19. Evaluation of the reliability and accuracy of fieldable vital signs monitoring devices has been a difficult problem. In the civilian sector, the problems are partially circumvented by limiting the operational and environmental requirements. Military vital signs monitors must perform reliably across extreme temperatures, over unique garments, in high noise and vibration environments and other hostile surrounds. A major obstacle in evaluating potential fieldable monitoring devices has been the unavailability of a reliable standard test-jig which accurately simulates the physiology of the human limb with respect to its vascular supply, blood pressure and heart rate. This project was undertaken in order to demonstrate the feasibility of creating such a device. The first task of this project was to first obtain a thorough understanding of how the human limb develops the physiologic signals that the various monitoring instruments detect and interpret as blood pressure and pulse rate. This was accomplished by formulating a theory which predicts limb volume changes in response to the pressurization of occluding blood pressure cuffs and the resulting changes in blood flow within the underlying arteries and veins. On the basis of this theory, a model arm was constructed so as to incorporate mechanical analogues of collapsible tubes. Simulated blood flow and pressure were driven by a programmable gear pump. Auscultatory, oscillometric, and statometric methods were used to evaluate the model. The success of the project is indicated by the fact that all of these techniques yield reasonable values of simulated pressures and pulse rates. The most important evidence for the success of this effort is that the model does not have to be "informed" about the specific technique that any available instrument utilizes. A major accomplishment is the development and successful implementation of a single theory which explains the physical and physiological phenomena associated with all three major noninvasive blood pressure measurement techniques. A number of problems and suggestions for future improvements in the device have been identified.

1 INTRODUCTION

Empirical evaluation of the reliability, accuracy, and reproducibility of vital signs monitoring (VSM) devices has historically been an intractable problem. In the civilian sector, the problem has been partially circumvented by drastically limiting the prescribed operational environment requirements.

In the case of military VSM devices, it is impossible to drastically constrain the operational environment requirements. Military vital signs monitors must perform reliably in conventional and NBC warfare situations, across extreme temperatures, over unique garments, in high noise and vibration environments, over a wide range of altitudes, and in contaminated surroundings. These severe operational requirements have prompted the Army, Air Force, and Navy to invest many millions of dollars over the past six years in an effort to develop a system capable of supporting battlefield casualties. As a consequence, the unique requirements of the DoD and the extensive funding of this research and development effort have resulted in significant advances in the state-of-the-art of vital signs monitoring instrumentation.

While these advances greatly surpass commercially available technology, they have not been accompanied by comparable advances in requisite test and evaluation methodology and instrumentation. As a result, we now find ourselves in the disheartening position of having sophisticated, high performance devices, but grossly inadequate methodology and instrumentation for credible evaluation of device reliability, accuracy, and reproducibility.

The purpose of this research and development effort is the development of testing and evaluation methodology and instrumentation which will permit the credible evaluation of VSM devices in both the advanced development phase and in the production quality control phase.

2 BACKGROUND

The task of evaluating medical devices for military deployment includes the determination of device survivability and functional performance. The issue of VSM device survivability can be adequately determined with existing test and evaluation (T&E) methodology and instrumentation. These procedures are documented in various military standards documents (e.g., MIL-STD 810D, 461, 462, etc.). In contrast to this, the issue of VSM device functional performance is not covered by any applicable military T&E standards; thus, guidance is sought from civilian/commercial

standards.

At the present time the Food and Drug Administration (FDA) has not promulgated performance standards for vital signs monitors that determine blood pressure and heart rate. The FDA's principal function regarding medical devices is to verify safety and manufacturers' claims regarding performance. The FDA informally employs a voluntary industry performance standard promulgated by the Association for the Advancement of Medical Instrumentation (AAMI SP-10) for the assessment of electronic blood pressure monitors. With regard to heart rate, we are not aware of any FDA or non-FDA performance standards.

AAMI SP-10 requires clinical evaluation of electronic blood pressure monitors. For each functional performance test condition, a minimum of fifty **noninvasively** instrumented human subjects or fifteen **invasively** instrumented human subjects are required.

Since commercial civilian devices normally have only ONE test condition (room temperature, bare arm, NO noise or vibration, near sea-level altitude), the experimental risk involved with the use of fifteen invasively instrumented human subjects (fluoroscopically instrumented with an intra-arterial catheter) is relatively small. However, if many different combinations of test conditions are required (as is the case with military requirements), the associated risk to human volunteers rapidly increases to a level at which invasive testing is not justifiable.

