## SUMMARY

WXXX.

This report covers work performed during an in-house program to evaluate the effectiveness of using the sound emitted from helicopter power train components as a data source for diagnosing their mechanical condition. A ground-based UH-1 helicopter sonic analyzer developed by the Curtiss-Wright Corporation under Government contracts was used in the evaluation.

Sound recordings were made on 87 UH-1 helicopters that had either the transmission or a gearbox scheduled for removal for routine overhaul. The mechanical condition of the components was then noted during the overhaul process, and these results were compared with the recorded signals in an attempt to correlate the mechanical condition with the acoustical signalc. The sonic analysis procedures were then revised to improve the effectiveness of detecting component malfunctions.

The Curtiss-Wright sonic analyzer shows good potential as a successful indicator of power train component anomalies for the UH-1 series helicopters based on the satisfactory performance shown during the field application program. Results indicate that before the sonic analyzer is used as an operational maintenance aid for the Army, it should be evaluated using the revised analysis procedures established during this program.

## FOREWORD

This effort was authorized as a portion of DA Task 1F162203A43405, "Diagnostic and Inspection Equipment". This report covers the work performed from July 1969 through December 1970.

The author acknowledges the support of Mr. Charles W. Bowen, Bell Helicopter Company, and of the personnel at the U.S. Army Aeronautical Depot Maintenance Center, Corpus Christi, Texas, in providing teardown data on the UH-1 transmission and gearboxes.

He also acknowledges the support given by the civilian and military personnel at Fort Stewart-Hunter Army Airfield, especially the personnel of the Aircraft Maintenance Brigade, commanded by Colonel Keith J. Bauer, who generously devoted many hours of effort in providing the requested maintenance data and in operating the aircraft. It was only through the outstanding support and cooperation of these people that this research effort was made possible.

The majority of the data correlation and analysis was performed by Mr. W. H. Dawson of the Curtiss-Wright Corporation, who was assisted by Mr. John Nobles of the Eustis Directorate, USAAMRDL. Their perseverance in manually processing and analyzing the voluminous raw data deserves special recognition.

## INTRODUCTION

The Army, in an effort to improve its capability and efficiency in aircraft maintenance, has programs under way to develop diagnostic equipment for use in determining the mechanical condition of Army aircraft components.

One approach that is being investigated uses the sound emitted by the aircraft as a source of information for determining the condition of the aircraft's mechanical components. A device using this principle is the ground-based UH-1 helicopter sonic analyzer, designated CWEA-4, built by the Curtiss-Wright Corporation under USAAMRDL-sponsored programs. This analyzer was designed and fabricated to monitor the mechanical condition of the rotating elements of the engine, transmission, shafting, and tail rotor gearboxes while the components are being operated on the ground at low power. It is designed to detect the majority of the mechanical anomalies, including gear fatigue failures, bearing failures, and gear tooth scuffing conditions.

Field application and evaluation of the sonic analyzer implied that correlation may indeed exist between the analyzer findings and the mechanical condition of the power train components. However, information on the actual mechanical condition of the components being analyzed was lacking, so further effort was needed to confirm the effectiveness of the device.

Therefore, this house task was established to collect field data on a large number of UH-1 helicopters and to correlate the mechanical condition implied by the sonic analyzer with the actual mechanical condition of the components noted during teardown inspections.

It was originally thought that the reject criteria established by previous research effort would prove to be effective in detecting faulty components, even though it was known that the reject criteria had been established on a theoretical basis. However, <sup>J</sup>uring the initial data analysis effort, it became apparent that these reject criteria and analysis procedures were only partially effective and that they needed to be revised. Thus, a contract was made with the Curtiss-Wright Corporation for their assistance in the analysis effort and for their recommendations on changes in the reject criteria and analysis procedures.

## SYSTEM DESCRIPTION

## CWEA-4 SONIC ANALYZER

The CWEA-4 sonic analyzer (Figure 1) consists of a power supply, the basic CWEA sonic analyzer with UH-1 helicopter plug-in module capability, three microphones, a tape programmer, and associated cabling.

Figure 1. CWEA-4 Sonic Analyzer.

The microphone system consists of three condenser microphones (Figures 2 through 6) located as follows:

Microphone 1

Located approximately 10 inches inside the transmission right inspection door and aimed at the center section of the transmission on the vertical center line for aircraft models UH-1A, UH-1B, and UH-1C. Microphone 2 Located approximately 10 inches inside the engine left inspection door and aimed at a point halfway between the engine  $N_1$  and  $N_2$  accessory drive gearboxes on a vertical line through the parcing line of the two gearbox 'nousings.

Microphone 3 Located approximately 2 inches from the right side of the 42-degree gearbox cover housing and aimed at the center of the gearbox.

A three-prong bracket was used to mount microphones 1 and 2 at the respective transmission and engine inspection doors on the UH-1A, UH-1B, and UH-1C model helicopters (Figure 4). On model UH-1D, a suction cup was used for the microphone 1 installation and a three-prong bracket for microphone 2 (Figure 5). A suction cup was used to mount microphone 3 on all model helicopters (Figure 6).

The analyzer unit itself receives a signal from one of the three microphones, rasses the signal through a narrow band-pass filter, and, for some cases, compares the amplitude of the signal with a predetermined amplitude. The normalized signal is then read on the condition-level meter. From this reading, the condition of the component being analyzed can be determined. The initial component limits were established by using the UH-1 helicopter data recorded at Fort Rucker, Alabama, in September 1966.<sup>1</sup> The analysis of these data resulted in a gain setting required to produce a half-scale deflection of the condition-level meter, which reads from 0 to 10. Reject limits for each component have been revised and are discussed later in this report.

Figure 4. Typical Installation of Microphones 1 and 2 on Models UH-1A, UH-1B, and UH-1C Helicopters.

