Received 29 November 2013; Revised 28 February 2015

Activities such as clinical investigations or financial processes are subject to regulations to ensure quality of results and avoid negative consequences. Regulations may be imposed by multiple governmental agencies as well as by institutional policies and protocols. Due to the complexity of both regulations and activities there is great potential for violation due to human error, misunderstanding, or even intent. Executable formal models of regulations, protocols, and activities can form the foundation for automated assistants to aid planning, monitoring, and compliance checking. We propose a model based on multiset rewriting where time is discrete and is specified by timestamps attached to facts. Actions, as well as initial, goal and critical states may be constrained by means of relative time constraints. Moreover, actions may have non-deterministic effects, *i.e.*, they may have different outcomes whenever applied. We present a formal semantics of our model based on focused proofs of linear logic with definitions. We also determine the computational complexity of various planning problems. Plan compliance problem, for example, is the problem of finding a plan that leads from an initial state to a desired goal state without reaching any undesired critical state. We consider all actions to be balanced, *i.e.*, their pre and post-conditions have the same number of facts. Under this assumption on actions, we show that the plan compliance problem is PSPACE-complete when all actions have only deterministic effects and is EXPTIME-complete when actions may have non-deterministic effects. Finally, we show that the restrictions on the form of actions and time constraints taken in the specification of our model are necessary for decidability of the planning problems.

1. Introduction

Regulations are commonly used to set the rules of conduct of numerous activities in order to ensure quality of results and avoid negative consequences. For example, while carrying out a clinical investigation (CI)—that is, a set of procedures in medical research and drug development, to test a new drug or other intervention on human subjects, it is important that conclusive data is collected and that the health of the subjects participating in the CI is not compromised. In order to collect the most conclusive data, for instance, drug samples have to be taken and all the necessary tests have to be carried out in well defined periods of time. Moreover, since these experiments might compromise the health of subjects, CIs are rigorously regulated by policies elaborated by governmental agencies such as the Food and Drug Administration (FDA) (FDA99). These regulations require prompt action whenever a serious and unexpected problem with any subject is reported. In the current state of affairs, there is little to almost no automation in the management of CIs and therefore the process is prone to human error. As described in (NBS+12), there is plenty of room for the use of automated assistants to help reduce human mistakes from happening. For instance, a computer assistant can automatically generate plans that guide the clinical staff on how a CI has to be carried out. An assistant can also monitor the execution of a CI and signal alarms whenever a deviation to the specification is detected.

This paper proposes a rewriting framework that can be used to specify collaborative systems, such as CIs, and can be used as the foundation for building automated assistants. Our model is an extension of the systems used for modeling collaborative systems proposed in (KRS11) with explicit time. An important feature of our model is that its specifications can be directly written and executed in Maude (CDE+07), a powerful tool based on rewrite logic (JM92). For more details see (NBS+12) where we address implementation.

A second feature of our framework is that its specifications can mention time explicitly. Time is often a key component used in policies specifying the rules and the requirements of a collaboration. For a correct collaboration and to achieve a common goal, participants should usually follow strict deadlines and should have quick reactions to some (unexpected) events. For instance, the paragraph 312.32 on Investigational New Drug Application (IND) safety (FDA99) includes explicit time intervals that must be followed in case of any unexpected, serious or life-threatening adverse drug experience: (The emphasis in the text below is ours.)

“(c) IND safety reports

(1) Written reports —(i) The sponsor shall notify FDA and all participating investigators in a written IND safety report of: (A) Any adverse experience associated with the use of the drug that is both serious and unexpected; [. . .] Each notification shall be made as soon as possible and *in no event later than 15 calendar days* after the sponsor’s initial receipt of the information [. . .]

(2) Telephone and facsimile transmission safety reports. The sponsor shall also notify FDA by telephone or by facsimile transmission of any unexpected fatal or life-threatening experience associated with the use of the drug as soon as possible but *in no event later than 7 calendar days* after the sponsor’s initial receipt of the information.”

The above clauses explicitly mention two different time intervals. The first one specifies that a detailed safety report must be sent to the FDA within 15 days after a serious and unexpected event is detected, while the second specifies the obligation of notifying FDA of such an event within 7 days.

In order to accommodate explicit time, we attach to facts a *natural number* called a *timestamp*. Timestamps can be used in different ways depending on the system being modeled. In the example above, the timestamp t of the fact $Dose(id)@t$ could denote that the subject with anonymous identification number id received a dose at time t . Alternatively, the timestamp, t_2 , of the fact $Deadline@t_2$ could denote the time of when some activity should end. Moreover, we keep track of time by assuming a discrete global time, using the special fact $Time@t$ that denotes that the current time is t . The global time advances by replacing $Time@t$ by $Time@(t + 1)$.

Agents change the state of the system by performing actions which are given as rewrite rules. In order to specify the type of time requirements illustrated above, a set of *time constraints* may be attached to actions. This set acts as a guard of the action, *i.e.* the action can only be applied if its time constraints are satisfied. Formally, a time constraint is a comparison involving exactly two timestamps, *e.g.*, $T_1 \leq T_2 + 7$ (see Eq. 1).

Besides allowing guards with time constraints, we also allow actions to have non-deterministic effects. In particular, actions are allowed to have a finite number of post-conditions specifying a finite number of possible resulting states. These actions are useful when specifying systems, such as CIs, containing actions that may lead to different outcomes, but it is not certain beforehand which one of the outcomes will actually occur. For instance, when carrying out a blood test for the presence of some substance, it is not a priori clear what the test result will be. Nevertheless, one can classify any result as either *positive* or *negative*. Depending on this result, one would need to take a different set of future actions. For example, if the blood test is positive, then one might not be suitable for participating as a subject in a particular CI, but may be suitable for other CIs. We classify actions that have more than one outcome as *branching actions*.

Finally, in collaborative systems agents collaborate in order to achieve a common goal, but they should also avoid *critical states* that, for example, violate policies. An example of a goal state for CIs would be to collect conclusive data without compromising the health of subjects, while a critical state would be a state that violates the FDA policies. In our model, critical, goal and initial states can also mention time explicitly by using time constraints.

This paper's contributions are the following:

- Timed local state transition systems are specified in order to formalize systems with explicit time. This specification takes necessary restrictions on the type of actions and time constraints so that explicit time requirements are expressible in the system, but at the same time it is precise with respect to complexity results of the associated planning problems so that we provide decidability.
- We determine the complexity of the *plan compliance* problem (KRS11), that is, the problem of determining whether there is a plan where the collaboration achieves the common goal and in the process no critical state is reached. It has been shown that the plan compliance problem is undecidable in general (KRS09). However, we get decidability in the important case when all actions are *balanced*, *i.e.*, pre and post-conditions of actions have the same number of facts. Intuitively, this restriction bounds the memory of agents, as they can remember at any point only a bounded number of facts. Additionally, we assume that the facts created by an action, that is, the new facts that appear in its post-condition, can only have timestamps of the form $T + d$, where T is the current global time and d a natural number. Under these two assumptions on actions, we show that (1) the plan compliance problem is PSPACE-complete

if no branching actions are allowed and (2) is EXPTIME-complete if branching actions are allowed. We also investigate the complexity of the reachability problem and the timed system compliance problems.

- We present a formal semantics of our model based on logic, namely, on linear logic with definitions (PSH93; BM07; DB08). In particular, we provide an encoding and prove that there is a one-to-one correspondence between the plans and the (cut-free) focused proofs (JMA92) of its encoding.

Regarding the first contribution described above, even in the case of balanced actions, we have to deal with the problem that a plan can generate timestamps T of unbounded numeric values. In particular, the state space is internally infinite since an *arbitrary* number of time advances can occur (as illustrated at the beginning of Section 4). In our previous work (KBNS10) we were able to solve a similar unboundedness problem caused by the presence of freshly created objects that are called *nonces* in protocol security literature. However, the solution proposed in (KBNS10) is not applicable to the problem of unboundedness of time. As a result, in this paper we have made special precautions in our choice of a novel equivalence relation among states based on the time differences of the timestamps of facts. This allows us to cover all plans of unbounded length caused by uncontrolled time advances, with providing our upper bounds for the timed collaborative systems (Theorem 4.1). We also show that our new technique introduced in this paper can be combined with the technique introduced in (KBNS10) to solve the unboundedness for both time and nonces in timed systems. In our experiments, we used this novel equivalence relation among states.

The paper is organized as follows. Section 2 introduces the formal model for timed collaborative systems called Timed Local State Transition Systems (*TLSTS*) as well as the plan compliance problem described above. (In (NBS+12), *TLSTS*es were only mentioned, but not formally introduced.) In Section 3 we give a formal semantics of our model based on focused proofs of linear logic with definitions. Section 4 introduces an equivalence relation between states of the system that allows us to handle the unboundedness of time with a finite space. The machinery introduced in this section is used in Section 5 to demonstrate the decidability of the plan compliance problem. Section 5 contains the complexity results mentioned above. Section 6 we show that relaxing any of the main conditions on rules described above leads to the undecidability of the reachability problem and thus the undecidability of the other compliance problem described above. Finally in Sections 7 and 8 we discuss related and future work.

This paper extends the conference paper (KBN+12) by providing in Section 3 a linear logic semantics to our model based on multiset rewriting and time constraints and also by providing full details for our complexity results for the plan compliance problem. In addition we investigate the reachability problem and the system compliance problem, which were not dealt in our conference paper (KBN+12). We also show in Section 6 that the restrictions we impose on the form of actions and time constraints in our systems are necessary for obtaining the decidability of these problems. Relaxing any of those restrictions leads to undecidability. These results are also novel with respect to our previous work (KBN+12).

2. Basic Definitions

Multiset rewriting models of collaborative systems with privacy and confidentiality have been introduced in (KRS09; KRS11; KBNS13). These models formalize the collaboration of a group of agents that work together in order to achieve a common goal. At the same time, confidentiality issues are addressed, such as private and shared information, leakage of private data and reachability of undesired states.

In this section we review the main concepts and formalize the timed extension of the model.

At the lowest level, we have a first-order alphabet Σ that consists of a set of predicate symbols P_1, P_2, \dots , function symbols f_1, f_2, \dots , constant symbols c_1, c_2, \dots , and variable symbols x_1, x_2, \dots all with specific sorts (or types). The multi-sorted terms over the alphabet are expressions formed by applying functions to arguments of the correct sort. Since terms may contain variables, all variables must have associated sorts. A *fact* is a ground, atomic formula over multi-sorted terms. Facts have the form $P(t_1, \dots, t_n)$ where P is an n -ary predicate symbol, where t_1, \dots, t_n are terms, each with its own sort.

In order to accommodate the dimension of time in our model, we associate to each fact a timestamp. *Timestamped facts* are of the form $P(t_1, \dots, t_n)@t$, where the number t is the timestamp of the fact $P(t_1, \dots, t_n)$. Among the set of predicates, we distinguish the zero arity predicate *Time*, which intuitively denotes the current global time of the system. For instance, the fact $Time@2$ denotes that the global time is 2. Here, we assume that timestamps are natural numbers. The intuitive meaning of a timestamp may depend on the system one is modeling. For instance, in our clinical investigations example, the timestamp associated to a fact could denote the time when a problem with a subject has been detected.

The *size of a fact*, P , denoted by $|P|$, is the total number of symbols it contains. We count one for each occurrence of a constant, variable, predicate, and function symbol, e.g., $|P(f(x))| = 3$, and $|P(x, c, x)| = 4$. For our complexity results, we assume an upper bound on the size of facts, as in (DLMS04; KRS11; KBNS10). This means that for all facts, $P(t_1, \dots, t_n)@t$, the arity of predicate symbols, n , and the depth of terms, t_1, \dots, t_n , are bounded. However, we make no assumptions on the depth of timestamps, t , that is, the size of timestamps may be unbounded.

A *state*, or *configuration* of the system is a finite multiset, $Q_1@t_1, \dots, Q_n@t_n$, of *grounded* timestamped facts, i.e., timestamped facts not containing variables. Configurations are assumed to contain exactly one occurrence of the predicate *Time*. We use W, X to denote the multiset resulting from the multiset union of W and X . For instance, the configuration

$$\{Time@5, Blood(id_1, scheduled)@7, Dose(id_1)@4, Status(id_1, normal)@5\}$$

denotes that that current time is 5, that the blood test for subject identified by id_1 should be taken on time 7, that the same subject took a dose of the drug at time 4, and his status is *normal*, i.e., no problem has been detected.

For simplicity we often omit the word “timestamped” and just use the wording fact.

In order to specify private and shared information in multiset rewrite systems, and following (KRS09; KRS11), we assume that the global configuration is partitioned into different local configurations each of which is accessible only to one agent. There is also a public configuration, which is accessible to all agents. As argued in (KRS11), this separation allows one to specify systems for which it is important to know which facts are owned and can be manipulated by an

agent of the system. Formally, this separation of the global configuration is done by partitioning the set of predicate symbols in the alphabet and it will be usually clear from the context. The time predicate *Time* is assumed to be public. For instance, in the above configuration all facts, except *Time*, belong to the health institution monitoring the subject id_1 .

Time constraints The time requirements of a system are specified by using *time constraints*. Time constraints are arithmetic comparisons involving exactly two timestamps:

$$T_1 = T_2 \pm d, T_1 > T_2 \pm d, \text{ or } T_1 \geq T_2 \pm d, \quad (1)$$

where d is a natural number and T_1 and T_2 are time variables, which may be instantiated by the timestamps of any fact including the global time.

A concrete motivation for time constraints to be relative is that, as in physics, the rules of a collaboration are also not affected by time shifts. If we shift the timestamps of all facts by the same value, the same rules and conditions valid with respect to the original state are also valid with respect to the resulting state. If time constraints were not relative, however, then one would not be able to establish this important invariant. Indeed, as we show in Section 6, the reachability problem is undecidable for systems with non-relative time constraints.

2.1. Branching Actions and Plans

Branching Actions Actions work as multiset rewrite rules. Actions are applied to configurations to produce new configurations, hence action application represents a process of changes of system states. As in (KRS11; KBNS10) we assume that each agent has a finite set of actions. However, we extend actions in two different ways: First, we add *guards to actions*; and second we allow actions to have a finite number of *non-deterministic effects*.

In their most general form, actions have the following form:

$$W \mid \mathcal{T} \longrightarrow_A [\exists \vec{x}_1.W_1] \oplus \cdots \oplus [\exists \vec{x}_n.W_n] \quad (2)$$

The subscript A is the name of the agent that owns this action. W is the pre-condition of this rule, while W_1, \dots, W_n are its post-conditions. All facts in W, W_1, \dots, W_n are public and/or belong to the agent A . \mathcal{T} is the guard of the action consisting of finitely many *time constraints* of the form shown in Equation 1. We assume that all free variables are universally quantified at the head of the rule. The existentially quantified variables specify the creation of fresh values, also known as nonces in protocol security literature.[†] By applying the rule for a ground substitution (σ), the pre-condition ($W\sigma$) to which this substitution has been applied is replaced with a post-condition ($W_i\sigma$) to which the same substitution has been applied. In this process, the existentially quantified variables (\vec{x}_i) appearing in the post-condition are replaced by fresh constants.

Finally, if $n > 1$, then we classify the action as *branching*, otherwise, when $n = 1$, we classify the action as *non-branching*.

