ABSTRACT The most promising field for wider application of refractory metals and compounds is: their use as protective coatings on metals and various nonmetallic materials. The article reviews results of systematic research to develop a technology for protecting refractory metals with coatings made from refractory compounds (carbides, nitrides, borides) of these metals. The research, conducted at the Institute of the Problems of the Science of Materials AN UkrSSR, included an investigation of the solid phase interaction between refractory compounds, between refractory metals and refractory compounds of these metals, and between refractory metal compounds and graphite. On the basis of the obtained results, an investigation was made and the optimum conditions for vacuum diffusion bonding and brazing TiC, ZrC, NbC, TaC, Mo₂C and WC carbides to Nb, Ta, Mo and W were determined. A satisfactory technology was also developed for coating graphite with TiC, ZrC, NbC, BNC and AlN coatings. In depositing aluminum-carbide and aluminum-nitride coatings, graphite specimens were placed into a graphite container filled with the required powder metal and annealed in a vacuum furnace for 2-3 hr at a temperature 50-100°C higher than the melting temperature of the metal. A homogeneous aluminum nitride layer was obtained in annealing graphite specimens in aluminum powder at 775-1475°K. Dense, strongly adhering titanium-carbide coatings with a microhardness of 144 kg/mm² were obtained with annealing graphite specimens in titanium powder at 1075°K for 2 hr. In a similar manner, zirconium-carbide coatings with a microhardness of 2750 kg/mm², and niobium carbide (Nb₂C) coatings with a

microhardness of 2380 kg/mm^2 , were obtained in annealing graphite specimens in corresponding metal powders at 2073°K for 2 hr and at 2173°K for 3 hr, respectively. Engineer A. N. Krasnov and Engineer T. V. Dubovic participated in the work. Orig. art. has: 3 figures and 8 tables.

NEW HEAT-RESISTANT MATERIALS FOR WORK IN CONTACT WITH REFRACTORY METALS

The development of modern technology is associated with the increased temperature of technological processes; for this reason refractory metals and their compounds have wider and wider use [16].

A highly promissive area for the use of refractory compounds is as coatings on metals and various nonmetallic materials, for example, graphite, which together with tungsten is considered the most promising high-temperature structural material, provided the problem of protecting it from oxidation and gas erosion can be solved [17, 18].

The quite good development of the technology of creating certain coatings, and also a comprehensive study of their properties, permits a significant expansion of the field of application of refractory compounds in high-temperature engineering.

In the area of refractory compounds the Institute of Problems of the Science of Materials, Academy of Sciences, Ukr. SSR is conducting systematic work in the indicated directions.

Study of the Solid-Phase Interaction of Refractory Compounds with Refractory Metals, Compounds, and Graphite

Works [19, 20] studied the behavior during heating in a vacuum ($5 \cdot 10^{-2}$ mm hg) of the powdered carbides: TiC, ZrC, HfC, NbC, TaC, Mo_2C , WC; nitrides: TiN, ZrN; borides: TiB_2 , ZrB_2 , TaB_2 , Mo_2B_5 , W_2B_5 ; and hot-extruded oxides: BeO, MgO, ZrO_2 , ThO_2 in contact with solid refractory metals: Nb, Ta, Mo, V. The interaction was studied of oxygen-free refractory compounds - carbides: TiC, ZrC, HfC, NbC, TaC, Mo_2C , and WC and nitrides: TiN, ZrN; borides: TiB_2 , ZrB_2 with oxides MgO and ZrO [21], and also carbides: TiC, ZrC, HfC, NbC, TaC, Mo_2C and WC; borides: Mo_2B_5 , W_2B_5 , TiB_2 , ZrB_2 , HfB₂, NbB₂, TaB₂ with graphite [22]. The interaction was studied of silicon carbide in contact with refractory metals: Nb, Ta, Mo, W and oxides: BeO, MgO, Al_2O_3 , ZrO_2 , ThO_2 and the interaction of TiB_2 , TiC, TiN with Ti, Zr, V, Nb, Ta, Mo, W.

By metallographical analysis of the zones of contact after heating it was established that, depending on the nature of the components, the temperature and the time (duration) of the test at the contact boundary of the refractory metals, there occur intermediate phases: chemical compounds or solid solutions, having high microhardness (from 1000 up to 4000 kgf/mm²).