Figure 5. Typical Installation of Microphone 1 on Model UH-1D Helicopter.

Figure 6. Typical Installation of Microphone 3 on Models UH-1A, UH-1B, UH-1C, and UH-1D Helicopters.

Sal Hasterso

The analyzer has the capability of operating in three different modes:

1.	Manual	The operator manually sets the test level, the gain I and II switches, the ratio select switch, the microphone select switch, and the lock select switch. The read switch is depressed and the con- dition level is read. This process has to be repeated for each component.
2.	Semiautomatic	In this mode of operation, a program tape is used. The program tape automatically sets all of the above logic, and the operator merely depresses the tape driver switch for each successive reading. The condition level is still read as above.
3.	Automatic	In this mode, the movement of the automatic tape is controlled by a clock. A predetermined reference signal is contained in the logic circuitry. If the amplitude of the monitored signal is above that of the reference signal, a magnetic latching relay is energized, stopping the tape $c$ id lighting the indicator lamp. (Because the reject limits were being changed during this program, the

automatic mode of operation was not used.

#### RECORDING EQUIPMENT

During the effort covered by this report, a four-channel tape recorder was used to shorten the on-line analysis time by recording the data for analysis at a later time. The recordings were also used to obtain spectrograms for use in a comprehensive analysis of the sonic data.

The recording equipment included an AMPEX SP-300 magnetic tape recorder and the three condenser-type microphones of the CWEA-4 analyzer. Direct recordings were made at tape speeds of 7½ inches per second. Three tracks were used to record the signals from the microphones, and a fourth track was used for narrative purposes to record data such as aircraft identity and test conditions. and the second se

#### MECHANICAL DATA

The mechanical data for the various rotating components were obtained by Curtiss-Wright Corporation prior to the fabrication of the module for the UH-1 series helicopters. These data consisted of power transmission speeds, shaft speeds, number of gear teeth for each gear concerned, dimensions of races and rolling elements of bearings, engine installation, and gearbox locations. A detailed description of the mechanical and acoustic analysis, the module design, and the analyzer fabrication is given in Reference 1.

The predicted frequencies of the various rotating components were computed for a flight-idle condition by using these data. These frequencies were, in turn, identified as a ratio between their frequency and the frequency of the  $N_1$  or  $N_2$ . Then, by electronically tracking either the  $N_1$  or the  $N_2$  speeds and selecting the predetermined frequency, the frequency associated with any particular component could be studied. The engine and transmission operating speeds for ground operation of the UH-1B and UH-1D helicopter models at flight-idle conditions were established as below:

Helicopter Component Used To Detect  $N_1$  and  $N_2$  Speeds

Helicopter Cockpit Instrument Tachometer Setting

N<sub>1</sub> – Engine Compressor Rotor UH-1B UH-1D

4500 rpm

60%

63%

N<sub>2</sub> – Transmission Input Drive Bevel Gear

It should be noted that these are nominal values, and some helicopter models will have to operate at  $N_1$  and  $N_2$  speed settings that may differ from the nominal speeds. During this in-house program, tracking was successfully accomplished within the range of 59 to 65 percent and 4400 to 4600 rpm. (This tracking capability is often termed as being "locked on".)

Gear train schematics for the power train components of the UH-1 helicopter are shown in Figures 7 and 8. The identification code used in these figures is as follows:

- 1. The number written in parentheses is used to identify and locate the individual component. This number corresponds to the number in the applicable table and on the program tape.
- 2. The number printed on the gear indicates the number of gear teeth.
- 3. The number underlined indicates the component shaft speed in revolutions per second (rps).

## DATA ACQUISITION

An instrument van (Figures 9 and 10) equipped with the sonic analyzer, recording equipment, and supplementary support equipment was taken to Hunter Army Airfield, Savannah, Georgia, where data were collected on UH-1 helicopters. By working closely with the aircraft maintenance personnel, it was possible to collect data on helicopters within a day or two of the time when a major component was to be removed from the aircraft for a scheduled overhaul. The components of interest for the study were the transmission, 42-degree gearbox, and 90-degree gearbox. abile releas freithe arread . " also where the said and

いっている しょうちょうしょう ちょうしょう ないない たいていてい たいてんしょう

The data were collected over a 5-month period from July to November 1969. In all, 87 recordings were made. Of these, 66 were on different aircraft with components scheduled for immediate removal for overhaul.

An identification procedure was established for those components being forwarded to the U.S. Army Aeronautical Depot Maintenance Center (ARADMAC), Corpus Christi, Texas, for overhaul, and the entire shipping process was closely monitored to ensure accountability of the components.

Figure 9. Instrument Van Used for Acquisition of Data of UH-1 Helicopters on the Flight Line.

ş

Figure 10. Interior of Instrument Van Containing CWEA-4 Sonic Analyzer.

Hunter Army Airfield proved to be an excellent facility for acquiring data on the UH-1 helicopter. Because of the high number of hours being accumulated on the aircraft and the large number of aircraft available, it was possible to have a UH-1 helicopter with the desired number of flight hours available for data acquisition efforts at essentially any time. A breakdown of the data acquired is shown in Figure 11.

#### MECHANICAL DATA INSPECTION AND REDUCTION

When the components arrived at ARADMAC for routine overhaul, they were intercepted by engineers from the Bell Helicopter Company, who in turn noted and recorded their condition during the teardown process.

The information on the condition of the components was forwarded to the Eustis Directorate for use in the analysis phase.

A glossary of common failure terms, compatible with American Gear Manufacturers Association and Anti-Friction Bearing Manufacturers Association standard terminology, was compiled and associated with examples taken from overhaul components to aid in achieving uniformity in reporting. This glossary appears as Appendix I.