[†] Fresh values are also often used in administrative processes, such as when a transaction number is issued. In particular, the transaction number has to be fresh. For a more detailed account for fresh values in administrative processes, see (KBNS13).

We say that a rule r of the form shown in Equation 2 creates a fact $F@T$, if $F@T$ does not appear in its pre-condition W , but appears in at least one of its post-conditions W_i .

With the exception of Section 6, we only consider in this paper systems with actions of the form shown in Equation 2. Actions are either the *time tick action* or *atomic actions*:

(*Time Tick Action*) The action formalizing the advancement of time is the following action belonging to the special agent *clock*:

$$Time@T \mid \{\} \rightarrow_{clock} Time@(T + 1). \quad (3)$$

The above action does not have any constraints, which is specified by the empty set $\{\}$. It is the only action of the agent *clock* and is the *only action* that can change the global time.

(*Atomic Actions*) The rest of the actions are instantaneous actions belonging to the remaining agents. We impose the following two conditions on actions depicted in Equation 2. Firstly, the global time $Time@T$ appears in the pre-condition, W , and in each of the post-conditions W_1, \dots, W_n exactly once. Secondly, if $Time@T$ is in the pre-condition W , then all facts created by the rule are of the form $P@(T + d)$, where d is a natural number, possibly zero. That is, all the facts created by this action have timestamps greater or equal to the global time. Notice that in this type of action the timestamp of $Time$ does not change, that is, these actions are *instantaneous*. Also notice that, for example, the following action is not allowed

$$Time@T, R@T_1, P@T_2 \mid T_1 < T \longrightarrow_A Time@T, R@T_1, S@T_1.$$

This is because the timestamp of the created fact $S@T_1$ is not of the form $(T + d)$. That is, actions cannot create facts with arbitrary timestamps, instead they are only allowed to create facts whose timestamps are in the present or in the future, that is equal to or greater than the current time.

As we discuss in Sections 4 and 6, the two conditions on the actions belonging the agents different from the *clock* agent, discussed above, play an important role for the decidability of the system.

Definition 2.1. A *timed local state transition system (TLSTS)* \mathcal{T} is a tuple $\langle \Sigma, I, R_{\mathcal{T}} \rangle$, where Σ is the alphabet of the language, I is a set of agents, such that $clock \in I$, and $R_{\mathcal{T}}$ is a finite set of actions owned by the agents in I of the two forms described above.

An *TLSTS* formalizes a collaborative system in which agents interact in order to achieve some common goal. *Initial configuration* is the multiset of facts denoting the initial state of the system, while the *goal configuration* is the multiset of facts denoting the final goal. However, since agents do not trust each other completely, they also want to avoid some critical situations, *i.e.* situations that are considered undesired or unacceptable. Therefore, agents may also have confidentiality policies, given as multisets of facts. Any configuration that conflicts with some confidentiality policy of any agent of the system is called *critical configuration*.

Agents change the state of the system by performing actions. We will consider various problems that involve the transformation of the given initial configuration into a goal configuration, avoiding critical configurations in the appropriate way.

Branching Plans A *branching plan*, or simply *plan* is a tree whose nodes are configurations and whose edges are labeled with a pair consisting of an action and a number, $\langle \alpha, i \rangle$. As depicted in Figure 1, a plan is constructed by applying an action to one of its leaves. Formally, consider

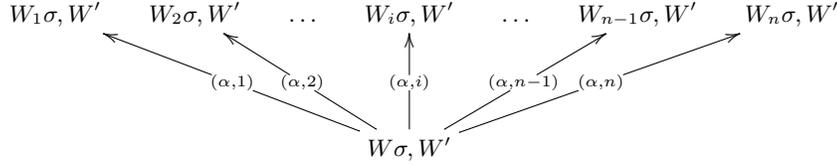

Fig. 1. A branching plan obtained by applying an action α of the form shown in Equation 2. Here σ is a ground substitution for α 's pre-condition W , while $W'_1\sigma, \dots, W'_n\sigma$ are ground instantiations of α 's post-conditions.

a branching action α of the form shown in Equation 2, that is, with pre-condition W and post-condition $W_1 \oplus \dots \oplus W_n$. We enumerate the post-conditions as W_1, \dots, W_n . When such an action is applied to a leaf of a plan labeled with W_I , the corresponding branch of the plan is extended by adding n leaves. The configuration labeling the i^{th} leaf is obtained by replacing α 's pre-condition, $W\sigma$, instantiated by a ground substitution σ in W_I by the corresponding post-condition of α , $W_i\sigma$, instantiated by the same substitution σ . The edge connecting W_I with i^{th} new leaf is labeled with $\langle \alpha, i \rangle$. In the process fresh values are created, replacing the existentially quantified variables, \vec{x}_i .

For example, let $\{Time@6, P(t_1)@1, Q(t_2)@4\}$ be a configuration appearing in a leaf of a plan \mathcal{P} . Then the following branching action is applicable:

$$Time@T, Q(Y)@T_1 \mid \{T > T_1 + 1\} \longrightarrow_A [\exists x. Time@T, R(Y, x)@T] \oplus [Time@T, S(Y)@T]$$

and it extends the plan \mathcal{P} creating the following two leaves $\{Time@6, P(t_1)@1, R(t_2, z)@6\}$ and $\{Time@6, P(t_1)@1, S(t_2)@6\}$, where z is a fresh value.

If only non-branching actions are used, the plan has a single branch, *i.e.* the plan is simply a sequence of actions.

Balanced Actions We classify an action as *balanced* if its post-conditions, W_i , and the pre-condition, W , have the same number of facts. In Equation 2, this means that the number of facts in W and W_i are the same for all $1 \leq i \leq n$. We classify a *TLSTS* as *balanced* if all its actions are balanced.

For any plan P obtained from a balanced system, one can easily prove that *all configurations in P have the same number of facts*, namely the number of facts in P 's initial configuration. Intuitively, this means the number of facts that can be owned by an agent in the system is bounded by the number of facts in the initial configuration. In the remainder of this paper, we use the letter m to denote this number. Moreover, since we assume facts to have a bounded size, denoted using the letter k , the use of balanced actions imposes roughly a bound on the storage capacity of the agents in the system. In particular, any configuration in a plan obtained from a balanced system, may have at most mk symbols. For more about balanced systems, we point the reader to (KRS11; KBNS13).

As we further discuss in Section 5, the assumption that all actions in the systems are balanced is crucial for showing that the reachability problem is in PSPACE. In fact, it was shown in previous work (KRS09) that this problem is undecidable if we allow actions to be un-balanced.

2.2. Planning Problems

Goals of a collaboration as well as the critical situations which have to be avoided often mention time explicitly. For instance, in the clinical investigations example discussed in the Introduction, the participants want to collect conclusive data without violating regulations. Moreover, the sponsor should send a safety report to the FDA whenever a serious and unexpected problem is detected within 15 days. Otherwise, the sponsor can be severely penalized. We extend the notion of *initial, goal and critical configurations* proposed in (KRS11) by attaching a set of time constraints to configurations. In particular, timed initial, goal and critical configurations have the following form:

$$\{Q_1@T_1, Q_2@T_2, \dots, Q_n@T_n\} \mid \mathcal{Y}$$

where \mathcal{Y} is a finite set of time constraints as shown in Eq. 1 such that its variables are in T_1, T_2, \dots, T_n .

For instance, in the clinical investigations example, a possible goal configuration is the one representing a situation when the data of a subject is collected in specified intervals for some number of times. The following goal configuration specifies that the goal is to collect the data of a subject 25 times in intervals of 28 days, but with a tolerance of 5 days:

$$\{Time@T, Data(Id, 1)@T_1, \dots, Data(Id, 25)@T_{25}\}$$

with the time constraints $T_i + 23 \leq T_{i+1} \leq T_i + 33$ and that $T > T_i$, for $1 \leq i \leq 25$. Formally, any instantiation of the variables T_1, \dots, T_{25} that satisfies the set of constraints above is considered a goal configuration.

Similarly, configurations:

$$\begin{aligned} & \{Detect(Id)@T_1, Report(Id, ok)@T_2\} \mid \{T_2 > T_1 + 15\} \\ & \{Time@T, Detect(Id)@T_1, Report(Id, no)@T_2\} \mid \{T > T_1 + 15\} \end{aligned}$$

are critical for the participants of a clinical investigation, since a problem was detected at time T_1 , but the written report was not sent to the FDA on time, *i.e.*, within 15 days of detecting the problem.

Adding time constraints to configurations is not a restriction of the model. Quite the contrary, time constraints provide a general mechanism to specify in a succinct fashion the set of goal and critical configurations expressing time requirements.

For simplicity, we often omit the word "timed" in initial/goal/critical configurations regardless of time constraints being attached or not.

As in (KBNS13), we assume that the goal and critical configurations are closed with respect to fresh values. That is, if a configuration C containing some nonces is a goal (respectively, critical) state, then $C\sigma$ is also a goal (respectively, critical), where σ is a renaming of nonce names. This assumption is sensible, as when defining critical and goal configurations, one cannot specify the nonce names in advance, since these are freshly generated during the execution of the process being modeled. The particular nonce name should not matter for classifying a configuration as critical or a goal configuration.

Planning Problems In (KRS11; KRS09) three compliance problems were introduced in the setting without explicit time or branching (actions with non-deterministic effects). These

variations of the planning problem differentiate in the approach to confidentiality issues. They express different degrees of trust between the agents of the system and consequently consider different demands on the collaboration process. Moreover, different compliance problems are not generally of the same computational complexity (KRS09).

We now restate two of these problems in our setting with explicit time and branching.[‡]

Given an initial configuration W_I and a finite set of goal and critical configurations, we call a *branching plan* \mathcal{P} *compliant* if it does not contain any critical configurations and moreover if all branches of \mathcal{P} lead from the initial configuration W_I to a goal configuration.

- (Timed plan compliance problem) Given a timed local state transition system \mathcal{T} , an initial configuration W consisting of timestamped facts and a finite, possibly empty, set of time constraints, a timed goal configuration Z , and a finite set of timed critical configurations, is there a compliant plan which leads from W to Z ?
- (Timed system compliance problem) Given a timed local state transition system \mathcal{T} , an initial configuration W consisting of timestamped facts and a finite, possibly empty, set of time constraints, a timed goal configuration Z , and a finite set of timed critical configurations, is no timed critical configuration reachable from W , and does there exist a plan leading from W to Z ?

In (KRS09), the plan compliance problem without explicit time was called weak plan compliance.

Notice the difference in the confidentiality demands in the above problems. System compliance is a very strong notion, demanding that no critical configuration is reachable no matter what happens. It is most suitable for modelling very low level of trust among the agents, who can confide in system being well-designed. Since the plan compliance only requires the existence of a plan that does not contain a critical state, it is suitable for systems with considerable trust among the agents. In fact, agents must trust each other to follow the plan, because if they deviate from the plan, then all guarantees of compliance are lost.

Although the above problems are stated as decision problems, we prove more than just existence of a plan. Ideally, we are also able to generate a plan when there is a solution. Unfortunately, the number of actions in the plan may be very large, potentially increasing the complexity of the plan generation. For this reason we follow (KRS11) and use the notion of “scheduling” a plan. However, since we are dealing with branching plans, whereas (KRS11) considered non-branching plans, we need to agree how the nodes of a branching tree are enumerated. Therefore, we assume fixed a *tree traversal procedure*. It can be any traversal procedure, for instance, depth-first traversal procedures (pre, in-order, or post-order) or a breadth-first traversal procedure. Assuming such a tree traversal procedure, a scheduling algorithm takes an input i representing the node in the agreed traversal and outputs the i^{th} action of the plan, which extends this node.

Definition 2.2. Assume pre-defined any tree traversal procedure. An algorithm is said to *schedule*

[‡] The third compliance problem, introduced as the *plan compliance problem* in (KRS09), was called *semi-critical plan compliance problem* in (KBNS13) where it was observed that, for systems without explicit time, this problem is reducible to an instance of the plan compliance problem with a larger set of critical configurations. This set includes the set of *semi-critical configurations* from which it is possible to reach a critical state of a particular agent without the participation of this agent. The same reduction can be obtained for *TLST*Ses.

a plan if it (1) finds a plan if one exists, and (2) on input i , if the plan contains at least i nodes, then it outputs the i^{th} action of the plan, otherwise it outputs *no*.

3. Formal Semantics using Linear Logic with Definitions

Tight connections between linear logic and multiset rewriting have been established in the literature (HM94; KRS11). For instance, Kanovich *et al.* (KRS11) established connections between linear logic provability and the reachability problem. These results are interesting as they provide a logical foundations to multiset rewriting using linear logic. Moreover, results established for multiset rewriting theory may also be used to establish novel results in linear logic. For example, Kanovich *et al.* (KRS11) also showed that the reachability problem of balanced systems is PSPACE-complete. From this result and the tight connection to linear logic, we can establish that the provability problem for the fragment of balanced bipoles (VN12) is also PSPACE-complete.

This section establishes a similar result for *TLSTSes* based on linear logic with definitions (PSH93; DB08), an extension of linear logic with fixpoint definitions. In particular, we provide an encoding for *TLSTSes* such that given an initial configuration W and a *TLSTS*, then there is a one-to-one correspondence between the set of plans from W to a goal state Z and the set of (cut-free) focused proofs (JMA92) of its encoding. This result together with our complexity results established in Section 5 allows us to infer complexity results for the reachability problem for the fragment below of linear logic with definitions. We believe that this is the first complexity results for the provability problem of fragments of linear logic that use definitions.

Readers that are not interested in Linear Logic may feel free to skip this section and proceed to Section 4.

3.1. Focused Proof System for Linear Logic with Definitions

The focused proof system, LLF, for linear logic is depicted in Figure 2 and was introduced by Andreoli (JMA92). Focused proofs can be regarded as the normal form proofs for proof search. In order to formally introduce LLF, we first classify the connectives 1 , \otimes , \oplus , and \exists as positive and the remaining as negative. This distinction is natural as the introduction rules for the positive connectives are not-necessarily invertible, while the rules for the negative connectives are invertible. The same distinction, however, does not apply so naturally to literals and hence these are *arbitrarily* classified as positive or negative. Positive polarity literals and formulas whose main connective is positive are classified as positive formulas and the remaining as negative formulas.

As one can see from an inspection of LLF in Figure 2, there are two different sequents in LLF: those containing \uparrow which belong to the negative phase where only negative formulas are introduced, and those containing \downarrow which belong to the positive phase and only positive formulas are introduced. The decide rules D_1, D_2 , reaction rules $R \uparrow, R \downarrow$ and the bang introduction rule $!$ mark transition between positive and negative phases.

