ABSTRACT

A ten percent random sample of map data is judged adequate to reproduce the first order spatial characteristics of the distribution pattern for the seven major types of depositional environments in the Mississippi Delta region of Southeast Louisiana. This conclusion is based on: 1) dendrographs which portray interdistance relationships among mean coordinate locations for the different environments, 2) the sampling properties of the Goodman-Kruskal measure of cross association as it is applied to nearest unlike neighbor samples, and 3) proximal maps which are reconstructions of the original pattern based on sample data.

In analyzing map patterns, principal component analysis can be used to depict spatial trends. Within the Mississippi Delta region, the natural levee, point bar, bay-sound, and beach environments show a marked linear trend whereas the swamp, lacustrine, and marsh environments are more isotropic. With respect to location, the lacustrine environment is situated in an intermediate position between nonmarine and marine depositional environments.

The total sample of 4025 data points taken from the environment distribution map of the Mississippi Delta region on which this study is based is contained in the Appendix.

APPENDIX Mississippi Delta environmental sample

Introduction

The detection of spatial order within a depositional environmental framework is dependent upon the elusive relationship that exists between the spatial arrangement and size of the areal units of observation and the degree of complexity of the underlying pattern. Traditionally, the interpretation of environmental map patterns has been accomplished by subjective analysis. Progress toward a more quantitative approach has been handicapped by the lack of suitable statistical measures for describing the spatial character of depositional environmental patterns by which different patterns can be compared and those obscured because of limited areal sampling detected. The primary objective of the present research is to develop a statistical methodology for analyzing environmental map patterns from the point of view that, ultimately, it should be possible to set minimum sampling requirements in advance of regional environmental studies in offshore areas where only limited sampling is economically justified.

Within the past decade, a considerable literature has emerged in the field of human geography, epidemiology, and quantitative plant ecology which relate to spatial analysis ([1],[2]). An excellent review article has appeared recently relating the analysis of spatial form to geographic theory [3]. For the most part, the studies have concentrated on areally distributed point processes where data are generated within artificially defined boundaries. For environments, the boundaries bear no direct relationship to geographic coordinates and the type of patterns found are best described as multiphase mosaics. The closest approach to the quantitative study of environment distribution patterns has been in the field of ecology [4]. There needs to be developed in geology statistical measures which will describe the spatial structure of environment distribution patterns. The statistical properties of such measures based on different size samples under different sampling plans could then be established. This report describes the results of a preliminary study directed toward this end.

percentage. The percentages reflect the relative areas covered by each of the different environments. Such information is of value in comparing environment areal coverage with other deltaic complexes. If we define the Total Information (T.I.) obtained from sampling as

$$T.I. = \sum_{j=1}^7 n_j$$

where n_j is the number of areal units of observation which contained j different environments, it is found that $T.I.=6296$. The portion of the total information used in this study comprised only the environment data gathered from the randomly located points within the areal observation units. This Relative Information (R.I.) defined as

$$R.I. = T.I. / \sum_{j=1}^7 n_j$$

is equal to .62 or 62 percent. While this may seem like an undue degradation of the original information, over one half of the areal units of observation contained only a single environment while ninety-two percent contained no more than two. For now at least, the areal coverage as represented by the sample is considered adequate. It may be necessary later to make more complete use of the original information.

Spatial Form

Beyond the direct observation of environment distribution maps and subsequent subjective evaluations, it is useful to have graphical aids for characterizing pattern structure. Two new forms of graphic display have been developed: 1)spatial principal components, and 2)environment centroid interdistance dendrographs. Each can be illustrated using the environmental data gathered in this study.

Spatial principal component analysis provides a rapid and effective means of portraying the spatial

one grid unit equals approximately 1.5 miles. Only one half of the matrix is filled due to the symmetry. Based on an unweighted pair group clustering of the coefficients, the dendrogram shown in Figure 4 is produced. The dendrogram depicts the marine versus nonmarine associations of the seven major environments. Further, it reveals the transitional character of the lacustrine environment. With a smaller sample, a similar pattern should result within statistical limits. Here again, statistical tests need to be developed. To see what does happen with a smaller sample, a random sample of 500 from the total of 4025 areal units of observation was chosen. The dendrogram that resulted is shown in Figure 5. While some rearrangement of the environments takes place, the basic pattern remains the same. As a first approximation, it is reasonable to conclude that the pattern generated from a sample of 500 points preserves the spatial order contained within the original data.