The component inspection data were reviewed at the Eustis Directorate both by Directorate personnel and a Curtiss-Wright engineer. The review consisted of classifying the condition of the components as normal, faulty, or questionable. In all, 363 components from 47 different helicopters were inspected. Of these components, 35 (about 9.6 percent) were found to be sufficiently deteriorated to be considered defective. Thirty-one of the defective parts were in the transmission, with 10 of these predicted to fail either "immediately" or "in less than 100 hours". Four of the defective parts were in the 90-degree gearboxes. A summary of the review is shown in Table I.

'Table I comprises all test recordings which were considered to be acceptable; that is, they had been properly recorded. These acceptable recordings are identified in the table by a run number. The transmission, 42-degree gearbox, and 90-degree gearbox components are identified with bearings and gears grouped separately. All test runs for which component inspection information (DFAS official formats, handwritten comments, etc.) was available are categorized and identified by a letter in the corresponding run number and component, which indicates the condition of the component. If no comments were received on a component, it has been assumed that its condition was considered to be normal by the inspector, but no letter is shown in the corresponding space.

The inspection information was reviewed in detail by a Curtiss-Wright engineer, and each component's condition was then classified as a failure (F), normal (N), or questionable (Q), and a notation was made in the appropriate space. These, plus supplemental notations, are as shown on the legend of Table I.

#### ACOUSTIC DATA REDUCTION

All of the acoustic recordings were reviewed to eliminate those which were considered to be unsatisfactory for analysis. The causes for elimination varied and could be attributed to one or more of the following:

- Recordings were of poor quality. This could at times be attributed to operator errors or to equipment malfunctions.
- Recordings were made during times when the aircraft's operating speeds exceeded the acceptable limits of the analyzer.

• The signal strength was so low as to cause suspicion in the reliability of the signal.

Narrow-band spectrograms were produced on all of the recordings, using a General Radio Type 1900A narrow-band analyzer having a constant bandwidth of 10 Hertz. The spectrograms proved to be extremely helpful in determining the quality of the recordings and for conducting studies of the various frequencies of interest.

The transmission and gearbox components which were programmed to be checked with the CWEA-4 analyzer were checked for their "go/no-go" condition, and their respective analyzer meter readings were recorded on UH-1 sonic analyzer acoustic log sheets (information from these sheets is presented in Tables II and III). The sheets include the following:

- 1. Itemized identification of components under investigation and described by schematic component number.
- 2. The microphone which is used to record the data. This subsequently identified the channel upon which the data of interest are recorded.

The structure of the state of the state of the second state of the sta

the section of the sector sector sector sectors

- 3. The lock which is used to ratio the frequency of interest.
- 4. The octal ratio of this frequency of the component being investigated. (See Appendix II for a description of the establishment of octal ratios.)
- 5. The condition level that is to be used to determine a go/no-go condition. Since this effort has been one of establishing the go/no-go condition level, the actual level was read and recorded on the sheet for subsequent analysis studies.

- 6. A schematic reference number of the component under investigation.
- 7. The Bell Helicopter part number of the component under consideration.

### DATA ANALYSIS

#### FREQUENCY/AMPLITUDE PROCEDURE

Prior to this house task, the procedure followed in analyzing a component using the UH-1 CWEA-4 sonic analyzer was to identify a frequency representative of the component under analysis and to establish an amplitude above which the component's condition was considered to be faulty. This method of analysis is quick and simple, inasmuch as the frequency of interest can be selected on the sonic analyzer and the amplitude can be read directly.

This method proved to be satisfactory for the bearing analysis, but it was unsatisfactory for the gear analysis.

The reason that it was unsatisfactory for gears and the subsequent revised technique used are discussed in the following section.

#### GEAR ANALYSIS PROCEDURE

A simple spectrum representing a faulty gear is shown in Figure 12(a). The fundamental frequency, two side-band frequencies, and one harmonic frequency are shown. Figures 12(b), (c), and (d) present spectrum representing three good gears of the same type.

The amplitudes of the frequencies of interest for the examples are as follows:

	Faulty Gear		Good Gears	
	Figure 12(a)	Figure 12(b)	Figure 12(c)	Figure 12(d)
ft	9	10	8	9
+f <sub>r</sub>	5	5	4	4
- f <sub>r</sub>	5	5	4	4
2f <sub>r</sub>	_5	_3		_6
Total	24	23	20	23

a strate or a strate of the strate of the

and the second states of the second second

Earlier criteria for the rejection of gears include the use solely of the exceedance of a preselected amplitude of the fundamental frequency or the exceedance of the ratio of the amplitudes of the fundamental frequency and one of the sideband frequencies. These criteria thus far have not produced satisfactory results. The reason for this is readily apparent. By comparing the amplitudes of

frequencies of interest in the various spectrums, it can be seen that the faulty gear could not be identified by noting the exceedance of any particular frequency amplitude. For example, it is seen that the amplitude of the fundamental frequency of one of the good gears exceeds that of the faulty gear. On the other hand, it can be observed that the summation of all of the frequency amplitudes of each gear results in values where the faulty gear value is higher than those of the good gears. The summation approach is used as the procedure for identifying faulty gears.

Figure 12. Continued.

### NORMALIZATION

0 L..... 1900

On the example spectrums of Figure 12, it was assumed that the noise levels of all the gears were the same. In real life, this is not the case, inasmuch as the noise level in the neighboring frequency range associated with any component is different from run to run. Therefore, in order to compare spectrums of various runs, the spectrums had to be normalized. There appeared to be a relationship between the noise level of a good gcar and the amplitude of the characteristic frequency, inasmuch as those spectrums that displayed a high noise level also displayed a high frequency amplitude. In other words, the signal-to-noise ratio appeared to remain mathematically relatable, even constant, for good gears of the same type. This is depicted graphically in Figure 13.