A key property of LLF is that it allows one to construct macro-rules that introduce synthetic connectives. For example, assume that the N_1, N_2, N_3 are all negative formulas. Then from the focusing discipline, there are only two possible ways to introduce the sequent $\vdash \Theta : \Gamma_1, \Gamma_2 \downarrow$

Introduction Rules

$$\begin{array}{c}
\frac{\vdash \Theta : \Gamma \uparrow L}{\vdash \Theta : \Gamma \uparrow L, \perp} [\perp] \quad \frac{\vdash \Theta : \Gamma \uparrow L, F, G}{\vdash \Theta : \Gamma \uparrow L, F \wp G} [\wp] \quad \frac{\vdash \Theta, F : \Gamma \uparrow L}{\vdash \Theta : \Gamma \uparrow L, ?F} [?] \\
\frac{}{\vdash \Theta : \Gamma \uparrow L, \top} [\top] \quad \frac{\vdash \Theta : \Gamma \uparrow L, F \quad \vdash \Theta : \Gamma \uparrow L, G}{\vdash \Theta : \Gamma \uparrow L, F \& G} [\&] \quad \frac{\vdash \Theta : \Gamma \uparrow L, F[c/x]}{\vdash \Theta : \Gamma \uparrow L, \forall x F} [\forall] \\
\frac{}{\vdash \Theta : \downarrow \mathbb{1}} [1] \quad \frac{\vdash \Theta : \Gamma \downarrow F \quad \vdash \Theta : \Gamma' \downarrow G}{\vdash \Theta : \Gamma, \Gamma' \downarrow F \otimes G} [\otimes] \quad \frac{\vdash \Theta : \uparrow F}{\vdash \Theta : \downarrow !F} [!] \\
\frac{\vdash \Theta : \Gamma \downarrow F}{\vdash \Theta : \Gamma \downarrow F \oplus G} [\oplus_l] \quad \frac{\vdash \Theta : \Gamma \downarrow G}{\vdash \Theta : \Gamma \downarrow F \oplus G} [\oplus_r] \quad \frac{\vdash \Theta : \Gamma \downarrow F[t/x]}{\vdash \Theta : \Gamma \downarrow \exists x F} [\exists]
\end{array}$$

Identity, Reaction, and Decide rules

$$\begin{array}{c}
\frac{}{\vdash \Theta : A_p^\perp \downarrow A_p} [I_1] \quad \frac{}{\vdash \Theta, A_p^\perp : \downarrow A_p} [I_2] \quad \frac{\vdash \Theta : \Gamma, S \uparrow L}{\vdash \Theta : \Gamma \uparrow L, S} [R \uparrow] \\
\frac{\vdash \Theta : \Gamma \downarrow P}{\vdash \Theta : \Gamma, P \uparrow} [D_1] \quad \frac{\vdash \Theta, P : \Gamma \downarrow P}{\vdash \Theta, P : \Gamma \uparrow} [D_2] \quad \frac{\vdash \Theta : \Gamma \uparrow N}{\vdash \Theta : \Gamma \downarrow N} [R \downarrow]
\end{array}$$

Fig. 2. The focused proof system, LLF, for linear logic (JMA92). Here, L is a list of formulas, Θ is a multiset of formulas, Γ is a multiset of literals and positive formulas, A_p is a positive literal, N is a negative formula, P is not a negative literal, and S is a positive formula or a negated atom.

$(N_1 \oplus N_2) \otimes N_3$:

$$\frac{\vdash \Theta : \Gamma_1 \uparrow N_1 \quad \vdash \Theta : \Gamma_2 \uparrow N_3}{\vdash \Theta : \Gamma_1, \Gamma_2 \downarrow (N_1 \oplus N_2) \otimes N_3} \quad \text{and} \quad \frac{\vdash \Theta : \Gamma_1 \uparrow N_2 \quad \vdash \Theta : \Gamma_2 \uparrow N_3}{\vdash \Theta : \Gamma_1, \Gamma_2 \downarrow (N_1 \oplus N_2) \otimes N_3}$$

Hence, the formula $(N_1 \oplus N_2) \otimes N_3$, under the focusing discipline, specifies such macro-rules which are obtained by applying the corresponding positive and a negative phase rules.

One can specify in a similar way a multiset rewrite rule r as a linear logical formula $F(r)$ in such a way that the macro-rule obtained by focusing on $F(r)$ corresponds *exactly* to the operational semantics of the rewrite rule r (HM94). But in order to specify in the same way the semantics of time constraints of *TLST*Ses, we need more machinery, namely definitions (PSH93; DB08). A *definition* is a finite set of *clauses* which are written as $\forall \vec{x}[P(\vec{x}) \stackrel{\Delta}{\triangleq} B]$: here P is a predicate and every free variable of B (the *body* of the clause) is contained in the list \vec{x} . The symbol $\stackrel{\Delta}{\triangleq}$ is not a logical connective but is used to indicate a definitional clause. We consider that every defined predicate occurs at the head of exactly one clause. Introduction rules for definitions are shown below, where a definition can be unfolded on both the positive phase and the negative phase:

$$\frac{\vdash \Theta : \Gamma \downarrow B\theta}{\vdash \Theta : \Gamma \downarrow P(\vec{c})} [def \downarrow] \quad \frac{\vdash \Theta : \Gamma \uparrow L, B\theta}{\vdash \Theta : \Gamma \uparrow L, P(\vec{c})} [def \uparrow]$$

The proviso for both of these rules is: $\forall \vec{x}[P(\vec{x}) \stackrel{\Delta}{\triangleq} B]$ is a definition clause and θ is the substitution that maps the variables \vec{x} to the terms \vec{c} , respectively. Thus, in either phase of focusing, if a defined atom is encountered, it is simply replaced by its definition and the proof search phase does not change.

We also include the rules for equality shown below:

$$\frac{\{(\vdash \Theta : \Gamma \uparrow L)\theta \mid \theta \in CSU(r, s)\}}{\vdash \Theta : \Gamma \uparrow L, r \neq s} [\neq_r] \quad \frac{}{\vdash \Theta : \cdot \downarrow r = r} [=_r]$$

where $CSU(s, r)$ denotes the complete set of unifiers of two terms. Since we are dealing with first-order logic terms, this set either contains one unifier, the most general unifier, or it is empty when the terms r and s are not unifiable. Notice that right equality introduction rule behaves exactly as the rule [1]. The proof theory of inference rules such as these is well studied (see, for example, (BM07; MM00; DB08)). Linear logic with definitions admits cut-elimination of LLF with definitions (MM00)[§] and the focusing discipline used above was shown to be complete (DB08). This paper will only need the $=_r$ rule.

3.2. Encoding TLSTSeS in Linear Logic with Definitions

Encoding Arithmetic Conditions We show how to express the semantics of TLSTSeS as search for cut-free focused linear logic proof with definitions. In particular, we use the following definitions to specify, for example, the arithmetic operations of \leq , $<$ and $+$ that appear in constraints:

$$\begin{aligned} x \leq y & \triangleq [x = zr] \oplus [\exists x' y'. (x = s(x')) \otimes (y = s(y')) \otimes (x' \leq y')] \\ x < y & \triangleq [\exists y'. (x = zr) \otimes (y = s(y'))] \oplus [\exists x' y'. (x = s(x')) \otimes (y = s(y')) \otimes (x' < y')] \\ Plus(x, y, z) & \triangleq [(x = zr \otimes y = z)] \oplus [\exists x' z'. ((x = s(x')) \otimes (z = s(z')) \otimes Plus(x', y, z'))]. \end{aligned}$$

where natural numbers are expressed by using the successor function s and the constant zr denoting the natural number zero. For instance, the definition for \leq contains two disjuncts: the left disjunct specifies the base case when the value of x is zero, and the right disjunct the inductive case, where both x and y are the successors of two numbers x' and y' such that $x' \leq y'$. The other arithmetic operations can be specified in a symmetric way.

As observed in (NM09), the definitions above can be used to compute an arithmetic operation in a single focused step. This is because the body of all the definitions above is positive. Therefore, once one focuses on one of the atoms defined above, one does not lose focus anymore and hence a proof consists necessarily of a single positive phase. For example, if we focus on the atom

[§] Technically it was shown that cut-elimination works when definitions satisfy certain conditions which are out of scope of this paper. The definitions that we need here fall under this fragment.

W_j^c as a set of constraints to the new time variables introduced. For instance, the post-condition of the following action,

$Time@T, P(x)@T_1, Q(y)@T_2 \mid \{T_2 > T_1 + 1\} \rightarrow_A \exists u. Time@T, P(u)@(T + 2), R(x)@T,$
 returns the sets $\{Time@T, P(u)@(T_2'), R(x)@T\}$ and $\{Plus(T, s(s(zr)), T_2')\}$.

Now, we are ready to encode actions in linear logic: an action of the form $W \mid \Upsilon \rightarrow_A \exists \vec{t}_1. W_1 \oplus \dots \oplus \vec{t}_n. W_n$ is encoded as the linear logic formula

$$F = \forall \vec{x} \left[\bigotimes^{\ulcorner W \urcorner} \otimes q_A \otimes \bigotimes^{\ulcorner \Upsilon \urcorner} \otimes \bigotimes_{j=1}^{j=n} W_j^c \multimap \bigoplus_{j=1}^{j=n} \left[\exists \vec{t}. \bigotimes^{\ulcorner W_j^f \urcorner} \otimes q_A \right] \right],$$

where \vec{x} are the free variables appearing in the rule together with all the new variables introduced by the translation $\ulcorner \cdot \urcorner$ and in the set W_j^c . Also, the atomic formula q_A is used only to mark that this action belongs to agent A . Moreover, the encoding of a set of transition rules $\ulcorner R_{\mathcal{T}} \urcorner$ is the set with the encoding of all the transition rules in $R_{\mathcal{T}}$, and the set of propositions used to mark a rule to an agent is defined as $Q_I = \{q_A : A \in I\}$. Intuitively, the encodings of actions are placed in the unbounded context in the left-hand-side of a sequent. However, since we are using a one-sided proof system, we use its negation in the one-sided LLF system with definitions:

$$F^\perp \equiv \exists \vec{x} \left[\left(\bigotimes^{\ulcorner W \urcorner} \otimes q_A \otimes \bigotimes^{\ulcorner \Upsilon \urcorner} \otimes \bigotimes_{j=1}^{j=n} W_j^c \right) \otimes \bigotimes_{j=1}^{j=n} \left[(\forall \vec{t}) \mathcal{X}^{\ulcorner W_j^f \urcorner} \wp q_A^\perp \right] \right].$$

Assume now that all atomic formulas have positive polarity, and consequently their negation negative polarity. The focused derivation introducing F^\perp necessarily has to be of the form below. Recall that the encodings of rewrite rules are in the classical context Θ , thus $F^\perp \in \Theta$.

$$\frac{\frac{\frac{\vdash \Theta : \Delta \Downarrow \bigotimes^{\ulcorner W \urcorner} \otimes \bigotimes^{\ulcorner \Upsilon \urcorner} \otimes \bigotimes_{j=1}^{j=n} W_j^c \otimes q_A \quad \vdash \Theta : \Gamma \Downarrow \bigotimes_{j=1}^{j=n} \left[(\forall \vec{t}) \mathcal{X}^{\ulcorner W_j^f \urcorner} \wp q_A^\perp \right]}{\vdash \Theta : \Gamma, \Delta \Downarrow \left(\bigotimes^{\ulcorner W \urcorner} \otimes q_A \otimes \bigotimes^{\ulcorner \Upsilon \urcorner} \otimes \bigotimes_{j=1}^{j=n} W_j^c \right) \otimes \bigotimes_{j=1}^{j=n} \left[(\forall \vec{t}) \mathcal{X}^{\ulcorner W_j^f \urcorner} \wp q_A^\perp \right]} \quad [\otimes]}{\vdash \Theta : \Gamma, \Delta \Downarrow F^\perp} \quad [n \times \exists]}{\vdash \Theta : \Gamma, \Delta \uparrow \cdot} \quad [D_2]$$

Since \otimes is a positive connective, the left-premise is necessarily introduced by a completely positive phase introducing all tensors in $\bigotimes^{\ulcorner W \urcorner} \otimes q_A \otimes \bigotimes^{\ulcorner \Upsilon \urcorner} \otimes \bigotimes_{j=1}^{j=n} W_j^c$ until one only focuses on atomic formulas. There are then two types of atomic formulas: the first type are atoms that have a definition, such as *Plus*, and those that do not have a definition, such as q_A . When one of the former is focused on, the focusing discipline forces its definition to be opened, thus computing the values of the timestamps of the facts in the post-conditions, specified in W_j^c . Moreover, as discussed above, these are proved without using any formulas from Δ . That is, the sequent below is proved in a single positive phase:

$$\vdash \Theta : \cdot \Downarrow \bigotimes_{j=1}^{j=n} W_j^c$$

The same happens when checking whether the rule guard is satisfied or not. In particular, the

following sequent should be proved in a single positive phase

$$\vdash \Theta : \cdot \Downarrow \bigotimes \Upsilon^\neg$$

and is provable if and only if the guard Υ is satisfied.

The second type of atoms are those that do not have definitions and appear in Υ^\neg and the fact q_A . Since these are assumed to have positive polarity, the only applicable rule when these are focused on is an initial rule. This forces Δ to be exactly the negation of the facts in Υ^\neg union the fact q_A^\perp . In contrast, for the right-premise of the derivation above, since \forall and \wp are negative connectives, the right-premise is necessarily introduced by a negative phase introducing these connectives. Hence, the macro-rule introducing an encoding of the transition rule is necessarily of the form, which corresponds to the one in Figure 1:

$$\frac{\vdash \Theta : \Gamma, q_A^\perp, \Upsilon_1^f \neg^\perp \sigma \uparrow \cdot \quad \dots \quad \vdash \Theta : \Gamma, q_A^\perp, \Upsilon_n^f \neg^\perp \sigma \uparrow \cdot}{\vdash \Theta : \Gamma, q_A^\perp, \Upsilon \neg^\perp \sigma \uparrow \cdot}$$

Notice that if the pre-condition or the constraints in Υ of the action are not satisfied, then there is no focused proof which focuses on the encoding of this transition. This handles the inductive case of the adequacy result of our encoding of *TLSTS* in Linear Logic with Definitions (Theorem 3.1).

Encoding of Partial Goal The base case of our adequacy result consists in checking if a partial goal is reached. This is specified in a similar way as before. Let the set of facts Z and the set of time constraints Υ constitute a goal configuration G . To check whether this goal configuration is reached, we encode G , written Υ^\neg as follows:

$$\exists \vec{x}. \bigotimes \Upsilon^\neg \otimes \Upsilon^\neg \otimes \top,$$

where \vec{x} is the set of time variables appearing in the goal configuration. This formula is necessarily introduced by the following focused derivation:

$$\frac{\frac{\frac{\frac{\vdash \Theta : \Delta \Downarrow \bigotimes \Upsilon^\neg \quad \vdash \Theta : \cdot \Downarrow \bigotimes \Upsilon^\neg \quad \vdash \Theta : \Gamma \Downarrow \top}{[2 \times \otimes]} [R \Downarrow, \top]}{\vdash \Theta : \Gamma, \Delta \Downarrow \bigotimes \Upsilon^\neg \otimes \Upsilon^\neg \otimes \top} [n \times \exists]}{\vdash \Theta : \Gamma, \Delta \Downarrow \exists \vec{x}. \bigotimes \Upsilon^\neg \otimes \Upsilon^\neg \otimes \top} [D_2]}{\vdash \Theta : \Gamma, \Delta \uparrow \cdot}$$

As before, since all atoms are assigned with positive polarity, the focusing discipline forces that Δ contains exactly the negation of the facts appearing in Υ^\neg , that all constraints in Υ are satisfied, and that Γ contains the remaining facts in the sequent. That is, the current configuration is a goal configuration.