The alternative to invasive testing is to noninvasively instrument the human test subjects. The AAMI standard requires a minimum of fifty such human subjects (having a wide range of blood pressures) and requires that the device performance be determined by comparison to the auscultatory method (detection of Korotkoff sounds via a stethoscope by a trained technician). In addition to the fact that multiple test conditions require multiple measurements on the 50+ human subjects, using the auscultatory method as a standard presents a MAJOR problem for testing under military operational conditions. The auscultatory method DOES NOT work in high noise and vibration environments; it is very unreliable when obtained through heavy garments (such as MOPP gear), and is biased by the subjectivity of the measurement obtained by the technician¹. While this subjectivity error can be controlled under normal conditions, testing under adverse conditions (e.g., extreme heat or cold) will significantly confound the measurement, necessitating that the experimental design include many more measurements than normally than are normally required.

Furthermore, the blood pressure and heart rate are very labile physiological parameters - they can change dramatically in very short time periods. Reasons for such changes include physical, physiological, and psychological stress. For example, systolic blood pressure has been shown to change as much as 50 mmHg in as little as 30 seconds². Heart rate can decelerate to zero in as little as one beat or can increase as much as 50% in a few seconds. All techniques measure a physiological parameter at a specific point in time. Unless one is certain that blood pressure and heart rate are

stable, the results from a single measurement become invalid in a very short time period and repeated measurements are essential. Furthermore, during rapidly changing blood pressure and heart rate conditions, both manual and automatic measurements yield erroneous results. That is, the measurement does not yield either the initial value nor the final value, but some intermediate value of questionable validity.

Multiple measurements on many human subjects takes a considerable amount of time. Each time a counter-pressure cuff is inflated to occlude blood flow to an extremity, it causes ischemia and disturbs the normal physiology of the extremity. This is a real limitation of all noninvasive blood pressure measurement techniques. Intermittent occlusion, separated by reasonable time intervals, permits restoration of normal physiology to the extremity. However, rapid repetition of occlusion by a cuff will, as time progresses, become more and more like continuous occlusion. This is contraindicated not only because of the adverse effects on the extremity, but also because it attenuates the physical phenomena normally employed in the measurement of blood pressure. While two or three measurements in rapid succession should not create problems, monitoring over a period of an hour or so should be done at about five minute intervals and monitoring for longer time periods should be done using longer time intervals between measurements. In this way, the effect of the previous measurement does not affect the results of the subsequent measurement.

The requirement for multiple human subjects results in the necessity for multiple cuff applications. Proper selection and application of the cuff is important for accurate determination of blood pressure. In both the oscillometric and statometric blood pressure measurement technique, the cuff is the ultimate transducer, without which a measurement cannot be achieved. In automated versions of the auscultatory technique, the microphone is normally located within the cuff, once again making proper cuff placement essential. Proper selection of cuff size, relative to the diameter of the extremity will prevent false or cuff hypertension³. Cuff hypertension is an erroneously high blood pressure reading that occurs because the pressure in the cuff is not completely transmitted to the underlying artery. This normally occurs when the cuff width is small compared to the circumference of the extremity. Cuff placement is also important in automated blood pressure measurement. In a device using the auscultatory technique, placement of the microphone over an artery maximizes signal detection and minimizes erroneous readings. In a device that uses the statometric technique, the distal sensing cuff acts analogous to a "microphone". The best placement requires that the middle of the air bladder be located over an artery, but without contacting the proximal occluding cuff (e.g. over the radial artery of the arm immediately below the elbow).

All instruments are subject to noise/vibration induced errors and "noise immunity" is always a matter of degree. While it is normally impossible to prevent vehicle-related noise/vibration during patient transport, this is not usually the case with patient-related noise/vibration. Patient motion

represents a significant impediment to the measurement of blood pressure; this is obvious for manual phenomena that either mimic or interfere with the signals that automated devices use for determining blood pressure. Gross movement of the whole arm or leg can create "false" pressures in the counter-pressure cuff, leading to a blood pressure that is either higher or lower than the correct reading. Flexion, extension, or rotation of the hand or foot, especially in a rhythmic fashion, can create signals identical to those used by the oscillometric and statometric techniques. The ultimate defense against patient motion artifacts is to prevent patient voluntary motion. The penultimate defense is to observe the patient's extremity during the measurement and exercise caution in interpreting the results if significant patient motion was observed during the measurement.