Now, in order to determine what the amplitude of a good gear signal would be for any observed noise level, it is first necessary to empirically derive an equation which gives an approximate relationship between the good gear signal amplitude and the noise level. This wist be done for each frequency of interest, inasmuch as the signal-to-noise ratio (equation to be derived) would not be expected to be the same for all of the signals generated by the various components. An example of how such an equation is derived follows, using the data related to the 90-degree gearbox bevel gears.

### 90-DEGREE GEARBOX GEAR ANALYSIS

Barris and an and a second

The mater readings for the 90-degree gearbox are presented in Table IV. Using the signal amplitude  $(f_t)$  and noise values of the 90-degree gearbox, as recorded in this table, a plot of signal versus noise has been made (see: Figure 14). Although the scatter of data is such that a straight line cannot be drawn through the majority of the points, a tirst-degree equation has been written to define the

average value of the fundamental frequency meter reading for various noise values:  $f_t = 2(n) + 2$ . It can be seen that the use of a higher order equation to define the average value would have resulted in a more accurate definition of the relationship. However, in order to maintain a relatively simple analysis procedure, the first-degree equation was used.

The gains used on the Curtiss-Wright signal conditioner are set so that the meter readings for good components should, on the average, read a value of 5. It can then be seen in Figure 14 that for a meter reading of 5, a noise level of 1.5 should be observed for a good component. Therefore, the procedure of normalizing the signal for a particular noise level is based on the noise level of 1.5.

Corrected values of the sonic analyzer meter readings are then established for the frequencies by using the following equation:

corrected f (f<sub>c</sub>) = 
$$2 (1.5 - n) + f^{+}$$

This equation then shows that at a noise level of 1.5,  $f_{tc} = f_t$ , and for any other noise level, the corrected value would be different from the value read from the meter. The corrected values of the analyzer meter readings, using this equation, are shown in Table V. Table VI summarizes the analysis of the 90-degree gearbox and bevel gears.

Side-Band and Second-Harmonic Meter Reading Corrections

and being any strike in the second of the second strike second strike the second term of the second strike second

Plots of the second-harmonic frequency and the upper and lower side-band frequency meter readings versus noise readings are presented in Figures 15, 16, and 17. The values used are from Table IV. Since the slope of the average value for the meter readings versus noise readings for all three figures was found to be essentially the same (.72), one general equation can be written to correct all three frequency readings for a normalized noise level of 1.5. The resulting

equation, expressed in terms of an approximating first-degree equation, is thus:

$$f_{-rc} = .72 (1.5 - n) + f_{-r}$$
  
$$f_{+rc} = .72 (1.5 - n) + f_{+r}$$
  
$$2f_{tc} = .72 (1.5 - n) + 2f_t$$

These corrected values are tabulated in Table VI.

Figure 15. 90-Degree Gearbox Bevel Gears – Second Harmonic Meter Readings (2ft) Versus Noise Readings

Figure 16. 90-Degree Gearbox Bevel Gears – Lower Side-Band Meter Readings (-fr) Versus Noise Readings.

Figure 17. 90-Degree Gearbox Bevel Gears – Upper Side-Band Meter Readings (+ft) Versus Noise Readings.

Establishment of Rejection Value

By plotting (Figure 18) the values of the sum of the four corrected frequency readings versus the test runs identified as being on good or faulty gears, it can be observed that a reject limit of 15.5 can be established.

Figure 18. Summation of Corrected Meter Readings for the 90-Degree Gearbox Bevel Gears.

### **42-DEGREE GEARBOX GEAR ANALYSIS**

Because the information received from the mechanical condition analysis was limited to only four gearboxes, none of which were reported as faulty, the reject limit for the 42-degree gearbox could not be statistically established. Table VII summarizes the information compiled on the four gearbox bevel gears, but no conclusions were drawn since the analysis was not complete; the information was recorded only as data for future investigations.

### TRANSMISSION GEAR ANALYSIS

Address of the

maximum and a substitution of

Input Drive Bevel Gears (1), (2), and (3)

There were no faulty input drive bevel gears reported on any of the transmission inspection reports, so they were all considered to be normal.' As additional data are collected in future efforts, reject limits for faulty gears (1), (2), and (3) will be established.

# Lower Planetary Gears (7), (8), and (9)

Using the same procedure as that discussed for the 90-degree gearbox analysis, a meter reading correction equation was established:

$$f_c = 1.25 (1.5 - n) + f$$

Applying this equation to the meter readings in Table VIII resulted in the corrected readings shown in Table IX. It was determined that the correction equation should be applied to all of the frequencies of interest except for the first-harmonic meter readings, where no correcting was found to be necessary.

As shown in Figure 19, a reject limit of 23 has been established for gears (7), (8), and (9). It can be easily seen that this limit will accept three of the four satisfactory gears and will reject all of the faulty gears.

A gear analysis summary for the lower planetary gears is presented in Table X.

44	28.5	Yes	Yes	Ring gear teeth chipped; sun gear and planetary pinions are OK.
52	29.5	Yes	Yes	Sun gear has excessive wear on teeth, with visible change in involute profile; destructive wear, etc.

# Upper Planetary Gears (10), (11), and (12)

Using the procedure previously described, meter reading correction equations were established:

for  $f_t$ :  $f_{tc} = 4.2 (1.5 - n) + f$ for  $+f_r$ :  $+f_{rc} = 4.2 (1.5 - n) + (+f_r)$ for  $-f_r$ :  $-f_{rc} = 1.0 (1.5 - n) + (-f_r)$ for  $2f_t$ : no correction necessary Applying these equations to the meter readings for the upper planetary gears in Table XI resulted in the corrected readings shown in Table XII and Figure 20. The upper planetary gear analysis is summarized in Table XIII.