Proximal Maps

It is not enough to reproduce the spatial order within environment map patterns based on summary statistics calculated from sample data but in addition, it is further desirable to reconstruct the underlying pattern. The problem of reconstructing patterns from sample data has been considered in the context of locating sample points in a way which minimizes the loss due to misclassification in the pattern reconstruction based on nearest neighbor relations [8]. For m-color patterns having a definite cell structure, it is possible to obtain an optimal sample spacing. For more complex patterns, however, such as are found in natural environments, the determination of an optimal spacing in closed form is rendered virtually intractable.

In an attempt to determine the effectiveness of pattern reconstruction of the Mississippi Delta complex based on sample data, a series of sampling experiments were performed in which random samples and subsequently systematic samples were drawn from the total population and the derived data used to generate proximal maps using the SYMAP computer program [9]. The different sample sizes drawn were 5,

Study Area and Population Sample

For this pilot study, it was decided to choose an area which had been mapped in considerable detail and which contained diverse environment elements arranged in a complex pattern. Further, it was desired that such an area would be representative of a major depositional environment framework found both in the Recent and in the geologic past. The area which best suited these requirements was the Mississippi Delta Region of Southeastern Louisiana. The Mississippi Delta complex is probably the best known of the world's delta systems. This area has been studied and extensively mapped over a period of several decades. The recent deposits, their depositional environments and areal distribution have been well documented ([5],[6]). The depositional environments of the Mississippi Delta complex excluding the offshore can be broadly subdivided into seven major types. These are the 1)natural levee, 2)point bar, 3)swamp, 4)marsh, 5)beach, 6)lacustrine, and 7)bay-sound. The areal distribution of these seven major environments is shown in Figure 1. This map constitutes the source of data for the present study.

The initial step was to convert the pattern represented in Figure 1 into digital form by superposing a fine mesh grid over the map and record the environments present within each areal unit of observation. For practical purposes, it was desired to obtain a point representation of the environment distribution pattern and so the type of environment chosen as representative of each areal unit was determined as that one which was situated at a randomly located point within. The grid overlay used to sample the deltaic complex pattern is shown in Figure 2. The finer grid containing one hundred areal units of observation each with a point located at random within was moved over the coarser grid which encompassed the map area to be sampled. The data obtained in this manner are listed in the Appendix. A total of 4025 areal units of observation were recorded. The aggregate composition of the environments contained within these areal units is given in Table 1. The eighth column in Table 1 lists the total number of each type of environment recorded at the points located at random within the areal units of observation and the last column gives the

percentage. The percentages reflect the relative areas covered by each of the different environments. Such information is of value in comparing environment areal coverage with other deltaic complexes. If we define the Total Information (T.I.) obtained from sampling as

$$T.I. = \sum_{j=1}^7 n_j$$

where n_j is the number of areal units of observation which contained j different environments, it is found that $T.I.=6296$. The portion of the total information used in this study comprised only the environment data gathered from the randomly located points within the areal observation units. This Relative Information (R.I.) defined as

$$R.I. = T.I. / \sum_{j=1}^7 n_j$$

is equal to .62 or 62 percent. While this may seem like an undue degradation of the original information, over one half of the areal units of observation contained only a single environment while ninety-two percent contained no more than two. For now at least, the areal coverage as represented by the sample is considered adequate. It may be necessary later to make more complete use of the original information.

Spatial Form

Beyond the direct observation of environment distribution maps and subsequent subjective evaluations, it is useful to have graphical aids for characterizing pattern structure. Two new forms of graphic display have been developed: 1)spatial principal components, and 2)environment centroid interdistance dendrographs. Each can be illustrated using the environmental data gathered in this study.

