (soil/leaf) surface is presumably in equilibrium with the liquid water within the soil/leaf-tissues. The model for the case of bare soil is expressed as follows,

$$G = \frac{B(\sigma)}{\sigma} \frac{I_s}{I_0} H |H|^{-\frac{1}{6}} \qquad B(\sigma) = 6 \left( \sqrt{1 + \frac{11}{36}\sigma} - 1 \right),$$
  

$$E = B(\sigma)H \qquad \sigma = \frac{\lambda^2}{C_p R_v} \frac{q_s}{T_s^2},$$

where  $R_n$  is the net radiation,  $T_s$  the surface temperature,  $q_s$  the surface specific humidity,  $I_s$  the thermal inertia of the soil,  $I_0$  is the "apparent thermal inertia of the air"  $\lambda$  is the latent heat of vaporization of liquid water,  $C_p$  the heat capacity of air at constant pressure, and  $R_v$  the gas constant of water vapor. *E*, *H* and *G* can be solved from the three nonlinear algebraic equations for given input of  $R_n$ ,  $T_s$ , and  $q_s$ , referred to as the MEP model of ET over non-vegetated land surfaces. **Figure 2** shows a test of the MEP model using field observations.

The MEP model of ET over vegetated surfaces can be obtained through setting G=0 in the above equations,

$$E = \frac{R_n}{1 + B^{-1}(\sigma)}, \qquad H = \frac{R_n}{1 + B(\sigma)},$$

where all variables are the same as those defined for the case of non-vegetated surfaces. Figure 3 shows an example of the MEP model predicted vs observed *E* and *H*.

The findings have been published in *Water Resources Research* (see below), which was one of the most popular papers (in terms of number of downloads).

Figure 2 Evaporation E, sensible heat flux H, and ground heat flux G predicted by the MEP model (broken red). according to Eq (1), versus the corresponding observed fluxes (solid blue) at Lucky Hills site of the Walnut Gulch Experimental Watershed 16 Nov-26 Dec 2007 [Wang and Bras, 2011]. Three rain events occurred during this period with three wetting and drying cycles of soil moisture (data not shown here, but can be found in [Wang and Bras, 2011]).

Figure 3 Latent Ε and sensible heat flux H (broken red), predicted by the MEP model using the observed  $q_s$ ,  $T_s$  and  $R_n$  (not shown) versus the observed fluxes (solid blue) at the Harvard Forest (an AmeriFlux site with eddy-covariance flux tower) during 19 August 8 September 1994 (data courtesy of Steven Wofsy of Harvard University).