## Transmission Spur Gears (13) and (14)

Because there were no faulty conditions reported for these spur gears, no statistical reject limit was established. It was noted that the gain setting assigned to the analysis program tended to give consistent readings, and it is thus believed that similar readings found in future analyses could be indicative of good gears of this type. As additional data are collected in future efforts, the establishment of reject limits will be possible.

## Transmission Output Drive Bevel Gears (15), (16), and (17)

The comments on gears (13) and (14) are also applicable to the output drive bevel gears (15), (16), and (17), inasmuch as there were no faulty conditions reported for these gears.

### BEARING ANALYSES

Bearing analyses for the transmission, 42-degree gearbox, and 90-degree gearbox are summarized in Tables XIV through XXIII.

#### SUMMARY OF ANALYSES

na dahar diki dan sedara mangan di kata mangkar minisi kata minisi kata mangkar kata kata kata kata kata kata s

Because the data acquisition effort was based on acquiring data on transmissions and gearboxes which were scheduled for overhaul, only a very low percentage of the components were found to be faulty. This is to be expected because the number of hours established for removal for overhaul are set at a level where it is anticipated that failures will seldom occur. The lack of a large number of faulty components and even the complete absence of any report of faulty conditions for some components restricted the scope of what could be accomplished by this effort.

The significance of the data processing and analyses can best be interpreted by reviewing Tables XXIV and XXV, which summarize the correlation of the analysis findings with the mechanical condition findings.

The column of data labeled "yes-yes" records the case where a defect was noted in the teardown inspection and where a defect was indicated by the analyzer. It can be seen that this category resulted in a high percentage of effectiveness: an 83-percent overall effectiveness for bearings and a 100-percent overall effectiveness for gears. Recalling that the reject criteria used in this analysis effort were established using the same data that were used to determine effectiveness, it is only natural to expect that there would be good effectiveness results; that is to say, when a reject limit was established, it was set at a value where it was observed to cause rejection of most of the reported faulty components and acceptance of most of the reported good components.

Likewise, this contributes to the low percentages in the "yes-no" column, which is depicting the situation where the component was found to be mechanically faulty during inspection but the analyzer failed to detect the faulty condition.

For the third column, the "no-yes" situation, the component was found to be in good mechanical condition but the analyzer classified the component as faulty. This is a "false alarm" situation and is one which did not occur excessively.

The fourth column, the "no-no" situation, is obviously the most common occurrence, because most components which are removed for overhaul are still in good condition.

### HOW BAD IS BAD?

During any diagnost c equipment research or development effort, the inevitable question is asked: "Just how bad is a component that is considered bad?" The answer to that question is difficult to define and seems to vary with the conditions.

A "bad" component, as defined in this report, is one where a defect was noted during the overhaul process which caused replacement of the component. It is readily apparent that by this definition, the condition could actually be one of severity, ranging from a barely detectable defect to a situation where the component disintegrated into a multitude of pieces.

Those "bad" components that had relatively minor defects could easily have been classified as "good", if the reject criteria used during the inspection-overhaul process had not been quite so stringent. A review of the effects of various reject limits produces interesting observations.

Figure 21 represents the hypothetical, but plausible, deterioration rates of three components of the same type. The point to be made here is that even though they are all three the same type, their rates of deterioration are different.

Figure 21. Wearout Rates of Three Components of the Same Type.

Figure 22 shows a desirable schedule of the inspection and overhaul procedure. Here, it is shown that the combination of the interval between inspections and the reject limit used during the inspections is providing assurance that a component of this type will not fail during the interval between inspections.

Figure 22. Reject Limit Established by the Inspection and Overhaul Procedure (First Example).

The number of hours that a component could have been operated if it had not been rejected during inspection comprises the useful life lost. It can be seen that if the reject limit were raised to some higher value representing a higher degree of deterioration, it would have the propitious effect of reducing the useful life lost, up to the point where the reject level becomes so high that a part is not rejected during the inspection process and then fails before the next inspection cycle. This can be seen to occur in case "A", if the reject limiwere higher than the optional reject limit shown in Figure 22.

Figure 23 shows the same curves, reject limit, and time-between-overhauls as Figure 22. However, in Figure 23, the phasing of the overhauls differs. It can be seen that this difference in phasing causes the components to be rejected earlier, thus creating the adverse effect of increasing the useful life lost.

and the second second second second second

Now, one might ask what would be the effect of eliminating the inspection/TBO procedure altogether and, instead, using an analyzer which continuously monitors the mechanical condition of the component. Figure 24 shows the effect of such a procedure. It can be seen that this procedure would be less desirable than the inspection/TBO procedure, if the same reject criteria are used, because it increases the useful life lost. This curious result is one for contemplation of the fallacy of using such an analyzer approach.

Figure 23. Reject Limit Established by the Inspection and Overhaul Procedure (Second Example).

. . .

- está

a service and a substance of the service of the ser

Figure 24. Reject Limit Established by an Analyzer Using Limit Criteria Set by Overhaul Procedure.

The fallacy of the approach and the obvious correction that should be made can be seen in Figure 25. Because the analysis process can be continuous, the need to allow for any deterioration that may occur after the inspection can be eliminated. This means that the analyzer reject limit could be evaluated to a level that is just short of the tailure point by an amount which would permit sufficient time to order a replacement component and so replace the component prior to complete failure.

Figure 25. Reject Limit Established by an Analyzer Using Limit Criteria Set by the Analyzer's Capabilities.

The effectiveness study that has been reported herein compared the ability of the analyzer to detect components that had been rejected by the inspection/overhaul process. By what has just been discussed, it is obvious that this may be an unfair test of effectiveness, because it has placed the burden on the analyzer to be able to detect deterioration levels that are lower than that necessary for an optimum inspection process using an analyzer.