One must also be aware of the pressure difference due to the position of the extremity. The vertical distance between the heart and the blood pressure sensor causes a systematic error in the blood pressure measurement⁴. For every five inches of vertical distance, the pressure error exceeds nine millimeters of mercury.

3 APPROACH

In order to fabricate a test fixture for vital signs monitors, we must completely understand the physics and physiology of each technique for noninvasive blood pressure measurement - auscultatory, oscillometric, and statometric.

3.1 General

In order to measure arterial pressure noninvasively, one must apply a blood pressure cuff around the arm. The cuff pressure is transmitted through the tissue and acts on the outside surface of the artery. If the external pressure acting on the artery is greater than the internal arterial pressure, the artery collapses, interrupting flow in the artery. Various techniques detect this event, reporting the cuff pressure required for the zero flow state as systolic pressure. These techniques also measure or estimate diastolic and mean pressures.

3.2 Auscultatory

The auscultatory method of measuring blood pressure consists of listening for Korotkoff sounds as the cuff is deflated from above systolic pressure to below diastolic pressure. There is disagreement as to the origin of these sounds⁵. Korotkoff⁶ believed that the sounds were caused by the arterial walls "slapping" against each other as pulses of blood passed through the partially occluded artery. Gittings⁷ believed that the sounds were caused

by sudden distention of the compressed, partially occluded artery. Other theories include a mechanism involving dynamic instability of a viscoelastic system of tissue⁸. Conrad et al believe that these sounds are caused by fluid turbulence⁹. No conclusive scientific evidence has yet been obtained to prove or disprove any of these theories.

In our attempt to model the human limb, we used a combination of Korotkoff's theory and that of Conrad et al. The vessel which we have designed permits the "slapping" of the artery as it closes upon partial occlusion. In addition, a microphone, which is fluidically coupled to the arterial line distal to the occluding cuff, is used to pick up the sound for further amplification. Thus, any sounds generated by turbulence or "slapping" can be sensed at this position.

3.3 BFS Theory

The BFS Theory^a (Blaumanis, Falk, and Samaras) describes the principles of the noninvasive measurement of blood pressure. Researchers in the field of venous occlusion plethysmography noticed that when an occluding cuff was applied to the arm and the cuff pressure was held at a pressure above venous occlusion pressure, the distally measured intravenous pressure, became equal to the cuff pressure¹⁰. We repeated these experiments and found that the intravenous pressure equals that of the cuff from a pressure just above venous occlusion until mean arterial pressure (MAP) is reached.

The explanation is as follows. Consider the limb, distal to the occluding cuff, as a control volume. Normally, on average, the arterial inflow equals the venous outflow. The entire pressure drop (arterial-venous) occurs at the level of the microcirculation, the arterioles and capillaries. Now, if the cuff is inflated to just above venous occlusion pressure (say 10 mmHg) the outflow will cease momentarily. As a result of the diminished flow, the total pressure drop is also diminished, since the latter is due primarily to the viscous frictional losses in the microcirculation. Thus, the reduced flow, due to outflow obstruction, results in an increased pressure within the down-stream elements of the vasculature, the venules and veins. The incipient increase in venous pressure under the occluding cuff will, therefore, tend to open the collapsed veins and flow will resume. At this point a dynamic equilibrium is established where venous pressure is, on average, equal to cuff pressure. If we now inflate the occlusion cuff to higher and higher pressures new equilibrium points will be established such that venous pressure rises to the level of the cuff pressure. Obviously a point must be reached where venous pressure will equal arterial pressure and flow will be zero. At this

^a An article is being prepared for publication in the open scientific literature.