Given the discussion above, we prove the following connection between linear logic with definitions and reachability using *TLSTS* by induction on the height of derivation trees and on the height/length of branching plans.

Theorem 3.1. Let $\mathcal{T} = \langle \Sigma, I, R_{\mathcal{T}} \rangle$ be a timed local transition system. Let W be an initial configuration and G be a goal configuration under the signature Σ . Then the sequent

$$\vdash \Upsilon R_{\mathcal{T}} \neg^\perp : Q_I^\perp, \Upsilon^\neg, \Upsilon^\neg \uparrow \cdot$$

is provable in linear logic with definitions where $\lceil X \rceil$ is the encoding as defined above iff there is a branching plan whose root is W and whose leaves contain G .

In fact, the adequacy we get is stronger than what is stated by the result above. The adequacy is on the level of derivations (NM10). That is, proof search in the linear logic encoding corresponds exactly to search using the encoded *TLSTS*. However, we must also notice that our encoding only deals with reachability and not with the Planning Problem as we do not check whether a state is critical. But, one can check whether a critical state C is reachable from an initial state by specifying the reachability goal G to be the critical state C .

4. Dealing with the Unboundedness of Time

Comparing our *timed* collaborative models introduced here with the results on the *untimed* collaborative systems in our previous work (KBNS13), we meet with a number of crucial difficulties. In the case of planning problems for the untimed systems with balanced actions, we are dealing with a *finite* (though huge) state space. Here the state space is *internally infinite*, since an arbitrary number of time advances is allowed in principle. For a straightforward example, consider a plan where time is eagerly advanced. That is, consider a plan with a single branch where time advances constantly:

$$Time@0, W \xrightarrow{clock} Time@1, W \xrightarrow{clock} Time@2, W \xrightarrow{clock} \dots$$

Since there are no bounds on the length nor depth of plans, the final value of the global time cannot be bounded in advance.

This section describes how to overcome the above problem by proposing an equivalence relation between configurations. The key idea is that since time constraints are relative, that is, they involve the difference of two timestamps, we do not need to keep track of the actual values of timestamps, in order to determine whether our time constraints are satisfied or not.

Truncated time differences Many formal definitions and results in this paper mention an upper bound D_{max} on the numeric values of a given planning problem. This value is computed from the problem itself: we set D_{max} to be an upper bound on the numbers appearing explicitly in a given planning problem. This bound is essential in our approach to handling the unboundedness of time, and in particular, with technicalities related to facts denoting future, that is facts with timestamps that are greater than the global time, which we explain in detail later on in this section.

In particular, instead of actual values of timestamps, we will store the time differences among the facts, but truncated by that upper bound. Formally, given a planning problem with the model \mathcal{T} , let D_{max} be a natural number such that $D_{max} > n + 1$ for any number n appearing in time constraints and actions in \mathcal{T} , and in the initial, goal and critical configurations. That is, D_{max} is the upper bound on any numeric value appearing either in a constraint ($T_i \circ T_j \pm n$, for $\circ \in \{<, >, =, \leq, \geq\}$), in a timestamp of a fact in some action (e.g. $F@(T + n)$), or in the timestamps of the initial configuration.

Then the *truncated time difference* of two timed facts $P@T_1$ and $Q@T_2$ with $T_1 \leq T_2$, denoted

by $\delta_{P,Q}$, is defined as follows:

$$\delta_{P,Q} = \begin{cases} T_2 - T_1, & \text{provided } T_2 - T_1 \leq D_{max} \\ \infty, & \text{otherwise} \end{cases} .$$

Intuitively, we can truncate time differences without sacrificing soundness nor completeness because time constraints are relative as defined in Eq. 1. Hence, if the time difference of two facts is greater than the upper bound D_{max} , then it does not really matter how much greater it is, but just that it is greater. For instance, consider the time constraint $t_1 \geq t_2 + d$ involving the timestamps of the facts $P@t_1$ and $Q@t_2$. If $\delta_{Q,P} = \infty$, this time constraint is necessarily satisfied.

Equivalence between configurations We use the notion of truncated time differences introduced above to formalize the following equivalence relation among configurations.

Definition 4.1. Given a planning problem with the *TLSTS* \mathcal{T} , let D_{max} be an upper bound on the numeric values appearing in \mathcal{T} and in the initial, goal and critical configurations. Let

$$\mathcal{S} = Q_1@T_1, Q_2@T_2, \dots, Q_m@T_m \quad \text{and} \quad \tilde{\mathcal{S}} = Q_1@\tilde{T}_1, Q_2@\tilde{T}_2, \dots, Q_m@\tilde{T}_m$$

be two configurations written in canonical way where the two sequences of timestamps T_1, \dots, T_m and $\tilde{T}_1, \dots, \tilde{T}_m$ are non-decreasing. (For the case of equal timestamps, we sort the facts in alphabetical order, if necessary.) Then \mathcal{S} and $\tilde{\mathcal{S}}$ are equivalent if for any $1 \leq i < m$ either of the following holds:

$$T_{i+1} - T_i = \tilde{T}_{i+1} - \tilde{T}_i \leq D_{max} \quad \text{or both} \quad T_{i+1} - T_i > D_{max} \quad \text{and} \quad \tilde{T}_{i+1} - \tilde{T}_i > D_{max} .$$

In order to illustrate the above equivalence, assume that $D_{max} = 3$ and consider the following two configurations:

$$\{R@3, P@4, Time@11, Q@12, S@14\} \quad \text{and} \quad \{R@0, P@1, Time@6, Q@7, S@9\} .$$

According to the above definition, these configurations are equivalent since their truncated time differences are the same. This can be observed by checking their *canonical* representation, called *δ -representation* defined below.

Definition 4.2. Let $\mathcal{S} = Q_1@T_1, Q_2@T_2, \dots, Q_m@T_m$ be a configuration written in canonical way where the sequence of timestamps T_1, \dots, T_m is non-decreasing (for the case of equal timestamps, we sort the facts in alphabetical order, if necessary) and let D_{max} be an upper bound in a planning problem (as per Definition 4.1). The *δ -representation* of configuration \mathcal{S} , denoted by $\delta_{\mathcal{S}}$, is the tuple

$$\langle Q_1, \delta_{Q_1, Q_2}, Q_2, \delta_{Q_2, Q_3}, Q_3, \dots, Q_i, \delta_{Q_i, Q_{i+1}}, Q_{i+1}, \dots, Q_{m-1}, \delta_{Q_{m-1}, Q_m}, Q_m \rangle .$$

A δ -representation is constructed from a given configuration by sorting its facts according to their timestamps and sorting facts in alphabetical order as tie-breaker. Then we compute the time difference among two consequent facts, $\delta_{Q_i, Q_{i+1}}$. For instance, both configurations given above have the following δ -representation:

$$\langle R, 1, P, \infty, Time, 1, Q, 2, S \rangle .$$

Here a value appearing between two facts, Q_i and Q_{i+1} , is the truncated time difference of the corresponding facts, $\delta_{Q_i, Q_{i+1}}$, e.g., $\delta_{R, P} = 1$ and $\delta_{P, \text{Time}} = \infty$. It is also easy to see that from the tuple above, one can compute the remaining truncated time differences. For instance, $\delta_{\text{Time}, S} = 3$, since $1 + 2 = 3$, while $\delta_{R, Q} = \infty$, since $1 + \infty + 1 = \infty$.

We now formalize the intuition described above that using time differences that are truncated by an upper bound instead of actual timestamps, we are able to determine whether a time constraint is satisfied or not.

Lemma 4.1. Let S and \tilde{S} be two equivalent configurations from Definition 4.1.

$$S = Q_1 @ T_1, Q_2 @ T_2, \dots, Q_n @ T_n \text{ and } \tilde{S} = Q_1 @ \tilde{T}_1, Q_2 @ \tilde{T}_2, \dots, Q_n @ \tilde{T}_n.$$

Then the following holds for all i and j such that $i > j$, and for all $a \leq D_{max}$:

$$\begin{aligned} T_i - T_j = a & \quad \text{if and only if} \quad \tilde{T}_i - \tilde{T}_j = a \\ T_i - T_j < a & \quad \text{if and only if} \quad \tilde{T}_i - \tilde{T}_j < a \\ T_i - T_j > a & \quad \text{if and only if} \quad \tilde{T}_i - \tilde{T}_j > a \end{aligned}$$

Proof. The only interesting case is the last one, which can be proved by using the fact that $a \leq D_{max}$ and that S and \tilde{S} are equivalent. Hence, $T_i - T_j > D_{max} > a$ is true if and only if $\tilde{T}_i - \tilde{T}_j > D_{max} > a$ is true, and $D_{max} \geq T_i - T_j > a$ is true if and only if $D_{max} \geq \tilde{T}_i - \tilde{T}_j > a$, since $T_i - T_j = \tilde{T}_i - \tilde{T}_j$. \square

Following Lemma 4.1, we say that a δ -representation Δ satisfies a constraint if a configuration W , such that $\delta_W = \Delta$, satisfies that constraint.

Handling time advances and action applications Our next task is to show that our equivalence relation using truncated time differences is well-defined with respect to actions. That is, we show that actions preserve the equivalence among configurations. This will allow us to represent plans using δ -representations only.

We extend action application to δ -representations. It follows from the Lemma 4.1 that the same action is applicable in configurations with the same δ -representation. We, therefore, say that an action is applicable in a δ -representation Δ if the same action is applicable in a configuration W , such that $\delta_W = \Delta$. That is, any action a that is applicable in some configuration S is applicable in its δ -representation δ_S , and the resulting δ -representation, $\delta_{S'}$, is the δ -representation of S' , where $S \rightarrow_a S'$:

$$\begin{array}{ccc} \delta_S & \rightarrow_a & \delta_{S'} \\ \wr & & \wr \\ S & \rightarrow_a & S' \end{array} \quad (4)$$

This is well defined if it is independent of the choice of configurations. Recall that there are two types of actions, namely time advances and instantaneous actions that belong to agents. Time advances only change the timestamp denoting the global time while the rest of the configuration remains unchanged. Therefore, when we advance time in a δ -representation, the position of *Time* and the truncated time differences involving *Time* need to be updated. Depending on concrete values of time differences, the fact *Time* may move to the right.

For example, for $D_{max} = 5$ and the configuration $\{R@0, P@1, \text{Time}@3, Q@5, S@7\}$ with

the time advance action $Time@T \rightarrow_{clock} Time@(T+1)$ we get

$$\{R@0, P@1, Time@3, Q@5, S@7\} \rightarrow_{clock} \{R@0, P@1, Time@4, Q@5, S@7\}$$

$$i.e. \quad \langle R, 1, P, 2, Time, 2, Q, 2, S \rangle \rightarrow_{clock} \langle R, 1, P, 3, Time, 1, Q, 2, S \rangle.$$

With another application of time tick action we then get:

$$\langle R, 1, P, 3, Time, 1, Q, 2, S \rangle \rightarrow_{clock} \langle R, 1, P, \infty, Q, 0, Time, 2, S \rangle.$$

Generally, the time advance action $Time@T \rightarrow_{clock} Time@(T+1)$ applied to

$$\Delta = \langle Q_1, \delta_1, \dots, Q_{i-1}, \delta_{i-1}, Time, \delta_i, Q_{i+1}, \delta_{i+1}, \dots, \delta_{m-1}, Q_m \rangle$$

results in the following δ -representation Δ' , alphabetically sorted whenever truncated time differences are equal to 0:

$$\begin{aligned} &\langle Q_1, \delta_1, \dots, Q_{i-1}, [\delta_{i-1} + 1], Time, \delta_i - 1, Q_{i+1}, \delta_{i+1}, \dots, \delta_{m-1}, Q_m \rangle, & \text{if } \delta_i \geq 1 \\ &\langle Q_1, \delta_1, \dots, Q_{i-1}, \delta_{i-1}, Q_{i+1}, \dots, Q_{i+l}, [\delta_{i+l} + 1], Time, \delta_{i+l} - 1, \dots, \delta_{m-1}, Q_m \rangle, \\ & & \text{if } \delta_i = \delta_{i+l-1} = 0, \delta_{i+l} > 0 \end{aligned}$$

where $[d]$ denotes d , for $d < D_{max}$, and denotes ∞ otherwise.

In case $\Delta = \langle Q_1, \delta_1, \dots, \delta_{m-1}, Time \rangle$, then $\Delta = \langle Q_1, \delta_1, \dots, [\delta_{m-1} + 1], Time \rangle$.

For the application of instantaneous actions recall that the fact $Time@T$ remains unchanged, while some facts from the pre-condition of the action are replaced with other facts whose timestamps are of the form $T+d$. We modify the δ -representation in the following way. We first remove the facts that appear in the pre-condition of the action and not in its post-condition. Then we insert the new facts from the post-condition, positioning them on the basis of their time difference to the fact $Time$, and alphabetically if necessary. Finally, we fill in the new time differences. This is best explained on an example. Consider the following δ -representation

$$\Delta = \langle B(d), 0, F(c), 1, G(a, b), 3, Time, 1, F(a), 2, F(d) \rangle$$

with $D_{max} = 3$ and the action

$$Time@T, G(x, y)@T_1, F(x)@T_2 \rightarrow \exists z. Time@T, G(y, z)@(T+1), F(y)@T$$

which is applicable to Δ with the substitution $\sigma(x) = a, \sigma(y) = b$. We remove those facts from the pre-condition that do not appear in the post-condition, namely $G(a, b)$ and $F(a)$, and get an expression

$$B(d), 0, F(c), 1, -, 3, Time, 1, -, 2, F(d).$$

Next we insert the facts that appear in the post-condition and not in the pre-condition. In our case above that is the fact $G(b, n)$, where n is a fresh value. The placement of these facts is determined by the timestamps appearing in the action, which are of the form $T+d$, where T is the global time. In our example the fact $G(b, n)$ comes with the timestamp $(T+1)$ and we get:

$$\langle B(d), 0, F(c), \infty, Time, 1, G(b, n), 2, F(d) \rangle.$$

after updating the truncated time differences. Notice that, for example, the relative time difference between facts $F(d)$ and $Time$ is still 3.

However, in order to prove that actions preserve the equivalence among configurations, we need

yet another assumption to be able to faithfully handle time advances. The problem lies within the *future facts*, that is, the facts with timestamps greater than the global time. If there is a future fact P such that $\delta_{\text{Time},P} = \infty$, then it is not the case that equivalence is preserved when we advance time. For example, consider the following two configurations equivalent with the upper bound $D_{max} = 3$:

$$\mathcal{S}_1 = \{Time@0, P@5\} \quad \text{and} \quad \mathcal{S}_2 = \{Time@0, P@4\}.$$

If we advance time on both configurations, then the resulting configurations, \mathcal{S}'_1 and \mathcal{S}'_2 , are not equivalent. In particular, the truncated time difference $\delta_{\text{Time},P}$ is still ∞ in \mathcal{S}'_1 , while it changes to 3 in \mathcal{S}'_2 . Notice that the same problem does not occur neither with present nor past facts, *i.e.*, the facts with timestamps that are smaller or equal to the global time.

Definition 4.3. Given an upper bound D_{max} in a planning problem (as per Definition 4.1), a configuration \mathcal{S} is called *future bounded* if for any future fact P in \mathcal{S} , the time difference $\delta_{\text{Time},P} \leq D_{max}$.