CONTRINSIONS

It is concluded that:

beth have been a such to the base of a strange by

- 1. The concept of using acoustic data generated by a helicopter under low power conditions to diagnose the mechanical condition of helicopter transmissions and gearboxes is feasible.
- 2. The ground-based CWEA-4 sonic analyzer developed by the Curtiss-Wright Corporation is a reliable and effective instrument for use in determining the mechanical condition of helicopter power train components by analyzing helicopter acoustic data.
- 3. The effectiveness of the sonic data analysis approach to diagnostics could be improved by additional data acquisition efforts and subsequent refinement of data acquisition techniques and reject criteria identification.

to me conserves

### RECOMMENDATIONS

It is recommended that:

and a state of the second s

- 1. Additional efforts be conducted using the sonic analysis techniques to check the condition of helicopter components where the condition is known. Both good and faulty conditions of components should be investigated.
- 2. Investigations be conducted to identify any relationships that exist between the loading and/or operating speeds of gears and bearings and the acoustic spectrums generated.
- 3. Additional analysis techniques be investigated to ensure that the optimum techniques are being applied.
- 4. Sensor studies be conducted to optimize the location and type of microphones that should be used. The studies should also determine whether or not a microphone is the best type of sensor to use to acquire the data necessary for the analysis techniques used.

#### APPENDIX I GLOSSARY OF FAILURE ANALYSIS TERMS

#### GEAR TOO'TH OR SPLINE

#### Wear

#### 1. Destructive Wear

Destructive wear is wear that has resulted in a corrosive change in the involute shape of the gear tooth. Destructive wear would be accompanied by extremely rough operations, nonuniform motion, and shock overloads which would probably result in tooth breakage.

2. Abrasive Wear

Under normal circumstances of lubrication, the occurrence of abrasive wear would be extremely infrequent. If sand and water are present in appreciable quantities, abrasive wear may be observed. Fully case-hardened gears are not likely to exhibit any significant abrasive wear. Medium hard and soft gears will frequently exhibit this type of wear.

3. Galling

Galling is a vrm of contact welding that results in the transfer of material i. m one gear member to another. It is also quite infrequent in moderate- to high-speed gearing, but is often seen in low-speed and stop/start type operations. An excellent example of spline galling occurs on the Model 206 sun gear spline.

4. Scoring

This type of wear is often referred to as "scuffing" and is evidenced by radial wear lines superimposed on a roughened thin layer of melted material. Bright, shiny wear on black oxided gear teeth must not be confused with true scoring. This condition, although considered normal for many applications, represents a lubrication state intermediate between thick film asperity separation and film failure nditions associated with scoring.

5. Frosting

The term frosting will be limited in use to fully hardened gear tooth profiles. It will be used to define the existence of a large number of

small round or elliptical patches which under high magnification exhibit the general appearance of minute scorings.

Corrosive Wear

This term should not be used to define the existence of ordinary oxidation corrosion which is cause for replacement of the component. True corrosive wear occurs most generally in overtemperature operations in the presence of extremely strong EP additive lubricant of the chlorine or sodium families and therefore will be an infrequent occurrence.

7. Interference Wear

Interference wear defines the effects of the tip of one gear tooth member's contacting the fillet or root area of its mating gear tooth. If this occurs in the helicopter transmission, it will probably be accompanied by an extreme overtemperature condition or an unusual type of support bearing failure which reduces the operating clearance or backlash of the gear set. Interference wear does not occur in correctly designed, properly operating gear sets.

8. Burning

Burning indicates surface tempering or softening of the tooth member. It will most probably be accompanied by a total loss of lubricant. Scoring, destructive wear, and tooth breakage may also be present. In general, burning is an advanced condition of the following term.

9. Discoloration,

This term is used to locate the existence of surface temper coloring of the active profile, the top land, or the coast side of the gear tooth. There is generally no appreciable softening of the metal to any significant depth. The condition may be indicative of marginal lubrication or excessive power operations.

10. Misalignment

South Karle Last Long

Misalignment indicates operation of the gear or spline set at axes skewed from those intended by the designer. When this terin is checked, at least one other term must also be checked to explain the physical result of the indicated misalignment.

11. Surface Treatment Worn Through

This term implies that the gear or spline in question was treated with an antiwear surface coating such as Electro-Film, Dicronite, or in some instances, soft metal plating.

#### Lin Oil Absention

This term indicates the partial or complete failure of the lubrication system in either the immediate area of concern or the entire transmission.

13. Corrosion – Other

This term is used to define the existence of ordinary oxidation corrosion which is cause for replacement of the component. This may occur during helicopter nonoperation intervals under severe moisture conditions or may occur in transit, storage, or handling due to improper preservation.

#### Surface Contact Fatigue

1. Destructive Pitting

Destructive pitting will be used to define the existence of advanced state of tooth profile deterioration. This term is used without concern as to the origin or generic identification. It further indicates that complete loss of function of the gear tooth is imminent.

2. Spalling – Fan Shape

This term will be used to define a pitting condition whose origin can be physically detected at the apex of the fan-shaped portion of the damaged area. This is a surface-initiated type of fatigue, which has its origin in the surface tensile cracking which leads to the gradual erosion and exfoliation of increasingly larger pieces of gear material as the fan widens out in the direction of sliding action. The cracks will ultimately undermine the entire case of case-hardened gear teeth as the spalling approaches the extremities of the addendum.