Spatial principal component analysis provides a rapid and effective means of portraying the spatial

trend for a particular environment. Let $V = \{(x_1, y_1), (x_2, y_2), \dots, (x_k, y_k); (x_i, y_i) \in E_j\}$ be defined as the set of paired x-y coordinates of the data representing the areal distribution of the j th environment, E_j . The principal components of which there are two are defined by

$$CP = \lambda P$$

where C is the covariance matrix of the x-y coordinates of V , P is a 2×2 orthogonal matrix whose column vectors are the linear coefficients of the first and second principal components, respectively, and λ is a 2×2 diagonal matrix whose diagonal elements represent the variance of each of the respective principal components. In the present context, these can be referred to as the spatial components. The spatial components for the seven major environments of the Mississippi Delta are shown in Figure 3. The axes for each of the environments is centered about the mean x-y position for each set of coordinates and the length of each axis is taken as twice the standard deviation. The orientation of the axes is determined by the linear coefficients of the component vectors. The spatial trends are readily observable. The elongate shapes of the natural levee, point bar, and the beach environments can be seen along with the more isotropic patterns of the swamp, marsh, and lacustrine environments. Rather surprising is the sharpness of the trend for the bay sound environment. Considering the depositional aspect, the first principal component whose axis is longest, gives the depositional strike of the sediments. It is indicative of the direction of sediment transport for fluvial and current related deposits. For a more limited sampling of the area than was undertaken in the present study, from such sampling if it is to be considered adequate, it should be possible to reproduce the spatial trends indicated in Figure 3. Statistical tests of significance should be developed.

A lower order measure of spatial structure are dendrographs which portray the interdistance relationships between the coordinate mean positions of the different environments. For the Mississippi Delta data, the matrix of pairwise mean coordinate positions for the seven major environments is given in Table 2. The interdistances are expressed in grid units where

one grid unit equals approximately 1.5 miles. Only one half of the matrix is filled due to the symmetry. Based on an unweighted pair group clustering of the coefficients, the dendrogram shown in Figure 4 is produced. The dendrogram depicts the marine versus nonmarine associations of the seven major environments. Further, it reveals the transitional character of the lacustrine environment. With a smaller sample, a similar pattern should result within statistical limits. Here again, statistical tests need to be developed. To see what does happen with a smaller sample, a random sample of 500 from the total of 4925 areal units of observation was chosen. The dendrogram that resulted is shown in Figure 5. While some rearrangement of the environments takes place, the basic pattern remains the same. As a first approximation, it is reasonable to conclude that the pattern generated from a sample of 500 points preserves the spatial order contained within the original data.

Proximal Maps

It is not enough to reproduce the spatial order within environment map patterns based on summary statistics calculated from sample data but in addition, it is further desirable to reconstruct the underlying pattern. The problem of reconstructing patterns from sample data has been considered in the context of locating sample points in a way which minimizes the loss due to misclassification in the pattern reconstruction based on nearest neighbor relations [8]. For m-color patterns having a definite cell structure, it is possible to obtain an optimal sample spacing. For more complex patterns, however, such as are found in natural environments, the determination of an optimal spacing in closed form is rendered virtually intractable.

In an attempt to determine the effectiveness of pattern reconstruction of the Mississippi Delta complex based on sample data, a series of sampling experiments were performed in which random samples and subsequently systematic samples were drawn from the total population and the derived data used to generate proximal maps using the SYMAP computer program [9]. The different sample sizes drawn were 5,

10, 20, 50, 100, 200, and 500, respectively. A proximal map is generated by assigning to each location on a fixed grid the type environment found for the nearest sample. Thus, proximal maps follow a nearest neighbor rule in their construction. Figures 6 and 7 contain proximal maps of the Mississippi Delta reconstruction for the different sample sizes noted above obtained for random samples and for systematic samples, respectively. In viewing the sequence of maps, the continuity of the natural levee environment does not become apparent until the sample size has reach 500. Furthermore, given the choice between random samples and systematic samples the latter are preferable since greater detail in the pattern structure results. Proximal maps produced in this way reveal the evolving pattern structure. The important question is how to decide when sufficient samples have been collected. It is anticipated some kind of multi-stage sampling procedure will be found to be optimal.