Recall from Section 2 that there are two types of actions, namely, the action that advances time and instantaneous actions belonging to agents. Moreover, recall that the latter actions are restricted in such a way that all created facts have timestamps of the form $T + d$, where T is the global time. This restriction allows us to show that actions preserve the future boundedness of configurations as states the following result.

Lemma 4.2. Let \mathcal{T} be a *TLSTS*, D_{max} be the upper bound in a planning problem (as per Definition 4.1), and \mathcal{S} be a future bounded configuration. Let \mathcal{S}' be the configuration obtained from \mathcal{S} by applying an arbitrary action in \mathcal{T} . Then \mathcal{S}' is also future bounded.

Proof. Let $\mathcal{S} \xrightarrow{a} \mathcal{S}'$, and assume \mathcal{S}' is not future bounded. Then there is a fact $Q'@T'$ in \mathcal{S}' such that $T' - T > D_{max}$, where T is the timestamp of *Time*, *i.e.* the global time in both \mathcal{S} and \mathcal{S}' . Since \mathcal{S} is future bounded, the fact $Q'@T'$ does not appear in \mathcal{S} , but is created by the action a . Hence, $T' = T + D$ for some number $D \leq D_{max}$, which contradicts with $T' - T > D_{max}$. \square

As per Definition 4.1 the initial configuration in a planning problem is future bounded, which as per above lemma implies that all configurations in a plan are also future bounded. Notice that even if we relax the assumption that the initial configuration is future bounded, we can make it future bounded by setting the value of D_{max} to be the greater than all the timestamps in the initial configuration, *i.e.*, D_{max} would still be the upper bound on the values of the given *TLSTS* and in the initial, goal, and critical configurations. The important result, given by the above lemma, is that future boundedness is preserved with action application.

Following Lemma 4.1 and Lemma 4.2, given a planning problem, we say that a δ -representation is an *initial / goal / critical / future bounded δ -representation* if it is the δ -representation of an initial / goal / critical / future bounded configuration. A *plan over δ -representations* is *compliant* for a given planning problem if it does not contain any critical δ -representations and if all of its branches lead from the initial δ -representation to a goal δ -representation.

We are now ready to show the main result of this section.

Theorem 4.1. For any given planning problem the equivalence relation between configurations given by Definition 4.1 is well-defined with respect to the actions of the system (including

time advances) and goal and critical configurations. Any plan starting from the given initial configuration can be conceived as a plan over δ -representations.

Proof. We first prove that the equivalence among configurations is well defined with respect to application of actions, *i.e.* that action application on δ -representations is unambiguous. It must be independent of the choice of configurations in (4). Consider the diagram below, where \mathcal{S}_1 and \mathcal{S}_2 are two equivalent configurations. Assume that \mathcal{S}_1 is transformed to \mathcal{S}'_1 by means of an action α . By Lemma 4.1 the configuration \mathcal{S}_2 also complies with the time constraints required in α , and hence the action α is applicable to \mathcal{S}_2 and will transform \mathcal{S}_2 into some \mathcal{S}'_2 . It remains to show that \mathcal{S}'_1 is equivalent to \mathcal{S}'_2 .

$$\begin{array}{ccc} \mathcal{S}_1 & \xrightarrow{\alpha} & \mathcal{S}'_1 \\ \wr & & \\ \mathcal{S}_2 & \xrightarrow{\alpha} & \mathcal{S}'_2 \end{array}$$

We consider our two types of actions, namely, time advances and instantaneous actions (see Section 2). Let the time advance transform \mathcal{S}_1 into \mathcal{S}'_1 , and \mathcal{S}_2 to \mathcal{S}'_2 . Since only the timestamp T denoting the global time in $Time@T$ is increased by 1, and the rest of the configuration remains unchanged, only truncated time differences involving $Time$ change in the resulting configurations. Because of the equivalence $\mathcal{S}_1 \sim \mathcal{S}_2$, for a fact $P@T_1^P$ in \mathcal{S}_1 with $T_1^P \leq T$, $Time@T$ and $\delta_{P,Time} = t$, we have $P@T_2^P$ with $T_2^P \leq \hat{T}$, $Time@\hat{T}$ and $\delta_{P,Time} = t$ in \mathcal{S}_2 as well. Therefore, we have $\delta_{P,Time} = [t + 1]$ both in \mathcal{S}'_1 and \mathcal{S}'_2 . On the other hand for any future fact $Q@T^Q$ with $\delta_{Time,Q} = t$ in \mathcal{S}_1 and in \mathcal{S}_2 , we get $\delta_{Time,Q} = t - 1$ in both \mathcal{S}'_1 and \mathcal{S}'_2 . Therefore, \mathcal{S}'_1 and \mathcal{S}'_2 are equivalent. From Lemma 4.2, we have that both \mathcal{S}'_1 and \mathcal{S}'_2 are future bounded.

For the second type of actions, namely the instantaneous actions belonging to agents, the reasoning is similar. Each created fact in the configuration \mathcal{S}'_1 and \mathcal{S}'_2 will be of the form $P@(T^1 + d)$ and $P@(T^2 + d)$, where T^1 and T^2 represent global time in \mathcal{S}_1 and \mathcal{S}_2 , respectively. Therefore each created fact has the same difference d to the global time in the corresponding configuration. This implies that the created facts have the same truncated time differences to the remaining facts. Hence \mathcal{S}'_1 and \mathcal{S}'_2 are equivalent. Therefore, action application on δ -representations shown in (4) is well defined.

Finally, as per Lemma 4.1, \mathcal{S}_1 is a goal (respectively, critical) configuration if and only if \mathcal{S}_2 is a goal (respectively, critical) configuration.

By induction on the length of the plan, it immediately follows that, given a planning problem, any compliant plan over configurations can be represented by a compliant plan over δ -representations. That is, the abstraction of configurations to δ -representations is complete.

It remains to show that the abstraction is also sound, namely that, from a compliant plan over δ -representations for a given planning problem, we can extract a concrete plan over configurations and that such a plan is compliant with respect to that planning problem. Any given δ -representation corresponds to an infinite number of configurations. For example, for the δ -representation $\langle Q_1, \delta_1, Q_2, \dots, Q_{m-1}, \delta_{m-1}, Q_m \rangle$, one of the corresponding configurations is

$$\{Q_1@0, Q_2@\tilde{\delta}_1, Q_3@(\tilde{\delta}_1 + \tilde{\delta}_2), \dots, Q_m@(\tilde{\delta}_1 + \dots + \tilde{\delta}_{m-1})\}$$

where $\tilde{\delta}_i = \delta_i$ if $\delta_i \leq D_{max}$, and $\tilde{\delta}_i = D_{max} + 1$ if $\delta_i = \infty$. We are, however, already given the initial configuration W_0 in the planning problem, for which we have $\Delta_0 = \delta_{W_0}$.

We prove the existence of a plan over configurations by induction on the length of the plan over δ -representations. Let $\Delta_0 \rightarrow_{a_1} \Delta_1 \rightarrow_{a_2} \cdots \rightarrow_{a_n} \Delta_n$ be a plan over δ -representations, compliant with the respect to the given planning problem. Then Δ_0 is the δ -representation of the initial configuration, *i.e.* $\Delta_0 = \delta_{W_0}$. For each $\Delta_{i-1} \rightarrow_{a_i} \Delta_i$, as per Lemma 4.1, since $\Delta_{i-1} = \delta_{W_{i-1}}$, the same action a_i is applicable to the configuration W_{i-1} , resulting in W_i . As proven above, and shown in (4), it follows that $\Delta_i = \delta_{W_i}$:

$$\begin{array}{ccccccc}
 \delta_{W_0} & & \delta_{W_{i-1}} & & \delta_{W_i} & & \delta_{W_n} \\
 \parallel & & \parallel & & \parallel & & \parallel \\
 \Delta_0 & \rightarrow_{a_1} \cdots \rightarrow_{a_{i-1}} & \Delta_{i-1} & \rightarrow_{a_i} & \Delta_i & \rightarrow_{a_{i+1}} \cdots \rightarrow_{a_n} & \Delta_n \\
 \wr & & \wr & & \wr & & \wr \\
 W_0 & \rightarrow_{a_1} \cdots \rightarrow_{a_{i-1}} & W_{i-1} & \rightarrow_{a_i} & W_i & \rightarrow_{a_{i+1}} \cdots \rightarrow_{a_n} & W_n
 \end{array}$$

Hence, we get a plan over configurations consisting of same sequence of actions as the given plan over δ -representations. Since none of the δ -representations $\Delta_i = \delta_{W_i}$ is critical, it is also the case that none of the configurations W_i is critical. Also, since $\Delta_n = \delta_{W_n}$ is the goal δ -representation, it follows that W_n is a goal configuration. Hence the plan $W_0 \rightarrow_{a_1} W_1 \rightarrow \cdots \rightarrow_{a_n} W_n$ is compliant with respect to the given planning problem. \square

The above theorem establishes that using δ -representations for writing plans is well defined, but it does not establish a bound on the number of δ -representations. To achieve this, we need the further assumption that all actions are balanced. Recall that balanced actions are actions that have the same number of facts in their pre- and post-conditions. By using balanced actions, the number of facts in any configuration of a plan is the same as the number of facts in the plan's initial configuration. Hence, as we describe in Section 5, we can establish that there is a finite number of δ -representations.

5. Complexity Results

This section enters into the details of the complexity of the planning problems for *TLST*Ses. These problems were introduced in (KRS11; KRS09) in the setting without explicit time or branching. At the end of Section 2 we have restated these problems in our setting with explicit time and branching. As already mentioned, different compliance problems are not always of the same computational complexity. For example, in the case of systems with non necessarily balanced actions and with no fresh values, system compliance is EXPSPACE-complete (KRS09), while the plan compliance problem is undecidable (KRS09). The system compliance problem becomes undecidable if the creation of fresh values is allowed in systems with possibly unbalanced actions (KBNS13). On the other hand, in balanced systems, even when fresh values are allowed both problems are PSPACE-complete (see Table 1). It is not a priori clear whether these problems are of the same complexity, nor what the complexity of each of the problems is, for the case of timed systems as well as for branching. We investigate the complexity of these variations of the planning problem next. Our complexity results for *TLST*Ses are summarized in Table 1.

Recall that facts are timestamped and that there is a finite, possibly empty set of time constraints attached to a timed initial, goal and critical configuration. Recall as well that for a given initial configuration W and a finite set of goal and critical configurations, we consider a branching plan

Table 1. Summary of the complexity results for the planning problems for balanced systems. We mark the new results appearing here with a \star .

Planning Problems	LSTSeS (No time, no branching)		TLSTSeS (Possible nonces)	
	No fresh values	Possible nonces	No branching	Possible branching
(Weak) Plan	PSPACE-complete (KRS11)	PSPACE-complete(KBNS10)	PSPACE-complete \star	EXPTIME-complete \star
System	PSPACE-complete (KRS11)	PSPACE-complete(KBNS10)	PSPACE-complete \star	EXPTIME-complete \star

\mathcal{P} compliant if it does not contain any critical configuration, and moreover if all branches of \mathcal{P} lead from configuration W to some goal configuration.

Throughout this section, we assume that all actions are balanced, *i.e.*, actions have the same number of facts in their pre and post-conditions, and that the size of facts is bounded.

5.1. Planning Problems for TLSTSeS with Non-Branching Actions only

We first investigate the complexity of planning problems for TLSTSeS when actions are non-branching and balanced and when the size of facts is bounded. We show that these problems are PSPACE-complete with respect to the parameters from the given planning problem.

PSPACE-hardness: It was shown in (KRS11; KBNS10) that one can faithfully encode a Turing machine with a fixed size tape using systems with balanced actions. In short, a configuration of a Turing machine is represented by a TLSTS configuration and to each instruction of a machine corresponds a sequence of balanced rewrite rules. The same idea works in our setting with time. It is easy to modify the encoding in (KRS11). Timestamps do not play any important role in such encoding. Also, critical configurations are not necessarily used in the encoding, so we can conclude that all three planning problems and the reachability problem for TLSTSeS with non-branching balanced actions and facts of bounded size are PSPACE-hard.

PSPACE upper bound: It is more interesting to show that the planning problems are in PSPACE when the size of facts is bounded and actions are non-branching and balanced. In particular, we will now use all the machinery introduced in Section 4 by using δ -representations of configurations to search for compliant plans.

In order to determine the existence of a compliant plan, it is enough to consider plans that never reach configurations with the same δ -configuration twice. If a plan reaches a configuration whose δ -representation is the same as a previously reached configuration, there is a cycle of actions which could have been avoided. The following lemma imposes an upper bound on the number of different δ -representations in a plan, given an initial finite alphabet. Such an upper bound provides us with the maximal length of a plan one needs to consider.

Lemma 5.1. Given a TLSTS \mathcal{T} under a finite alphabet Σ , an upper bound on the size of facts, k , and an upper bound, D_{max} , on the numeric values appearing in the planning problem, namely, in \mathcal{T} and in the initial, goal and critical configurations, then the number of different δ -representations,

denoted by $L_T(m, k, D_{max})$, with m facts (counting repetitions) is such that

$$L_T(m, k, D_{max}) \leq (D_{max} + 2)^{(m-1)} J^m (D + 2mk)^{mk},$$

where J and D are, respectively, the number of predicate symbols and the number of constant and function symbols in the initial alphabet Σ .

Proof. Let $\langle Q_1, \delta_{Q_1, Q_2}, Q_2, \dots, Q_{m-1}, \delta_{Q_{m-1}, Q_m}, Q_m \rangle$ be a δ -representation with m facts. There are m slots for predicate names and at most mk slots for constants and function symbols. Constants can be either constants in the initial alphabet Σ or names for fresh values (nonces). Following (KBNS10), we need to consider only $2mk$ names for fresh values (nonces). Finally, only time differences up to D_{max} have to be considered together with the symbol ∞ and there are $m - 1$ slots for time differences in a δ -representation. \square

Intuitively, our upper bound algorithm keeps track of the length of the plan it is constructing and if the length of such a plan exceeds $L_T(m, k, D_{max})$, then the same δ -representation has been reached twice. This is possible in PSPACE since the number of different δ -representations given above, when stored in binary, occupies only polynomial space with respect to its parameters.

For the below results, we assume that, given a $TLSTS$ \mathcal{T} , and a finite set of goal and critical configurations, it is possible to check in polynomial space whether a configuration is critical, whether it is a goal configuration, and whether an action is valid, *i.e.* whether it is an instance of an action from \mathcal{T} that is applicable in a given configuration.

Theorem 5.1. Let \mathcal{T} be a $TLSTS$ with balanced non-branching actions. Then the plan compliance problem is in PSPACE with respect to m, k , and $\log_2 D_{max}$, where m is the number of facts in the initial configuration, k is the upper bound on the size of facts, and D_{max} is the upper bound on the numeric values appearing in the model \mathcal{T} , and in the initial, goal and critical configurations.

Proof. Assume given three programs, \mathcal{C}, \mathcal{G} , and \mathcal{A} , such that they return the value 1 in polynomial space when given as input, respectively, a configuration that is critical, a configuration that contains the goal configuration, and a pair of a configuration and a transition that is valid, that is, an instance of an action in the $TLSTS$ \mathcal{T} is applicable to the given configuration, and return 0 otherwise.