3. Arrested Pitting

This term will be used to indicate the existence of very small shallow pits that are not propagating into larger failure areas. A good example of this frequently occurs in the flank of the -108 planet pinions in contact with the nitrided -331 ring gears. This type of pitting has also been observed on spiral bevel gears and is frequently associated with the waviness condition referred to as "barber pole". This pitting is often considered corrective in that it progresses immediately to the point of relieving local compressive stress of overload.

and the set is a structure of a structure of a structure of a structure of the structure of t

4. Pitch Line

Pitch-line pitting belongs to the family of rolling contact fatigue and is topy-one ourface-in-wright. It is not control associated with a condition of lubrication distress but generally occurs at relatively high cycles of loading. In fully hardened, properly designed gears, it is seldom seen in less than 100,000 cycles of operation.

5. Addendum Origin

Checking this term merely signifies the site of origin of one of the above types of pitting or spalling.

6. Dedendum Origin

Checking this term merely signifies the site of origin of one of the above types of pitting or spalling.

7. Case Crushing

Case crushing means sheer failure of the core-case interface in casehardened gear teeth. Generally, insufficient case depth for the load magnitude is indicated. Multiple cracking, often both transverse and longitudinal, is generally observed in the tooth face. ው በው በው የሚያስት የሚያስት የሚያስት በው የሚያስት የሚያ የሚያስት የሚያ

#### Breakage

1. Fatigue

Fatigue will be used to define high cycle repeating stress failure with a fracture surface being well defined with the customary clamshell or bench marks. Unless otherwise defined, it will be assumed that the failure origin is in the root fillet area of the gear tooth.

2. Wear

This term should not be used alone in the breakage category but merely serve as a modifier to indicate that some other form of breakage was accelerated by the presence of wear.

3. Overload

In the instance of properly manufactured gears, the occurrence of overload breakage is evidenced by low cycle fatigue with few, if any, bench marks. The failure interface may in fact resemble the crystalline appearance of a static failure.

#### 4. Misalignment

Misalignment is operations at skewed axes which result in a particular form of breakage defined elsewhere in this category.

5. Quench Cracks

Quench cracks are generally cracks that occur at or near the interface of the core-case structure and result from either excessive case depth or improper location of the part relative to the quenching dies during the hardening process.

6. Grinding Cracks

Grinding cracks result from excessive temperature between the wheel and tooth interfaces during manufacture, which induces a tensile stress field in excess of the elastic properties of the material. This type of crack is generally found to occur orthogonally to the direction of the grinding wheel passage.

7. Impact

Impact b eakage is that which results from sudden stoppage or debris in mesh. It will be a completely static fracture and will be accompanied by extreme deformation of the failed tooth in all cases except static fractures in nitridec gears.

#### Debris in Mesh

1. Moderate Damage

Moderate damage is defined as that level of damage which does not impair the basic functional operation of the gear tooth.

2. Heavy Damage

Heavy damage is defined as that level of damage which impairs the  $d_{f}$  tional operation of the gear tooth and leads to catastrophic failure of the gear.

#### Bearings

1. Spalling

This term is used to define a flaking condition whose origin may be of

the classical subsurface fatigue mode or a surface-initiated type of fatigue.

2. Pitting

This term is used to indicate the existence of very small, shallow pits that are not propagating into larger failure areas.

3. Corrosion

This term is used to define the existence of ordinary oxidation corrosion that is cause for replacement of the componen. This may occur during helicopter nonoperation intervals under severe moisture conditions with or without the presence of highly contaminated oil.

4. Denting

Dents (indentations) in the raceway occur when foreign particles are introduced into the bearing and are pressed between the rolling elements and the rings. Item 5 or Item 6 should be marked in conjunction with this failure mode. Denting is not to be confused with brinelling, which is explained in Item 13 below.

5. External Debris

This indicates that the debris which caused bearing damage did not originate from the bearing itself, but from another (external) failed or damaged part.

6. Internal Debris

This indicates that the debris which caused the bearing damage originated within the subject bearing; for example, debris from inner race failure causing damage to the outer race.

7. Break

This term is used to define the condition where the bearing element is fractured completely through the element cross section.

- 8. Crack
  - a. Grinding Cracks

Grinding clacks result from exc . We temperature between the wheel and bearing element interfectors during manufacture which induces a tensile stress field in excess of the elastic properties of the material. This type of crack generally occurs orthogonally to the direction of the grinding wheel passage.

b. Rubbing Cracks

If a hardened bearing ring under rotation rubs against a stationary part, rubbing cracks may develop. These cracks always run perpendicular to the direction of rubbing.

c. Defective Material: Cracks

Cracks caused by defective material ordinarily have an easily recognizable character, but their actual cause can often be determined only by metallurgical investigation.

9. Smearing

Smearing occurs because of rolling element skidding in the absence of sufficiently viscous lubrication. Smearing, as the name implies, is evidenced by a smeared-appearing deterioration of the raceway surface.

10. Glazing

This is a form of smearing whereby the affected area on the raceway becomes shiny appearing, similar to the finish on a new ball. Metal flow has taken place during this mode of failure.

11. Wear

ì

This is the deterioration of the bearing rolling surfaces through normal use. Abrasives in the lubricant and poor lubrication accelerate the wear process.

12. Grooving

Greoving is continuous circumferential indentation on balls produced by balls' running on retaining diameter of counterbored raceway.

13. Brinelling

Brinelling is a term applied to a bearing which has been statically loaded to an extent such that the raceways and rolling elements are permanently deformed. A brinelled bearing has indentations in the raceways and often has corresponding flats on the rolling elements.

## 14. Fretting

Fretting is generally considered to be a corrosive form of wear cursta by very slight movement between two metal surfaces under very high contact pressure. The formation of an iron-oxide paste between two fretting steel members is not uncommon. 'It is often seen between the inner ring and the shaft.'

#### 15. Creeping

Creeping is a relative movement between the bearing inner ring and the shaft, caused by inadequate interference fit for the applied load. Creeping causes not only undesirable ring wear but also excessive shaft wear. Creeping is evidenced by circumferential scoring on the bearing bore and shaft. It may be an advanced stage of fretting.