point an interesting question arises: when net flow is just reduced to zero by venous occlusion, what is the venous pressure and therefore the cuff pressure? At first it may be tempting to suggest that these pressures should be equal to the systolic arterial pressure. In fact, however, the pulse pressure is virtually entirely damped in the microcirculation so that nothing corresponding to systolic pressure ever appears on the venous side of the circulation. The venous pressure in the outflow-occluded stump is, in fact, equal to mean arterial pressure. This fact, which we have confirmed by direct measurement, also has a sound theoretical basis. The average driving force for flow in the microcirculation is the root-mean-square (RMS) pressure. To the extent that the RMS pressure can be equated to the more traditionally defined "mean arterial pressure", we see that the magnitude of the latter is most closely related to measurable dynamic events in the limb, particularly the rate of change of volume as a result of blood flow. Thus, mean arterial pressure, which has heretofore been defined by acclamation or measured by an electronic integration, in the so-called BFS theory emerges as a real physical force. Our current concept of the reality of MAP is fundamental to understanding the physiologic mechanisms of the oscillometric and statometric methods of measuring blood pressure.

3.4 Oscillometric

In the oscillometric blood pressure method, it has been empirically observed that as cuff pressure is decreased from an initial pressure above systolic pressure, the lowest cuff pressure which gives maximum oscillations in the cuff pressure is MAP¹¹. Systolic and diastolic pressures are estimated using an empirically-based dual slope estimation technique. The MAP determination, furthermore, has never been physically or physiologically explained. We believe that the BFS Theory describes the maximum oscillations occurring at the point where cuff pressure is equal to MAP.

The oscillations are small and unchanging when the cuff is above systolic pressure. This is caused by the "leading edge" effect. The edge of the cuff proximal to the occlusion is influenced by pulses in the proximal artery, or "stump". As the cuff deflates through systolic pressure, the pulse amplitudes increase. This is caused by the pulses partially passing through the occlusion and creating a pulsating pressure in the cuff. The venous pressure distal to the cuff increases, and approaches the mean arterial pressure distal to the occlusion. When the cuff pressure is equal to MAP, the arterial pressure and venous pressure distal to the occlusion are also equal to MAP. As the cuff deflates a very small amount, the venous pressure (MAP) will be greater than the cuff pressure (just below MAP). Outflow from the distal limb commences. Since the cuff is sensing pulses which represent a net flow

phenomenon, the pulses sensed by the cuff start to decrease in amplitude. Thus, the pulse amplitudes measured by the cuff have a maximum at MAP.

3.5 Statometric

The statometric technique is a blood pressure measurement technique that uses a low frequency (on the order of 0.15 Hz) limb volume change to determine blood pressure¹². In this technique a limb volume sensor is placed distal to an occlusion cuff. As the occlusion cuff is inflated above systolic pressure the distal limb becomes ischemic. Within a few seconds the normal autoregulatory mechanisms attempt to compensate for the ischemia. In effect the vascular capacity is increased by vasodilation. As the occlusion cuff is slowly deflated through systolic pressure, the distal limb volume starts to increase. As the cuff pressure is further reduced to the level of MAP there is a rapid change in the rate of filling of the distal limb. This occurs because, as predicted by the BFS theory, venous outflow will begin when cuff pressure is slightly less than MAP. At this point the limb volume vs. pressure curve shows an inflection point which corresponds to the beginning of outflow and an occlusion cuff pressure equal to MAP. Thus systolic pressure is the point at which the limb volume first begins to increase and MAP is the point at which the rate of increase changes most rapidly. Diastolic pressure is calculated using the relation, $D = \frac{1}{3}(3M - S)$.

4 DESIGN

Fig. 1 shows the schematic diagram of the fluidic system of the test fixture. This system is separated into two sections. The first section is called the heart (inside the wood box), and the second is called the arm (limb).

Figure 1. Schematic Diagram of the Artificial Arm and Heart

4.1 Heart

The functional diagram of the heart section is shown in Fig. 2. The inlet of a gear pump^b is attached to a reservoir (simulating the venous pool). The level of the fluid in the reservoir creates a pressure head on the inlet of the pump representing central venous pressure. The outlet of the pump is attached to the arm as well as a restriction simulating the peripheral resistance of the rest of the body.

The reservoir is heated with an electrical heating element. This element is controlled with a bang-bang controller. The temperature^c measured in the reservoir is compared to a

^b Cole Parmer: Pump Head Model #7002-18, Motor Model #7144-91, and Power Supply Model #2630-90.

^c The temperature sensor is Analog Devices AD590.

threshold temperature of 37°C. The comparator output controls the heater. To prevent overheating of the reservoir, the fluid is constantly circulated at a minimal rate. This prevents any potential for localized temperature gradients and possible damage to the reservoir or heater. When the heater is on, the red light on the front of the wood box is on. This is to indicate to the user that the heater system is active.