Let m be the number of facts in the initial configuration W . Moreover, assume as inputs an upper bound, k , on the size of facts, an upper bound, D_{max} , on the numeric values appearing in the planning problem, that is in the given $TLSTS$ \mathcal{T} , in the initial, goal and critical configurations, programs \mathcal{G}, \mathcal{C} , and \mathcal{A} , as described above, and a natural number $0 \leq i \leq L_T(m, k, D_{max})$.

We modify the algorithm proposed in (KBNS10) in order to accommodate explicit time. The algorithm must return “yes” (*i.e.* ACCEPT) whenever there is compliant plan from the initial configuration W to a goal configuration, that is a configuration S such that $\mathcal{G}(S) = 1$. In order to do so, we construct an algorithm that searches non-deterministically whether such a configuration is *reachable*. Then we apply Savitch’s Theorem to determinize this algorithm. However, instead of searching for a plan using concrete values, we rely on the equivalence described in Section 4 and use δ -representations only. Theorem 4.1 guarantees that this abstraction is sound and faithful.

From \mathcal{G}, \mathcal{C} , and \mathcal{A} , it is easy to construct new functions $\mathcal{G}', \mathcal{C}'$, and \mathcal{A}' that use δ -representations instead of configurations. In particular, since time constraints associated to goal and critical

configurations are also relative, these can be checked by using the truncated time differences in δ -representations.

The algorithm begins with W_0 set to be the δ -representation of W and iterates the following sequence of operations:

- 1 If W_i is representing a critical configuration, *i.e.*, if $C'(W_i) = 1$, then return FAIL, otherwise continue;
- 2 If W_i is representing a goal configuration, *i.e.*, if $\mathcal{G}'(W_i) = 1$, then return ACCEPT; otherwise continue;
- 3 If $i > L_T(m, k, D_{max})$, then FAIL; else continue;
- 4 Guess non-deterministically an action, r , from \mathcal{T} applicable to W_i , *i.e.*, $\mathcal{A}'(W_i, r) = 1$. If no such action exists, then return FAIL. Otherwise replace W_i with the δ -representation W_{i+1} resulting from applying the action r to the δ -representation W_i . This is done as expected, by updating the facts, updating the positions of facts and the corresponding truncated time differences and continue;
- 5 Set $i = i + 1$.

We now show that this algorithm runs in polynomial space. We start with the step-counter i : The greatest number reached by this counter is $L_T(m, k, D_{max})$. When stored in binary encoding, this number takes only space polynomial in the given inputs:

$$\log(L_T(m, k, D_{max})) \leq (m - 1) \log(D_{max} + 2) + m \log(J) + mk \log(D + 2mk).$$

Therefore, one only needs polynomial space to store the values in the step-counter.

We must also be careful to check that any δ -representation, W_i , can be stored in polynomial space to the given inputs. Since our system is balanced, the size of facts is bounded, and the values of the truncated time differences are bounded, hence the size of any δ -representation, $\langle Q_1, \delta_{Q_1, Q_2}, Q_2, \dots, Q_{m-1}, \delta_{Q_{m-1}, Q_M}, Q_M \rangle$, in a plan is polynomially bounded.

Finally, the algorithm needs to keep track of the action r guessed when moving from one configuration to another and for the scheduling of a plan. It has to store the action that has been used at the i^{th} step. Since any action can be stored by remembering two δ -representations, one can also store these actions in space polynomial in the inputs. \square

The reachability problem is an instance of the plan compliance problem with an empty set of critical configurations, hence the reachability problem for TLSTSes with balanced non-branching actions is in PSPACE as well.

Next we turn to system compliance problem. Recall that besides the existence of a compliant plan it is additionally requested that no critical configuration is reachable by any sequence of actions in the given system.

Theorem 5.2. Let \mathcal{T} be a TLSTS with balanced non-branching actions. Then the system compliance problem is in PSPACE with respect to m , k , and $\log_2 D_{max}$, where m is the number of facts in the initial configuration, k is the upper bound on the size of facts, and D_{max} is the upper bound on the numeric values appearing in the model \mathcal{T} , and in the initial, goal and critical configurations.

Proof. In order to show that the system compliance problem is in PSPACE we modify the algorithm proposed in (KRS11) to accommodate timestamps and time constraints. Again we rely

on the fact that NPSpace, PSPACE, and co-PSPACE are all the same complexity class. We use the same notation from the proof of Theorem 5.1 and make the same assumptions. In particular, we use the algorithms \mathcal{G}' , \mathcal{C}' , and \mathcal{A}' that run in polynomial space and that check whether a timed configuration is a goal configuration, a critical configuration, or if an action is valid in the given TLSTS \mathcal{T} . Again we rely on the equivalence between configurations described in Section 4 and use δ -representations only. Theorem 4.1 guarantees us that this abstraction is sound and faithful.

We first need to check that none of the critical configurations is reachable from the initial configuration W . To do this we provide a non-deterministic algorithm which returns “yes” exactly when a critical configuration is reachable. The algorithm starts with W_0 set to be the δ -representation of W . For any $i \geq 0$, we first check if $\mathcal{C}'(W_i) = 1$. If this is the case, then the algorithm outputs “yes”. Otherwise, we guess an action r such that $\mathcal{A}'(r) = 1$ and that it is applicable to the δ -representation W_i . If no such action exists, then the algorithm outputs “no”. Otherwise, we replace W_i with the δ -representation W_{i+1} resulting from applying the action r to δ -representation W_i . This is done as expected, by updating the positions of facts and the corresponding truncated time differences. Following Lemma 5.1 we know that at most $L_T(m, k)$ guesses are required, and therefore we use a global step-counter to keep track of the number of actions. As shown in the proof of Theorem 5.1, the value of this counter can be stored in PSPACE.

Next we apply Savitch’s Theorem to determinize the algorithm. Then we swap the accept and fail conditions to get a deterministic algorithm which accepts exactly when all critical configurations are unreachable.

Finally, we have to check for the existence of a compliant plan. For that we apply the same algorithm as for the timed plan compliance problem from Theorem 5.1, skipping the checking of critical states since we have already checked that no critical configurations is reachable from W . From what has been shown above we conclude that the algorithm runs in polynomial space. Therefore the system compliance problem is in PSPACE. \square

5.2. Planning Problems for TLSTSes with possibly Branching Actions

We now consider the plan compliance problem when actions may be branching. In particular, we show that when actions are balanced then the plan compliance problem is EXPTIME-complete with respect to the number of facts, m , in the initial configuration, the upper bound, k , on the size of facts, the upper bound, D_{max} , on the numbers explicitly appearing in the planning problem, and the upper bound, p , on the number of post-conditions of an action. For these complexity results we use alternating Turing machines (CKS81).

An alternating Turing machine (ATM) is a non-deterministic Turing machine with states that are either existential or universal states. An alternating Turing machine in an existential state accepts if *some* transition from that state leads to an accepting state, while an alternating Turing machine in a universal state accepts if *every* transition from that state leads to an accepting state. Configurations of ATMs, as with standard Turing machines, consist of a tape contents, head position and a state. Computations of alternating Turing machines can be represented as trees, which is similar to the representation of branching plans in TLSTSes.

EXPTIME-hardness: The lower bound for the plan compliance problem can be inferred from a similar lower bound described in (KV01). It was shown that one can encode alternating Turing

machines by using propositional actions that are balanced and branching. Time does not play an important role for that encoding.

EXPTIME upper bound: Our upper bound algorithm uses an alternating Turing machine. In particular, we show that the plan compliance problem is in alternating-PSPACE (APSPACE) with respect to the number of facts, m , in the initial configuration, the upper bound on the size of facts, k , the upper bound, D_{max} , on the numbers appearing explicitly in the planning problem, and the upper bound, p , on the number of post-conditions of any action. That is, an alternating Turing machine can solve the plan compliance problem using polynomial space. From the equivalence between APSPACE and EXPTIME shown in (CKS81), we can infer that the plan compliance problem is in EXPTIME with respect to the same parameters.

We also assume here that, given a $TLSTS$, and a finite set of goal and critical configurations, it is possible to check in APSPACE whether a δ -representation is a goal δ -representation or a critical δ -representation and whether an action is valid, *i.e.* whether it is an instance of an action from \mathcal{T} that is applicable in the given δ -representation.

Theorem 5.3. Let \mathcal{T} be a $TLSTS$ with balanced actions. Then the plan compliance problem is in EXPTIME with respect to m , k , and $\log_2 D_{max}$, and p , where m is the number of facts in the initial configuration, k is the upper bound on the size of facts, D_{max} is the upper bound on the numeric values appearing in the model \mathcal{T} , and in the initial, goal and critical configurations, and p is the upper bound on the number of post-conditions of actions in \mathcal{T} .

Proof. We exploit the fact that the complexity classes APSPACE and EXPTIME are equivalent (CKS81) and show that the plan compliance problem can be solved by an alternating Turing machine in polynomial space.

As with the proof of Theorem 5.1, we rely on the equivalence relation described in Section 4 by using the δ -representations of configurations. Theorem 4.1 ensures that such an abstraction is sound and complete.

We define the following function $\text{FIND}(i, X)$, which takes a natural number, i , specifying the depth of a plan and a δ -representation, X , and returns ACCEPT if a compliant plan of depth i starting from X exists, and returns FAIL otherwise. Recall from Lemma 5.1 that it suffices to consider plans of depth bounded by $L_T(m, k, D_{max})$. Our upper bound algorithm is the following: Initialize $i = L_T(m, k, D_{max})$ and W_i as the δ -representation of the initial configuration W . Then proceed as follows:

- 1 If W_i is a critical δ -representation then FAIL, else continue;
- 2 If W_i is a goal δ -representation, then ACCEPT, else continue;
- 3 If $i = 0$ then FAIL, else continue;
- 4 Guess non-deterministically an action $X \mid \mathcal{Y} \rightarrow_A \exists x_1.X_1 \oplus \dots \exists x_n.X_n$, that is applicable to W_i , yielding δ -representations $W_{i-1}^1, \dots, W_{i-1}^n$;
If no such action exists return FAIL;
- 5 If all executions of $\text{FIND}(i-1, W_{i-1}^1), \dots, \text{FIND}(i-1, W_{i-1}^n)$ return ACCEPT, then return ACCEPT, otherwise return FAIL;

The fifth step is where we need the extra capabilities of an alternating Turing machine as we require that *all* executions of FIND return ACCEPT. Given the proof of Theorem 5.1 and the

bound, p , on the number of post-conditions of actions, it is easy to check that the alternating Turing machine runs in polynomial space. \square

Theorem 5.4. Let \mathcal{T} be a TLSTS with balanced actions. Then the system compliance problem is in EXPTIME with respect to m , k , and $\log_2 D_{max}$, and p , where m is the number of facts in the initial configuration, k is the upper bound on the size of facts, D_{max} is the upper bound on the numeric values appearing in the model \mathcal{T} , and in the initial, goal and critical configurations, and p is the upper bound on the number of post-conditions of actions in \mathcal{T} .

Proof. Similar to proof of Theorem 5.2 we first check that a critical δ -representation is not contained in any tree of actions of the system with the root W . As per Lemma 5.1 it is enough to consider trees of depth bounded by $L_T(m, k, D_{max})$.

For that search we define the function CHECK(i, X), which takes a natural number, i , specifying the depth of a tree and a δ -representation, X and returns ACCEPT if a critical δ -representation cannot be reached from X in a tree of depth i , and returns FAIL otherwise. The function CHECK(i, W_i) is defined as follows: We initialize $i = L_T(m, k, D_{max})$ and set W_i to be the δ -representation of the initial configuration W and proceed as follows:

- 1 If W_i is a critical δ -representation, then FAIL, else continue;
- 2 If $i = 0$ then ACCEPT, else continue;
- 3 Guess non-deterministically an action $X \mid \mathcal{Y} \rightarrow_A \exists x_1.X_1 \oplus \dots \exists x_n.X_n$, that is applicable to W_i , yielding δ -representations $W_{i-1}^1, \dots, W_{i-1}^n$;
If no such action exists return ACCEPT;
- 4 If all of the executions of CHECK($i - 1, W_{i-1}^1$), \dots , CHECK($i - 1, W_{i-1}^n$) return ACCEPT, then return ACCEPT, otherwise FAIL.

The forth step is where we use the extra capabilities of an alternating Turing machine as we require that *all* executions return ACCEPT. Consequently, it will return FAIL if *any* execution of CHECK returns FAIL, *i.e.* if any branch reaches a critical δ -representation.

Then, if the function CHECK returned FAIL our upper bound algorithm stops and returns FAIL. Otherwise the algorithm proceeds by checking for the existence of a compliant plan as per algorithm given in the proof of Theorem 5.3. In case FIND($0, W_0$) = ACCEPT the algorithm returns ACCEPT, and returns FAIL otherwise.

Given the proof of Theorem 5.1 and the bound, p , on the number of post-conditions of actions, it is easy to check that the alternating Turing machine runs in polynomial space. Since the above algorithm is in APSPACE, it is in EXPTIME. We can conclude that the system compliance problem for systems with possibly branching actions is in EXPTIME. \square

As mentioned in Section 2, in addition to checking for the existence of a plan in the given planning problem, we are also able to schedule a plan in all of the above cases. We take the additional input j and, in the case a compliant plan exists, we output the j -th action of the plan. For our PSPACE results from Section 5.1, we store the action for which the counter i is equal to j . Since an action can be stored as two δ -configurations, we can remember the j -th action in polynomial space with respect to inputs. For our EXPTIME results from Section 5.2, we assume given the tree traversal procedure and in case the compliant plan exists, following our algorithm we run the fixed traversal strategy and output the j -th action.

6. Relaxing the restrictions on TLSTsEs

In the previous section, we demonstrated that several problems, including the reachability problem, are decidable (PSPACE-complete or EXPTIME-complete) when assuming that actions have the following restrictions:

- 1 All actions are Balanced;
- 2 The timestamps of all facts created by an action are of the form $T + d$, where T is the current time and d a natural number;
- 3 Time constraints of an action are of the form show in Eq. 1, *i.e.*, $T_1 = T_2 \pm d$, $T_1 > T_2 \pm d$, or $T_1 \geq T_2 \pm d$, involving exactly two timestamps and a natural number d .

Besides the intuitions given in Section 2 for these restrictions, we show in this section that relaxing any one of these restrictions leads to the undecidability of the reachability problem. The undecidability of the reachability problem implies the undecidability of the planning problems we study in Section 5.

Kanovich *et al.* (KRS09) have already shown that the reachability problem is undecidable when unbalanced actions are allowed. Thus, we show that the two remaining conditions are indeed necessarily for the decidability of the reachability problem. In Section 6.1, we demonstrate that if we only relax condition 2 above, then the reachability problem is undecidable in general, while in Section 6.2 we show that if we only relax condition 3 above then the reachability is also undecidable in general. In order to obtain these undecidability results, we show that the reachability problem can be reduced to the termination problem of a two counter Minsky machine, which is known to be undecidable (MM61). We briefly review Minsky machines:

A Two-Counter Machine proposed by Minsky (MM61) is a machine that contains two registers r_1 and r_2 , a set of states, \mathcal{S} , and a set of instructions, Ψ . A configuration of a Minsky machine is a tuple $\langle k, i, j \rangle$, where k is the state of the machine, i is the value stored in the register r_1 and j the value stored in the register r_2 .