Identification of the phases formed was carried out by the microhardness method [19-22] or by the microhardness method in combination with x-ray phase analysis. However, in a number of situations it was not possible to draw a simple conclusion as to the nature of the intermediate phases formed.

The typical structure of several contact boundaries of two refractory materials after heating is shown in Fig. I.13:

a - microstructure of the boundary of HfC-Nb after heating at a temperature of 2273°K for a period of five hours. The forming phase in the form of a wide layer adjoins the metal and penetrates into the sample along the grain boundaries. Microhardness of the phase at a load of 50 gf is 4250 ± 350 kgf/mm², which corresponds to the microhardness of solid solution HfC-NbC;

b - microstructure of the ZrO_2 -SiC boundary after heating at a temperature of 2073°K for a period of two hours. On the surface of the oxide there forms a layer of gray color with metallic lustre and microhardness of $2160 \pm 150 \text{ kgf/mm}^2$. According to x-ray analysis the new phase is a zirconium carbide with a small content of carbon (~5% by weight).

With the increase of interaction temperature, the carbon content in the zirconium carbide in contact with the silicon carbide is reduced to a zirconium carbide with a composition close to stoichiometric.

The temperatures at the beginning of the reactions for analysed compositions are given in Tables I.17-I.20.

Diffusion Welding and Brazing of Refractory Compounds with Refractory Metals

The most promising method of joining refractory materials is vacuum diffusion welding. Fusion welding in the given situation turns out to be unacceptable because of technical difficulties (high melting point) as well as because of the insufficient heat stability of these materials. For selection of diffusion welding conditions the results on research of solid-phase interaction in a vacuum can be used. However, in a number of instances the temperatures at the beginning of the reaction and the nature of the interaction of the refractory materials during diffusion welding are different from those observed in those situations where one or both of the components are taken in powder form.

According to the method described in work [23], the conditions of vacuum diffusion welding of the carbides TiC, ZrC, NbC, TaC, Mo₂C, WC with the refractory metals Nb, Ta, Mo, W were studied. The research took place in the temperature range 1473-2273°K. Holding at a given temperature was 5-15 min, pressure - 0.5-1.5 kgf/mm². The quality of the weld junctions was checked by metallographic analysis. With the purpose of explaining the nature of the phases formed during welding, the microhardness of the substances was changed in the zone of contact.

The temperatures at which the weld junction of the carbides with metals starts to be formed are given in Table I.17.

As follows from Table I.17, the starting temperatures of formation of the weld junction differ significantly from the beginning temperature of the reaction of solid metals with powdered refractory compounds (Table I.20).

During metallographic research it was established that with increasing temperature, the quality of the weld junction for all compositions became better. At the contact boundary there occur most often solid solutions of carbon in metal or solid solutions of carbides (Fig. I.13 c,d). The composition of the solid solutions

depends on the welding temperature; during this the formation of carbides or their solid solutions is preceded, as a rule, by the formation of a solid solution of carbon in metal at lower temperatures. The characteristic of the weld junction during optimal welding conditions is given in Table I.21.

For compounds of materials not forming a chemical bond, the diffusion welding method in the form used by us for carbides is inapplicable. For example, the diffusion welding method cannot be used to weld boron nitride and carbonitride with refractory metals Nb, Ta, Mo, W, since these materials do not interact with each other in a solid state.

For compounds of materials not forming a chemical bond, it is necessary to introduce an intermediary body - a "binder" - mutually soluble with these materials. For compounds of boron nitride and carbonitride with refractory metals a method of brazing was developed using, as the brazing material, refractory compounds that are chemically active relative to these materials.

Fig. 1:14. Microstructure of junctions of refractory materials: a) BN-Ta (1 - BN, 2 - braze, 3 - Ta); b) BNC-Mo (1 - BNC, 2 - braze, 3 - Mo). Magnification 100 $\times$.

The braze was in the form of finely dispersed powder or pellets with a thickness of up to 2 mm. Brazing took place in an induction furnace in an argon atmosphere at temperatures of 2073-2573 $^{\circ}$ K. The quality of the joint was checked by metallographic analysis. The

results of the research are given in Table I.22, the photographs of the weld microstructure — in Fig. I.14 a, b. As follows from the table, the best refractory brazes turned out to be disilicide of molybdenum and zirconium.