16. Spinning

Spinning is an advanced stage of creeping. The relative movement between inner ring and shaft is much greater than in creeping and the sliding surfaces may become polished. The iron-oxide from the fretting phase may still be present and assist in further wear.

17. Incorrect Installatic

This term will be used when the bearing has obviously been damaged during installation or has been installed incorrectly. A common example is forcing an assembled roller bearing over the inner race with the rollers misaligned, causing marks (smeared streaks) on the inner race.

18. Diassembly Damage

This term will be used when the bearing was damaged at disassembly.

19. Discoloration Due to emperature

Discoloration of bearing elements indicates operation with marginal lubrication or at excessive power conditions.

## APPENDIX II SAMPLE CALCULATIONS

The following sample calculations are based on data from engine models T53-L-9, T53-L-9A, and T53-L-11:

1. Compressor

Example: 1st stage = 26 blades,  $N_1 = 15,088$  rpm

a. Fundamental rotational frequency

 $f_r = \frac{f}{60} = \frac{1 \text{ of compressor rotor, } N_1 (rpm)}{60} = \frac{15,088}{60} = 251.5 \text{ cps}$ 

b. Compressor rotor blade passage frequency

 $C_1 = f_r \times no.$  of rotor blades = 251.5  $\times$  26 = 6539 cps

2. Accessory Drive Gearbox - Gas Producer Driven

Example: Inner drive spur gear (4b),  $N_1 = 15,088$  rpm, gear (1) = 34 teeth, gear (2) = 63 teeth, gear (3) = 21 teeth, gear (4a) = 40 teeth, and gear (4b) = 24 teeth (refer to Figure 7 of Reference 2 for location of these gears)

## a. RPM of gear

an an in the second second

$$N_{gear}(4b) = N_1 \times \frac{No. \text{ of teeth on drive gear (1)}}{No. \text{ of teeth on driven gear (2)}} \times \frac{No. \text{ of teeth on driven gear (2)}}{No. \text{ of teeth on driven gear (3)}}$$
$$= 15,088 \times \frac{34}{63} \times \frac{21}{40} = 4274.9 \text{ rpm}$$

b. Rotational frequency

$$f_{gear}(4b) = \frac{rpm \text{ of } gear}{60} \times no. \text{ of } gear \text{ teeth} = \frac{4274.9}{60} \times 24$$
$$= 1710 \text{ cps}$$

## 3. Bearing Formulas

Example: No. 1 main engine bearing,  $N_1 = 15,088$  rpm, d<sub>B</sub> = 0.5000 in., d<sub>1</sub> = 2.2720 in., d<sub>2</sub> = 3.2720 in., and m = 13

a. Fundamental rotational frequency

$$f_r = \frac{rpm \ of \ shaft}{60} = \frac{15,088}{60} = 251.5 \ cps$$

b. Frequency caused by irregularity on inner race

$$f_1 = f_r m \frac{d_2}{d_1 + d_2}$$
  
= 251.5 × 13 ×  $\frac{3.2720}{2.2720 + 3.2720}$  = 1929.6 cps

## c. Frequency caused by irregularity on outer race

$$f_2 = f_r m \frac{d_1}{d_1 + d_2}$$
  
= 251.5 × 13 ×  $\frac{2.2720}{2.2720 + 3.2720}$  = 1339.9 cps

## d. Frequency caused by spin of rolling element

$$f_{\rm b} = f_{\rm r} \frac{d_2}{d_{\rm B}} \frac{d_1}{d_1 + d_2}$$
  
= 251.5 ×  $\frac{3.2720}{0.5000}$  ×  $\frac{2.2720}{2.2720 + 3.2720}$  = 674.5 cps

e. Frequency caused by rough spot on rolling element

$$f_{\rm b}' = 2f_{\rm b} = 2 \times 674.5 = 1349.0 \text{ cps}$$

f. Frequency due to rotation of train of rolling elements

$$f_t = \frac{f_2}{m} = \frac{1339.9}{13} = 103.1 \text{ cps}$$

4. Ratios

ţ

È,

Example: Component frequency = 7504 cps Tracking frequency = 6525 cps and a first a start of the star

Ś

a. Decimal Ratio

Decimal ratio = 
$$\frac{\text{component frequency}}{\text{tracking frequency}} = \frac{7504}{6525} = 1.15003$$

b. Octal Ratio

والمناقطونية فلاحاد وتحدد معاضا لمحاد معدمور والدوائي

Convert the decimal ratio to an octal ratio as follows:

- (1) The number to the left of the decimal ratio is the first number of the octal number.
- (2) Multiply all digits to the right of the decimal point in the decimal ratio by 8. The number to the left of the decimal point in this product is the first number to the right of the decimal point in the octal number.
- (3) Multiply all digits to the right of the decimal point in the product obtained in (2) by 8. The number to the left of the decimal point in this product is the second number to the right of the decimal point in the octal number.

فيعتا فالدهما ستخلصهم مالانتها بالالمالية والمعالم

and a state of the second second state of the second second second second second second second second second s

- (4) Continue this process until the desired number or decimal places for the octal ratio are obtained.
- (5) Round off the last decimal place using the number 4 as the mid-point since these numbers are to base 8.

Example: Decimal ratio = 1.15003 Multiply 0.15003 × 8 = 1.20024 0.20024 × 8 = 1.60192 0.60192 × 8 = 4.81536 0.81536 × 8 = 6.52288 0.52288 × 8 = 4.18304

Therefore, the octai ratio = 1.1146 rounded off to 4 decimal places. If the octal number had been 1.11475, the number rounded off to 4 decimal places would be 1.1150.