There are only four types of instructions each of them leading from one state, k , to another state, j or j_1 or j_2 , but with the following side effects on the value of registers:

- **(Add r_i)** ins_k : $r_i = r_i + 1$; **goto** ins_j ;
- **(Subtract r_i)** ins_k : $r_i = r_i - 1$; **goto** ins_j ;
- **(0-test r_i)** ins_k : **if** $r_i = 0$ **goto** ins_{j_1} **else goto** ins_{j_2} ;
- **(Jump)** ins_k : **goto** ins_j ;

(1) An Add r_i instruction increments the register r_i ; (2) A Sub r_i instruction is applicable only when r_i has a positive number and decrements it; (3) A 0-test r_i instruction is a branching instruction leading to one state if r_i contains zero and to another state otherwise; finally (4) a Jump instructions simply moves from one state to another without changing the values stored in the registers. Minsky showed that the problem of determining whether a final state, a_0 , is reachable from an initial state is undecidable. We assume, with loss of generality, that in the initial state the registers r_1 and r_2 are set to zero.

6.1. Relaxing Advances of Timestamps

This section shows that by relaxing the restriction that timestamps of facts created by actions should be necessarily of the form $T + d$, where T is the current time of the enabling configuration

and d a natural number. We generalize actions to be of the following form:

$$\begin{aligned} & \text{Time}@T, W, P_1(\vec{c}_1)@T_1, \dots, P_n(\vec{c}_n)@T_n \mid \Upsilon \rightarrow_A \\ & \exists u. \text{Time}@T, W, P'_1(\vec{c}'_1)@(T + f_1(T_1, \dots, T_n)), \dots, P'_m(\vec{c}'_m)@(T + f_m(T_1, \dots, T_n)), \end{aligned}$$

where in the timestamps of the created facts a polynomial $f_i(T_1, \dots, T_n)$ is added to the global time, T . Polynomial $f_i(T_1, \dots, T_n)$ may contain timestamps T_1, \dots, T_n that appear as timestamps of facts in the precondition of the action. We say that such an action is *linearly-time-advancing* if all polynomials $f_i(T_1, \dots, T_n)$ are linear.

Given the actions of the above form, we show that the reachability problem for these systems is undecidable already for systems with balanced actions that are linearly-time-advancing. This means that all compliance problems discussed in Section 2 are also undecidable for such systems.

Theorem 6.1. Given a TLSTS with balanced and linearly-time-advancing actions, the reachability problem is undecidable.

Proof. The proof is obtained by reducing the reachability problem of TLSTSeS with actions that are balanced and linearly-time-advancing to termination of Minsky machines. We encode an arbitrary Minsky machine M as follows:

For each state label k , we associate a zero arity predicate St_k , called state fact, denoting the current state of the machine. Moreover, we use two zero arity predicates R_1 and R_2 to keep track of the value stored in the registers r_1 and r_2 , respectively. Our actions will enforce that at any given configuration there is exactly one state fact and exactly one occurrence of a R_1 and a R_2 fact. We encode the values stored in the registers r_1 and r_2 , by using the timestamps of the state facts, and by using the facts R_1 and R_2 appearing in a configuration as follows:

If $St_k@T$, $R_1@T_1$ and $R_2@T_2$ are the occurrences of the state fact and R_1, R_2 in a configuration, then such a configuration specifies that the machine is in state k , the value stored in the register r_1 is $(T_1 - T)$ and the value in r_2 is $T - T_2$. For instance, the following configuration $\{\text{Time}@7, St_a@1, R_1@3, R_2@5\}$ specifies M 's configuration $\langle a, 3, 5 \rangle$.

Each of M 's instructions is encoded by the corresponding balanced linearly-time-advancing actions. The actions of the encoding have the following shape:

$$\begin{aligned} & \text{(Add } r_1) \text{Time}@T, St_k@T_1, R_1@T_2, R_2@T_3 \rightarrow_A \\ & \quad \text{Time}@T, St_j@T, R_1@(T + T_2 - T_1 + 1), R_2@(T + T_3 - T_1) \\ & \text{(Add } r_2) \text{Time}@T, St_k@T_1, R_1@T_2, R_2@T_3 \rightarrow_A \\ & \quad \text{Time}@T, St_j@T, R_1@(T + T_2 - T_1), R_2@(T + T_3 - T_1 + 1) \\ & \text{(0-test } r_1 \text{ if) Time}@T, St_k@T_1, R_1@T_2, R_2@T_3 \mid \{T_1 = T_2\} \rightarrow_A \\ & \quad \text{Time}@T, St_{j_1}@T, R_1@T, R_2@(T + T_3 - T_1) \\ & \text{(0-test } r_1 \text{ else) Time}@T, St_k@T_1, R_1@T_2, R_2@T_3 \mid \{T_1 < T_2\} \rightarrow_A \\ & \quad \text{Time}@T, St_{j_2}@T, R_1@(T + T_2 - T_1), R_2@(T + T_3 - T_1) \\ & \text{(0-test } r_2 \text{ if) Time}@T, St_k@T_1, R_1@T_2, R_2@T_3 \mid \{T_1 = T_3\} \rightarrow_A \\ & \quad \text{Time}@T, St_{j_1}@T, R_1@(T + T_2 - T_1), R_2@T \\ & \text{(0-test } r_2 \text{ else) Time}@T, St_k@T_1, R_1@T_2, R_2@T_3 \mid \{T_1 < T_3\} \rightarrow_A \\ & \quad \text{Time}@T, St_{j_2}@T, R_1@(T + T_2 - T_1), R_2@(T + T_3 - T_1) \\ & \text{(Jump) Time}@T, St_k@T_1, R_1@T_2, R_2@T_3 \rightarrow_A \\ & \quad \text{Time}@T, St_j@T, R_1@(T + T_2 - T_1), R_2@@(T + T_3 - T_1) \end{aligned}$$

It is easy to show that each action faithfully encodes the corresponding instruction in M . For

instance, consider the first action above encoding an (**Add** r_1) instruction. At the precondition the values stored in the registers r_1 and r_2 are, respectively, $T_2 - T_1$ and $T_3 - T_1$. In the post-condition, however, since the facts have to advance in time, the timestamp of the fact St_j , denoting the next instruction, is changed to the current global time T . Therefore, the timestamps of the facts R_1 and R_2 have to be updated to $T + T_2 - T_1 + 1$ and $T + T_2 - T_1$, where the value in the register r_1 is increased by one. Also notice that (**0-test** r_i) instructions are split into two actions: one for the case when the test is satisfied ((**0-test** r_i **if**) and the other for the case when the test is not satisfied (**0-test** r_i **else**). The goal is to reach a configuration that reaches the final state a_0 , which is encoded by the fact St_{a_0} .

For soundness, the only problem could be with the action that advances the global time. However, since all actions above take into account the global time and recompute the timestamps of R_1 and R_2 so that they correspond to the correct values stored in the respective registers, the system is sound. For completeness, one can show that if we do not advance time, the values of the timestamps of R_1 and R_2 correspond exactly to the values stored by the registers r_1 and r_2 , since the timestamps of facts St_k , encoding instructions, are always zero. Hence, the encoding in our system is complete.

Finally, notice that we do not require critical configurations, we use only one agent A , and no actions above updates values with fresh ones. \square

Since the reachability problem is undecidable and in the proof we do not make use of any critical states, all of the compliance problems mentioned in Section 2 are undecidable.

Corollary 6.1. Given a *TLSTS* with balanced actions that are linearly-time-advancing, then the plan compliance and the system compliance problems are undecidable.

6.2. Relaxing Time Constraints

Instead of relaxing the timestamps of the facts in the post-condition, we now relax the form of time constraints in the guard of actions and investigate the complexity of the reachability problem for such systems. Recall that in our models, *TLSTSes*, time constraints are necessarily of the form $T_1 \circ T_2 + d$, where $\circ \in \{>, \geq, =, <, \leq\}$ and d is a natural number. We relax this condition by allowing actions to contain constraints of the form $T_1 \circ f(T_1, \dots, T_n)$, where f is a linear polynomial and T_1, \dots, T_n are the timestamps appearing in the precondition of the corresponding action. We call this type of actions *linearly-constrained actions*. We show that the reachability problem for *TLSTSes* with balanced and linearly constrained actions is also undecidable.

Theorem 6.2. Given a *TLSTS* with balanced and linearly-constrained actions, then the reachability problem is undecidable.

Proof. As in the proof of Theorem 6.1, we reduce the reachability problem for *TLSTSes* to the termination of an arbitrary Minsky Machine M .

As in the proof of Theorem 6.1, the difference between the timestamps of R_1 (respectively, R_2) and St_k will denote the value of the register r_1 (respectively, r_2). We also use the auxiliary predicate Aux , and a predicate $Update_i^\gamma$ for each instruction γ and $i \in \{1, 2\}$ together with the *Time* predicate to encode the effects of the instructions of M , such as the instruction to add a

value to a register. The initial configuration consists of six facts with three copies of Aux .

$$\mathcal{I} = \{St_1@0, R_1@0, R_2@0, Aux@0, Aux@0, Aux@0, Time@0\}.$$

where we assume w.l.o.g. that the values in both registers is zero. A goal configuration is any configuration containing the facts $G = \{St_{a_0}@T_1, Aux@T_2, Aux@T_3, Aux@T_3\}$.

Each of M 's instructions is encoded using a collection of auxiliary actions. Consider the following instruction, γ , that adds the register r_1 :

$$\text{(Add } r_1) \text{ } ins_k: r_1 = r_1 + 1; \text{goto } ins_j$$

This instruction is encoded by the following four balanced and linearly-constrained actions:

$$\begin{aligned} \text{(Action } \gamma \text{ 1)} \quad & Time@T, R_1@T_1, R_2@T_2, St_k@T_3, Aux@T_4, Aux@T_5, Aux@T_6 \rightarrow_A \\ & Time@T, R_1@T_1, R_2@T_2, St_k@T_3, St_j@T, Update_1^\gamma@T, Update_2^\gamma@T \\ \text{(Action } \gamma \text{ 2)} \quad & Time@T, R_1@T_1, R_2@T_2, St_k@T_3, St_j@T_4, Update_1^\gamma@T_5 \mid \{T = T_4 + T_1 - T_3 + 1\} \rightarrow_A \\ & Time@T, R_1@T, R_2@T_2, St_k@T_3, St_j@T_4, Aux@T \\ \text{(Action } \gamma \text{ 3)} \quad & Time@T, R_1@T_1, R_2@T_2, St_k@T_3, St_j@T_4, Update_2^\gamma@T_5 \mid \{T = T_4 + T_2 - T_3\} \rightarrow_A \\ & Time@T, R_1@T_1, R_2@T, St_k@T_3, St_j@T_4, Aux@T \\ \text{(Action } \gamma \text{ 4)} \quad & Time@T, St_k@T_3, St_j@T_4, Aux@T_5, Aux@T_6 \rightarrow_A \\ & Time@T, St_k@T_3, Aux@T, Aux@T, Aux@T \end{aligned}$$

The first action is applicable only when the current state is k , specified by the fact $St_k@T_3$ in the enabling configuration. It replaces the Aux facts with $St_j@T, Update_1^\gamma@T, Update_2^\gamma@T$. The first fact encodes the new state j . Since the timestamp of St_j is T , whereas the values in the registers are computed with respect to the timestamp T_3 of St_k , namely $T_1 - T_3$ and $T_2 - T_3$, we need to update the timestamps of R_1 and R_2 to be relative to T . This is the purpose of the facts $Update_1^\gamma@T, Update_2^\gamma@T$ and of the second and the third action. The second action updates the timestamps of R_1 when the current time is exactly $T_4 + T_1 - T_3 + 1$, that is, the previous value stored in the register r_1 plus 1 and relative to the timestamp of St_j . The third action is similar and corresponds to updating the timestamp of R_2 . Only, after the second and third action have been applied can the fourth action be enabled and applied, as this requires two Aux facts in the precondition. The fourth action then simply forgets the previous state, k , by replacing St_k with Aux .

The actions encoding other type of instructions are similar. We show below the encodings of the instructions for Subtracting, instruction for the 0-test for the register r_1 and the JUMP instruction. The remaining actions for register r_2 are similar.

γ is a **Subtract instruction** for r_1 :

(Action γ 1) $Time@T, R_1@T_1, R_2@T_2, St_k@T_3, Aux@T_4, Aux@T_5, Aux@T_6 \mid \{T_1 > T_3\} \rightarrow_A$
 $Time@T, R_1@T_1, R_2@T_2, St_k@T_3, St_j@T, Update_1^\gamma@T, Update_2^\gamma@T$

(Action γ 2) $Time@T, R_1@T_1, R_2@T_2, St_k@T_3, St_j@T_4, Update_1^\gamma@T_5 \mid \{T = T_4 + T_1 - T_3 - 1\} \rightarrow_A$
 $Time@T, R_1@T, R_2@T_2, St_k@T_3, St_j@T_4, Aux@T$

(Action γ 3) $Time@T, R_1@T_1, R_2@T_2, St_k@T_3, St_j@T_4, Update_2^\gamma@T_5 \mid \{T = T_4 + T_2 - T_3\} \rightarrow_A$
 $Time@T, R_1@T_1, R_2@T, St_k@T_3, St_j@T_4, Aux@T$

(Action γ 4) $Time@T, St_k@T_3, St_j@T_4, Aux@T_5, Aux@T_6 \rightarrow_A$
 $Time@T, St_k@T_3, Aux@T, Aux@T, Aux@T$

γ is a **0-test instruction** for r_1 :

(Action γ 1 if) $Time@T, R_1@T_1, R_2@T_2, St_k@T_3, Aux@T_4, Aux@T_5, Aux@T_6 \rightarrow_A \mid T_1 = T_3$
 $Time@T, R_1@T, R_2@T_2, St_k@T_3, St_{j_1}@T, Aux@T_5, Update_2^\gamma@T$

(Action γ 1 else) $Time@T, R_1@T_1, R_2@T_2, St_k@T_3, Aux@T_4, Aux@T_5, Aux@T_6 \rightarrow_A \mid T_1 > T_3$
 $Time@T, R_1@T_1, R_2@T_2, St_k@T_3, St_{j_2}@T, Update_1^\gamma@T, Update_2^\gamma@T$

(Action γ 2) $Time@T, R_1@T_1, R_2@T_2, St_k@T_3, St_{j_i}@T_4, Update_1^\gamma@T_5 \mid \{T = T_4 + T_1 - T_3\} \rightarrow_A$
 $Time@T, R_1@T, R_2@T_2, St_k@T_3, St_{j_i}@T_4, Aux@T$

(Action γ 3) $Time@T, R_1@T_1, R_2@T_2, St_k@T_3, St_{j_i}@T_4, Update_2^\gamma@T_5 \mid \{T = T_4 + T_2 - T_3\} \rightarrow_A$
 $Time@T, R_1@T_1, R_2@T, St_k@T_3, St_{j_i}@T_4, Aux@T$

(Action γ 4) $Time@T, St_k@T_3, St_{j_i}@T_4, Aux@T_5, Aux@T_6 \rightarrow_A$
 $Time@T, St_k@T_3, Aux@T, Aux@T, Aux@T$

γ is a **Jump instruction**:

(Action γ 1) $Time@T, R_1@T_1, R_2@T_2, St_k@T_3, Aux@T_4, Aux@T_5, Aux@T_6 \rightarrow_A$
 $Time@T, R_1@T_1, R_2@T_2, St_k@T_3, St_j@T, Update_1^\gamma@T, Update_2^\gamma@T$

(Action γ 2) $Time@T, R_1@T_1, R_2@T_2, St_k@T_3, St_j@T_4, Update_1^\gamma@T_5 \mid \{T = T_4 + T_1 - T_3\} \rightarrow_A$
 $Time@T, R_1@T, R_2@T_2, St_k@T_3, St_j@T_4, Aux@T$

(Action γ 3) $Time@T, R_1@T_1, R_2@T_2, St_k@T_3, St_j@T_4, Update_2^\gamma@T_5 \mid \{T = T_4 + T_2 - T_3\} \rightarrow_A$
 $Time@T, R_1@T_1, R_2@T, St_k@T_3, St_j@T_4, Aux@T$

(Action γ 4) $Time@T, St_k@T_3, St_j@T_4, Aux@T_5, Aux@T_6 \rightarrow_A$
 $Time@T, St_k@T_3, Aux@T, Aux@T, Aux@T$

The auxiliary facts $Aux, Update_i^\gamma$ are necessary for the soundness and completeness of our encoding. In particular, actions can only be applied in the following order:

Action γ 1, $n \times$ *Clock*, **Action γ i**, $m \times$ *Clock*, **Action γ j**, $h \times$ *Clock*, **Action γ 4**

where n, m, k is a number of time advances, possibly zero, and $\{i, j\} = \{1, 2\}$, that is, either Action γ 1 is applied before Action γ 2 or vice-versa.