TABLE I.21. Characteristics of weld junctions of carbides with metals during optimal welding conditions.

Welded materials	Temperature, °K	Pressure, kg/cm ²	Time, min.	Forming phase (mole composition in %)	Characteristics of weld zone
TiC—Mo	1973	0,5	10	Mo ₂ C	Narrow dense band of the new phase
TiC—W	—	Did not succeed in bonding			—
ZrC—Nb	1873	1,5	10	NbC	Dense band of the new phase with 20-30 mm width

Diffusion Coatings of Refractory Compounds on Graphite

The possibility of practical utilization of graphite in high-temperature processes is highly restricted because of the strong oxidation, erosion and burn-up in gas flows and interaction with carbide-forming metals. Along with this, protection of the graphite

from oxidation, burn-up, and interaction with the metals is an important scientific-technical problem. Promising materials for application of coatings can be refractory compounds, primarily carbides, nitrides, borides, and silicides of metals and their alloys. Apart from protection from oxidation, refractory-compound coatings possessing hardness and wear-stability permit increasing the mechanical properties of the graphite.

We investigated the conditions of applying coatings of titanium, zirconium and niobium carbides, boron carbonitride, and aluminum nitride onto graphite.

The process of coating carbides and aluminum nitrides consists of two consecutive stages.

1. Vacuum coating of the metallic layer from the liquid phase.
2. Diffusion annealing - carbidization (nitration) of the metallic layer.

The samples were placed in a graphite holder, covered with the powdered metal and heated in a vacuum furnace to temperatures 50-100°C higher than the melting point of the metal. The metal layer can also be deposited by another method, in particular, by plasma spray-coating, permitting coating of an article of large dimensions. When applying AlN coatings to graphite the method of plasma spray-coating of the metallic layer was utilized.*

Diffusion annealing of graphite specimens with metallic coatings took place in a vacuum resistance furnace with a graphite heater at a temperature range 1773-2173°K. Thanks to carbon diffusion in the solid metal, carbidization of the metallic layer took place, the composition and properties of the formed carbides being dependent

*Engineers A. N. Krasnova and T. V. Dubovik helped to develop aluminum nitride coatings on graphite.

on the temperature and time of diffusion annealing (Fig. I.15 a, b, c). This is particularly noticeable for titanium carbide which has a wide region of homogeneity. We experimentally established the conditions of annealing during which the carbide coatings had compositions close to stoichiometric. For each annealing temperature it is possible to calculate the time required for changing the metallic layer into carbide, proceeding from the thickness of the layer and data also on the carbon diffusion in metal [24]. In Table I.23 are given the optimal conditions of producing titanium-, zirconium- and niobium-carbide coatings on the graphite.

For depositing the aluminum nitride layer on the graphite, diffusion annealing was carried out in a nitrogen environment in a graphite-tube resistance furnace.

Various conditions of nitration and charging were tested. A uniform layer of aluminum nitride was obtained during nitration in aluminum-powder charging in the temperature range 773-1473°K; heating was carried out at a rate of 10 deg/min, holding at maximum temperature was selected depending on the annealing temperature.

Boron carbonitride was deposited on graphite by means of baking, in a nitrogen medium, of the charge layer calculated to produce boron carbonitride. For this, the charge, mixed in the binder (solution of nitrocellulose in acetone), was deposited on the graphite specimens, which then were dried and placed in a graphite holder with a covering made of a cake of boric acid with carbon black. Baking took place in a graphite-pipe resistance furnace at a temperature of 2373°K and a time of 1-3 h (dependent on the deposited layer). The coating received had good cohesion with the graphite backing and a uniform composition throughout the layer.

TABLE I.23. Characteristic of carbide coatings at optimal conditions of diffusion annealing.

Carbide	Anneal ing, time	Temperature, °K	Lattice constant to X	Micro- hardness kgf/mm ²	Carbon content % by weight
TiC	2	1973	4,319	3144	20,0
ZrC	2	2073	4,688	2750	11,8
Nb ₂ C	3	2173	3,18 : 5,00	2380	11,2