Figure 2. Functional Diagram of the Heart

A control system is required for maintaining the arterial pressure stable and equal to the desired pressure. The controller consists of three parts. The first part is an open loop controller. The computer controls the pump via a digital-to-analog converter (DAC); the desired pressure is converted to voltage and applied to the pump power supply. The conversion was determined by applying a voltage to the pump and measuring the arterial pressure^d. The empirically determined equation for this is:

$$V_{\text{pump}} = -0.1334[V_{\text{press}}^3] + 1.2178[V_{\text{press}}^2] - 1.2401[V_{\text{press}}] + 1.2732.$$

The desired arterial pressure waveform is calculated using the following equation.

$$P(t) = \sum_i [A_i \cos(t \cdot \text{HR} / 2\pi) + B_i \sin(t \cdot \text{HR} / 2\pi)]$$

$$\text{where } i = \{1, 2, 3, 4, 5, 6\}$$

$$A_i = \{-10.14, -0.30, -0.15, 1.08, 0.21, 0.42\}$$

$$B_i = \{6.79, -3.29, -0.97, -0.24, 0.07, 0.63\}$$

The second part of the control system is a bang-bang controller. A solenoid valve^e is controlled by comparing the real arterial pressure and the desired arterial pressure. The

^d The pressure transducers are Data Instruments Model #EA9300002, 0-15 psig.

^e Asco Model #8262C6 12V normally closed valve.

inherent capacitance in fluid inertia, as well as the capacitance of the simulated artery, result in a time delay from the pump applying pressure to the pressure sensed by the arterial transducer; this time delay was measured to be 120 milliseconds.

Therefore, the desired pressure signal must be temporally synchronized to the real pressure. The computer delays the desired signal by 120 msec and then sends, via a second DAC, the desired pressure to the bang-bang comparator. Fig. 3 shows the functional diagram of this concept.

The third part of the control loop is an adaptive controller implemented in the software. Since the arm and the "rest of the body" are parallel (and very different) circuits, the actual arterial pressure varies as the arm is partially occluded (taken out of the circuit). The error between the desired pressure (systolic and diastolic) and the actual pressure (systolic and diastolic) is calculated every two pulses. This error is used to modify two coefficients which are applied to the oscillating component and the offset component of the desired waveform applied to the pump. This adaptively controls the pump depending on the actual and desired arterial pressures. These three parts of the control system are necessary to control this complex and dynamic circuit.

In order to calibrate the device, application of the calibration assembly allows pressurization of the reservoir and the cuff. This static pressure is transmitted to the whole fluidic system as well as the cuff pressure transducer. The arterial, venous, and cuff pressure transducers can be calibrated simultaneously.

4.2 Arm

In order to provide an anthropomorphic test fixture, the arm is constructed from a modified IV training arm. Fig. 4 shows the fluid schematic. The plumbing consists of a simulated artery, an expandable bag (simulating the distal limb volume), a restriction (simulating a capillary), and a simulated vein. Fig. 5 shows the side view of the limb. The artery

Figure 3. Fluid Delay Compensation Circuit

Figure 4. Functional Diagram of the Arm

and vein are located on the upper arm. A chamber of oil, covered by a rubber membrane, is the cuff pressure sensor. This is fluidically coupled to a pressure transducer. The cuff pressure is transmitted through the skin and membrane to the oil, and in turn, the transducer. Another pressure transducer is used as a microphone. It is attached to the arterial line distal to the artery. Sounds generated by the artery (Korotkoff sounds) are sensed by this transducer, amplified, and played back through a speaker located under the skin at the elbow on the arm.

Figure 5. Physical Location of Arm Components

There are two major technological advances in the limb - the occluding vessel and the simulation of ischemia.

4.2.1 Vessels

The initial design of the occluding vessels (artery and vein) was a flexible tube (penrose rubber). We placed this rubber tube inside a closed chamber of water which had one pressurization port. The rubber tube had water flowing through it at a certain internal pressure. Unlike Kresch & Noordergraaf^{13,14}, Conrad¹⁵, and Holt¹⁶, who imply that flow is zero when internal pressure is equal to external pressure, we observed that the flow was not zero when the chamber pressure was equal to or greater than the internal tube pressure (occlusion). We discovered that (as did Kresch and Noordergraaf, 1972) as the rubber tube collapsed, extremely small channels remained at the outer ends (Fig. 6). The chamber pressure had to be very large in order to collapse the small channels.