We can prove by induction on the size of plans that for a given Minsky machine M and its encoding \mathcal{T}_M as described above, then M reaches the final state a_0 if and only if \mathcal{T}_M reaches a goal configuration from the initial configuration \mathcal{L} .

Notice that we do not need any critical configurations.

Since the termination problem is undecidable, so is the reachability problem for *TLSTS*es with balanced and linearly-constrained actions. \square

We can conclude that since the reachability problem is undecidable and in the proof we do not make use of any critical states, all the compliance problems mentioned in Section 2 are undecidable for systems with balanced and linearly-constrained actions.

Corollary 6.2. Given a *TLSTS* with balanced actions that are linearly-constrained, then the plan compliance and the system compliance problems are undecidable.

7. Related Work

The specification of regulations has been the topic of many recent works. In (BDMN06; BMDS07; LMS09), a temporal logic formalism for modeling collaborative systems is introduced. In this framework, one relates the scope of privacy to the specific roles of agents in the system. For instance, a patient's test results, which normally should not be accessible to any agent, are accessible to the agent that has the role of the patient's doctor. We believe that our system can be adapted or extended to accommodate such roles depending on the scenario considered. In particular, it also seems possible to specify in our framework the health insurance scenario discussed in (LMS09). De Young *et al.* describe in (DGJ+10) the challenges of formally specifying the temporal properties of regulations, such as HIPAA and GLPA. They extend the temporal logic introduced in (BDMN06) with fixed point operators, which seem to be required in order to specify these regulations. A temporal logic to specify regulations, such as the FDA Code of Federal Regulations (CFR), as properties of traces abstractly representing the operations of an organization are given in (DJLS08). Notions of permissions and obligations are introduced to deal with regulatory sentences as conditions or exceptions to others. An algorithm to check conformance of audit logs to security and privacy policies expressed in a first-order logic with restricted quantification is presented in (GJD11). In the case of incomplete logs a residual policy is returned.

Temporal logics are suitable for specifying the temporal properties that need to be satisfied by the traces of a system's operation. Our approach starts with an executable specification of a system using rewriting logic, combined with a mechanism to specify and check properties of executions. Specifically, critical and goal configurations defined in the equational sublogic allow us to express properties needed for generating plans for patient visits, and for monitoring clinical investigations including FDA reporting regulations. Timestamps allow us to express both temporal properties and timing constraints. Moreover, this approach allows us to use existing rewriting tools, such as Maude (CDE+07), to implement our specifications and analyses.

The Petri nets (PNs) community has investigated many related problems involving time. In particular, the coverability problem of PNs is related to our partial goal reachability problem for *TLSTS*es of a simple form - without branching actions, or critical states, or fresh values (KRS09). In (dFRA+00), de Frutos Escrig *et al.* show decidability results for the coverability problem of a type of Timed PNs with discrete time. There seem to be connections between our timestamps of facts and their time (age) associated to tokens as well as connections between our time constraints and their time intervals labeling the arcs in these PNs. However, the complexity of their decision procedures is extremely high, as compared with our upper bounds. Notice that branching actions

and critical states are not considered there. Despite these connections, we did not find any work that captures exactly the model presented in this paper.

Real time systems differ from our setting since dense time domains, such as the real numbers, are required, while in our intended applications, such as clinical investigations, discrete numbers suffice. The models introduced in (AM04; KOS98; ÖM07) deal with the specification of real time systems and also explore the complexity of some problems. We give more detailed comparison with Timed Automata in the following section.

Kanovich *et al.* in (KOS98) propose a linear logic based framework for specifying and model-checking real time systems. In particular, they demonstrate fragments of linear logic for which safety problems are PSPACE-complete. Interestingly, their examples are all balanced which is in accordance to some of our conditions. However, as discussed in (DGP08), their model is limited since one is not allowed to specify properties which involve different timestamps. In our formalism, such properties can be specified using time constraints. In (ÖM07) conditions are identified for which the problem of checking whether a system satisfies a property, specified in linear temporal logic, is decidable. As their main application is for real time systems, they also assume dense time domains, although discrete time domains can also be accommodated. They identify non-trivial conditions on actions which allow one to abstract time and recover completeness. We are currently investigating whether a simpler definition of balanced actions and relative time constraints can provide more intuitive abstractions for systems with dense times.

7.1. Comparison with Timed Automata

Timed Automata (AD94) have been introduced as finite automata extended with real-time clocks two decades ago and have since well proved their significance. They have been successfully used for the verification of many systems involving real-time. It is impressive the amount of work and results that have been achieved, which also include powerful implementations and tools.

Our Timed Local State Transition Systems offer another framework for timed systems which enables us to formalize systems with explicit time including the regulations and the requirements in collaborative systems with confidentiality. While there are some similarities between Timed automata and our *TLSTS* formalism, as both involve time, there are also some important differences in both the constructs available in the language and also in the complexity results obtained, including the proofs.

We highlight some differences:

- Instead of only considering the reachability problem, we deal with more general and complicated planning problems, namely, the plan compliance and system compliance problems. Thus solutions to the tasks we are dealing with should intertwine the *positive features*, that is to reach a goal, with the *negative features* - only those solutions that do not go through any critical states are acceptable;
- As we illustrated in the paper, the use of actions with non-deterministic effects (branching actions) is also an important feature of *TLSTSes*, allowing one to reason with a wider range of systems and problems. It does not seem possible to model such actions using Timed Automata;
- We allow actions to create fresh values or nonces. This is an important feature of our model enabling us to specify and verify security protocols (KBNS13; KBNS10) and other processes that require unique identification such as our clinical trials example. Indeed, as our work is

closely related to security, the feature of fresh values is very much of interest to us since it is essential in the field of security, going back to (HRU76). As actions can create a potentially infinite number of distinct nonces, systems have in principal an infinite number of configurations. Thus it is surprising that we can still guarantee PSPACE/EXPTIME-completeness for our planning problems even though actions can create an unbounded number of nonces.

Traditionally, Timed Automata do not address nonces. More recently there have been some solutions in the Timed Automata literature for handling nonces. For example, (CEHM07) formalize the generation of nonces using timed automata, but they need to assume that in advance there is a *fixed finite bound on the number of nonces*.

These differences on the constructs available lead to differences in the complexity proofs. In order to illustrate these differences, consider the following timed version of the classical Towers of Hanoi puzzle, where each move takes one time unit.

Timed Towers of Hanoi Puzzle: Initially, at moment t_0 , a stack of n disks $a_1, a_2, a_3, \dots, a_n$ of increasing size arranged from the largest at the bottom to the smallest on top is placed on a peg b_1 . The other two pegs, b_2 and b_3 , are empty.

The move is allowed only if it places a smaller disk a_i on top of a larger disk a_j , here $i < j$. The processing time of the move is assumed to be 1 nanosecond.

The objective is to move, in the shortest time, the stack from the peg b_1 to the peg b_3 , in such a way that no disk is ever placed on a smaller one.

To formalize the problem, we will use the following predicates:

- (a) $\text{On}(x, y)$ stands for “ x is placed on top of y ”
- (b) $\text{Clear}(x)$ means that “nothing is on top of x ”

Accordingly,

- (c) $\text{On}(x, y)@t$ stands for “ x is placed on top of y at moment t ”
- (d) $\text{Clear}(x)@t$ means that “ x becomes available at moment t ”

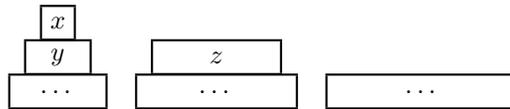

The initial configuration, W , can be formalized as:

$$\begin{aligned} \text{Time}@t_0, \text{Clear}(a_1)@t_0, \text{On}(a_1, a_2)@t_0, \dots, \text{On}(a_n, a_{n+1})@t_0 \\ \text{On}(a_n, b_1)@t_0, \text{Clear}(b_2)@t_0, \text{Clear}(b_3)@t_0 \end{aligned} \quad (5)$$

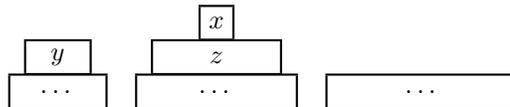

The goal configuration, G , is formalized as:

$$\begin{aligned} \text{Time}@t, \text{Clear}(a_1)@t', \text{On}(a_1, a_2)@t_1, \dots, \text{On}(a_n, a_{n+1})@t_n \\ \text{Clear}(b_1)@t_1, \text{Clear}(b_2)@t_2, \text{On}(a_n, b_3)@t_3 \end{aligned} \quad (6)$$

Consider a move action that transforms, in 1 nanosecond, a configuration of the form

into a configuration of the form

Formally, this move action is axiomatized as a multiset rewriting rule in the form of a scheme:

$$\begin{aligned} & \text{Time}@t, \text{Clear}(x)@t_1, \text{On}(x, y)@t_2, \text{Clear}(z)@t_3 \mid \{ t_1 \leq t, t_2 \leq t, t_3 \leq t \} \\ & \longrightarrow \text{Time}@t, \text{Clear}(x)@(t+1), \text{Clear}(y)@(t+1), \text{On}(x, z)@(t+1) \end{aligned} \quad (7)$$

“At the present moment t , if x and z are still available, and x is placed on top of y , then x and y become available at the next moment $t+1$, and x will be placed on top of z by the next moment $t+1$.”

Here x, y , and z are distinct, x is some a_i , y is either b_1 , or b_2 , or b_3 , or a_k , z is either b_1 , or b_2 , or b_3 , or a_j such that $i < j$.

One can check that the number of the propositional instances (of the untimed variables, x, y, z) of the move action (7) is $O(n^3)$. Thus *the size of the actual input* to the planning/reachability problem within this example is polynomial: $O(n^3)$, which results in that our general PSPACE decision procedure developed for the actions with deterministic effects is running at most in the *polynomial space with respect to n* .

As compared to the Timed Automata formalism (AM04), any timed automaton representing the system in this example has at least $2^n - 1$ states. Therefore, given such an automaton as the input, the general reachability decision procedure developed for timed automata will run at least in *polynomial space but polynomial with respect to 2^n* .

This phenomena occurs because we consider first-order rules in our system, while Timed Automata is given as a set of its states and transitions / arrows between the states extended with a finite set of clocks of the same rate. Thus, when we try to instantiate a problem, such as the Timed Towers of Hanoi shown above, using Timed Automata there is an explosion on the number of states.

Finally, we point to an important difference on the formalization of the complexity proofs, in particular, in the way in which configuration equivalence is established. One uses time-regions to establish the equivalence relation between Timed Automata configurations. These are *highly multidimensional structures* - the dimension is proportional to the number of clocks involved. Their states can be conceived of as the result of the horizontal time cut, since all ingredients of a state, such as clock values etc, are being taken just at the present moment. The result of the transition depends only upon the present state - that is, given the present, the future does not depend on the past.

The use of δ -configurations to establish the equivalence of configurations is a one-dimensional structure: a sequence of atomic events (that might have happened at different moments) ordered in accordance with their time moments. The sequence is equipped with the sequence of adjusted time distances between the events adjacent vertically in time. As such we are able to model “history-sensitive” transitions, which are directly dealing not only with the present moment but with the history of the corresponding events that happened in the past. This allows us to model deadlines, for example.

We show that such a seemingly straightforward one-dimensional structure works perfectly well even in the branching case of actions with non-deterministic effects. Since we allow any number of nonce updates, an additional twist to the decidability problem is that we have to cope with a potentially infinite number of nonces, which causes a potentially infinite number of δ -configurations, as well.

8. Conclusions and Future Work

This paper introduced a model based on multiset rewriting that can be used for specifying policies and systems which mention time explicitly. We have shown that the planning problems for balanced systems not containing branching actions are PSPACE-complete and that the same problems for balanced systems possibly containing branching actions are EXPTIME-complete. We have also shown that the restrictions on the form of actions and time constraint taken in the definition of our model, *TLSTS*, are necessary to obtain the decidability of the reachability and planning problems.

We also provided the semantics of *TLSTS*es as a linear logic with definitions theory. Our adequacy result capitalized on the completeness of the focusing strategy for this logic.

There are many directions which we intend to follow. In (NBS+12), we describe how an assistant can help the participants of clinical investigations to reduce mistakes and comply with policies. We are extending our current implementation into a small scale prototype in Maude in order to collect more feedback from the health care community. One main challenge, however, is to specify procedures in a modular fashion. One might need to specify intermediate languages that are closer to the terminology and format used in the specification of CIs, but that are still precise enough to translate them into a *TLSTS*. We hope that the work described in (DJLS11) may help us achieve this goal.

We would also like to extend our model to include dense times. This would allow us to specify policies for which real-times are important. For instance, (APG+10) describes how one can reduce human errors by connecting medical devices and configuring them according to some hospital policies.

Another interesting problem to explore is checking whether a given plan, for example, a plan embedded in a protocol, complies with regulations no matter how it is executed. Such checks would help protocol design and review, and FDA audits as well as sponsors to monitor CIs and detect mistakes as early as possible.

Finally, recently we have formalized Progressing Collaborative Systems that may create fresh values (KBNS13), inspired by security protocols and administrative and business processes. Such systems are efficient, *i.e.* the processes are always advancing and are completed in a bounded number of transactions. This is reflected in the complexity of the planning problems with progressing behavior. We are currently looking into extending the notion of progressing to systems with time. We are also investigating sensible notions of timed intruder models. We believe that one can apply the machinery introduced in this paper together with the notion of Bounded Memory Protocols (KBNS14) to specify sensible security protocols that mention time.