Pattern Cross Association

In addition to graphic forms which characterize the spatial order within environment distribution patterns and pattern reconstructions based on sample data, there needs to be devised statistical measures of map pattern structure. Such measures would be of value in assessing the relative strength of a given pattern and for comparing one pattern with another. More important, they could provide a means for determining the minimum sample size necessary to achieve a prespecified level of confidence in establishing a particular type pattern. The interpretation that is given to point patterns derives largely from nearest neighbor relations. In the Mississippi Delta data, the areal distribution pattern is defined by the type of environment occurring at the various grid locations. It is worthwhile to consider the degree of cross association that exists between the type of environment and the nearest sample. Since, for different environments, different areal coverages are involved, it is advantageous to consider the cross association that exists between samples and the nearest sample at which a different type environment is observed. This is referred to as the nearest unlike neighbor. For the Mississippi Delta data, the matrix of

nearest unlike neighbors is given in Table 3. The last row and column give the row and column sums, respectively. As a measure of cross association, the Goodman-Kruskal measure, λ_b , has been used [10]. This statistic measures the relative decrease in probability of error in trying to predict the nearest unlike neighbor of a sample point. For a given set of observations, λ_b is defined as

$$\lambda_b = \frac{\sum_{a=1}^m v_{am} - v_m}{v - v_m}$$

where v_{am} is the largest entry in the a th row, v_m is the largest entry for the column sums and v is the sample size. For the matrix in Table 3, $\lambda_b = .356$. This is interpreted as the measure of pattern strength for the areal distribution pattern represented in Figure 1.

It is of interest to consider the sampling properties of λ_b for different size samples. This kind of information is a prelude for determining a minimum sample size. As an initial experiment, random samples of size 10,20,50, and 100 were drawn from the total of 4025. For each sample size, the sampling was repeated 10,20,50,100,200,500, and 1000 times. For each set of repeated sampling for fixed sample size, the average value of λ_b was calculated. The results are shown in Figure 8. The damped oscillatory behavior of the observed values with increasing sample size is readily apparent. From these curves, it was possible to establish a product sampling rule of the form

$$S = kn$$

where S represents the total sample, k is the number of repeated sampling for a sample size n . For $S = 1000$, the following values of k and n were selected: 100,10 (k,n); 50,20; 20,50; 10,100; 5,200; 1, 1000. The results of random sampling according to this rule in which the average values of λ_b were calculated are shown in Figure 9. From this, it is inferred that a size somewhere in the range from 200 to 500 random samples would be adequate for reproducing the nearest unlike neighbor relations

that exist for the population.

Summary

The primary aim of this preliminary investigation has been to develop graphical aids for describing the spatial form of environment distribution patterns. Spatial principal components and dendrographs depicting interdistance environmental relations both have proven effective. Pattern reconstruction from sample data has been accomplished by proximal mapping. The most important consideration, however, is the problem of minimum sample size required to reproduce a given pattern structure. For the Mississippi Delta complex considered in this study, a threefold argument based on environmental mean coordinate interdistance dendrographs, proximal maps, and cross association measures of nearest unlike neighbors leads to the conclusion that a ten percent random sample of the total area in the delta is sufficient to reproduce the underlying pattern structure. Systematic sampling leads to a more accurate representation while multistage sampling is expected to yield optimal results.

Appendix. Mississippi Delta environmental sample.

The Appendix contains a tabulation of the number and types of environments recorded for each of 4025 areal units of observation from the grid overlay shown in Figure 2 which was used to sample the areal pattern given in Figure 1. In the column headings, B refers to the Block number and G refers to the Grid number used to locate each areal observation unit in Figure 2. E refers to the type environment recorded at the randomly located point within each unit of observation. EVS refers to the set of environments found within each areal unit. The environments are arranged in the following order: natural levee, point bar, swamp, marsh, beach, lacustrine, and bay-sound. The presence or absence of a type environment within an areal unit is indicated by the number one or zero, respectively.

13. ABSTRACT <p>A ten percent random sample of map data is judged adequate to reproduce the first order spatial characteristics of the distribution pattern for the seven major types of depositional environments in the Mississippi Delta region of Southeast Louisiana. This conclusion is based on; 1)dendrographs which portray interdistance relationships among mean coordinate locations for the different environments, 2) the sampling properties of the Goodman-Kruskal measure of cross association as it is applied to nearest unlike neighbor samples, and 3)proximal maps which are reconstructions of the original pattern based on sample data.</p> <p>In analyzing map patterns, principal component analysis can be used to depict spatial trends. Within the Mississippi Delta region, the natural levee, point bar, bay-sound, and beach environments show a marked linear trend whereas the swamp, lacustrine, and marsh environments are more isotropic. With respect to location, the lacustrine environment is situated in an intermediate position between nonmarine and marine depositional environments.</p> <p>The total sample of 4025 data points taken from the environment distribution map of the Mississippi Delta region on which this study is based is contained in the Appendix.</p>