Figure 6. Illustration of Tube Collapse

Since penrose rubber was not suitable as an *in situ* occluding vessel, we developed our own occluding vessel. Fig. 7 shows the mechanical drawing of this vessel.

The fluid pressure (e.g., arterial pressure) causes the thin rubber membrane to "bulge" and fluid is allowed to pass through the vessel. If the occluding pressure (from the cuff) is equal to the fluid pressure, the fluid cannot create the bulge, and the vessel is occluded. The forces arising from the fluid pressure and the external pressure are in balance (since the areas on which the forces act are equal). As one would expect, the arterial pulses can be measured in the oscillating movement of the rubber membrane, and in turn, in an occluding cuff applied to this vessel. This design results in a practically-realizable Starling resistor¹⁷.

Figure 7. Mechanical Drawing of GMS Starling Resistor

4.2.2 Ischemia

In the human, the arm becomes ischemic when the artery is occluded and the distal portion of the arm ceases to receive blood. This causes vasodilatation, which decreases the intravascular pressure. Blood flows into the arm when the cuff pressure is deflated below systolic pressure, because of this intravascular pressure decrease. If the intravascular pressure, distal to the occlusion, remained constant (at MAP), then the inflow of blood (when the occlusion is no longer total) would be prevented. This is because, in order to create significant flow, there must be a pressure drop. In the prototype test fixture, ischemia is simulated using a valve^f (dump valve in Fig. 1). This valve, when opened, allows some of the fluid in the limb distal volume (see Fig. 1) to empty directly into the reservoir. This

^f Asco Model #82628210 12V normally closed valve.

volume reduction causes the "intravascular" pressure to decrease. In effect, the same result as vasodilatation has been created. The simulation of ischemia is essential to the operation of the three blood pressure measurement techniques. Each of these techniques operates on the fact that as the cuff deflates below systolic pressure, the blood flow into the limb becomes significant.

4.3 Electrical Hardware

The electrical schematics are located in Appendix A. The first schematic is the computer interface board. There are anti-aliasing filters for each transducer. There is an eighth order low pass Butterworth filter for the arterial transducer. The arterial transducer signal requires the use of a Butterworth filter to reject the oscillations due to the control valve. There are fourth order low pass Bessel filters for the other transducers. Also on the board are two comparators (essentially bang-bang controllers); the valve controller and the heater controller. The second schematic shows the circuit located in the arm box, consisting of the valve drivers, the transducer drivers, and the audio amplifier for the Korotkoff sounds. There are fuses to protect the electronics from any current surge or electrical short. They can be found on the power supply box on the computer stand. The fuse next to the power cord (on the AC side of the power transformer) is a four amp fuse, and the other fuse (on the DC side of the power transformer and located next to the round connector) is an eight amp fuse.

4.4 Computer Software

The software code is located in Appendix B. The program is written in C, and it includes Halo graphics software and C-Tools (used for the interrupt service routine support). The program is modular to allow for modification if necessary. Its function can be seen in the video manual showing the setup, calibration, operation, and troubleshooting of the test fixture.

The program consists of three parts. The first part is the vital signs menu and help functions. This utilizes the Halo graphics routines and the arrow and enter keys on the keyboard to choose vital signs parameters or obtain on-line help. The second part is the main shell of the program. This updates the screen approximately every second. The screen consists of two traces, a process diagram, a manometer, a user-entered header, the time and date, and the numerical information describing the arm. Both the on-line help and the video tape are necessary to view for further understanding of the operation of the arm. The last part is the interrupt service routine. This acquires data and controls the pump and control valve. This routine is entered as an interrupt to the processor every twenty milliseconds.

5 RESULTS

The prototype test fixture simulates the circulatory physiology of a human limb. The auscultatory technique, the oscillometric technique, and the statometric technique measure the arterial pressure in the arm (controlled by the pump and fluidic system). This prototype test fixture eliminates all of the inherent problems of testing noninvasive vital signs monitors with many human subjects.

With the use of this test fixture, one does not need many human subjects and multiple measurements. One can set various blood pressures and heart rates, place the fixture in any environment, and test the vital signs monitor accurately.

The problem of the vital signs being very labile is no longer an issue here. The test fixture maintains the desired blood pressure. There is no physical or psychological stress. The fixture has been tested for eight hours continuously, and the blood pressure remained constant (within 2 mmHg) during that time.

The test fixture does not need time to equilibrate after a blood pressure measurement. The user can take vital signs measurements several seconds apart (after the previous one ends).

The problem of cuff placement is magnified in many subjects. The cuff must be applied multiple times (as many as there are subjects). The cuff needs only to be applied once on the test fixture.

The test fixture makes no voluntary movements. Any movements are passive and caused by the user or the environment (shake table or vehicle). The patient movement problem does not appear.

There exists no pressure error due to differences in vertical height of the heart and the measuring site. The arterial pressure transducer is on the same vertical level as the artery. The pressure error is zero.

Due to time and budgetary constraints, this prototype test fixture was minimally tested. There are some problem areas with the arm that the user must understand to properly use it. The next section discusses these problems in detail.

6 PROBLEM AREAS AND SUGGESTIONS FOR FURTHER WORK

There are several problem areas that we have encountered in this development effort. Time and budgetary constraints prohibited us from investigating these areas more completely. In order for one to use the arm properly, one must fully appreciate these problems areas and their effects on the function of the arm.

The first problem area is the control loop. The adaptive part of the control loop depends solely on the heart rate, since the systolic and diastolic pressures are computed every two pulses. Overshoots are increased and small oscillations are extended in time as the heart rate decreases. We have observed that in the prototype test fixture, the oscillometric technique operates more inconsistently as the heart rate is lowered. We believe that further development will allow fine tuning and more complete testing of the control loop, and in turn, allow consistent operation of the oscillometric technique over the whole heart rate range.

The second problem area is the cuff pressure transducer's nonlinearity and cuff placement criticality. This transducer consists of a chamber of oil covered with a thin rubber membrane. This chamber is fluidically coupled to a pressure transducer. The cuff pressure couples to this chamber through the skin. We have found that the overall (cuff to pressure transducer) cuff pressure measuring system is slightly nonlinear. The cuff pressure is higher than the transducer measurement for low cuff pressures. We believe that further development will allow us to redesign the cuff pressure transducer chamber so that the system is linear, or as a minimum, deterministic. The user must calibrate the cuff transducer immediately after each and every cuff application. We have found that the cuff placement is extremely critical to the pressure transmission from the cuff to the transducer. A redesign of this chamber will eliminate the need for the frequent calibration.

The third problem area is the noise of the solenoid valve opening and closing. This sound propagates through the fluid lines and is sensed by the microphone. This sound, along with the Korotkoff sounds, are amplified. The valve sounds result in the difficulty in hearing the Korotkoff sounds. We believe that further development will permit us to obtain a specially fabricated valve with rubber stops (instead of the metal ones); this will eliminate the valve sounds.

The fourth problem area is the "dump valve" control. This valve is modelling the ischemia, and is controlled by the relationship between the cuff pressure and the systolic pressure. When the cuff pressure is greater than systolic pressure, there is no flow in the arm. A flow transducer (or differential pressure measurements) in the arterial line would allow better control of this valve. We have found that the problem of the cuff pressure transducer magnifies the problem here. If the cuff pressure transducer is inaccurately measuring the cuff pressure, the "dump valve" is opened at the wrong time, and the distal limb is emptied too early or too late. Both of these scenarios lead to the inconsistent operation of the oscillometric and the statometric techniques. Further development might result in another method (fluidic) of modelling the ischemia.

The prototype test fixture is fragile and minimally tested. The scientific progress in understanding and modelling the underlying physical and physiological principles of noninvasive blood pressure measurement is considerable. This, unfortunately, minimized the time for ruggedizing and testing the final test fixture.

7 CONCLUSIONS

The prototype test fixture fills a void in checking, calibrating, and maintaining vital signs monitors. This test fixture will allow accurate monitoring and control of the simulated dynamic arterial pressure; this eliminates all of the associated problems in testing noninvasive vital signs monitors (see the Results section). The test fixture has a great potential in both the military and civilian environments; it should allow routine checking of all vital signs monitors, and it should improve maintenance of vital signs monitors.
