ACKNOWLEDGEMENT

We acknowledge the valuable assistance of Mr. N. Gelber in the determination of the nitrogen content of the nitrate esters used in this study.

ABSTRACT

A quantitative infrared analysis of the N=O asymmetric stretching vibration band for the nitrate esters, ethyl nitrate, amyl nitrate, ethylene glycol dinitrate, glycerol trinitrate, and cellulose nitrate (12.53%) is presented. Two solvents, chloroform and tetrahydrofuran were used; in both cases the validity of Beer's law appears well established over a reasonable range of concentration and cell path length.

CONCLUSION

For the five nitrate esters studied, Beer's law for the absorbance of the N=O asymmetric stretching band is found to be generally obeyed. In other words, from a measure of the absorbance one could calculate the amount of a given nitrate ester present in solution. The low absorptivity a for cellulose nitrate deserves some comment. The band shape for cellulose nitrate is significantly broader and consequently measurement of the absorbance at the band maximum is not a true indication of the absorption intensity. A more realistic measurement would be the integrated intensity of the band.

RECOMMENDATION

It is recommended that this study be extended to a number of cellulose nitrates covering a wide range in nitrogen content. An important point to establish is whether the absorptivity a for the N=O asymmetric stretching vibration is a constant or a function of the nitrogen content.

INTRODUCTION

Organic nitrate esters are the most prominent ingredients in solid propellant formulations. Among the most commonly known esters of this type are glycerol trinitrate (nitroglycerin), cellulose nitrate (nitrocellulose), ethylene glycol dinitrate, butane triol trinitrate, and pentaerythritol tetranitrate. But the list of all organic nitrate esters evaluated to date in propellant formulations would probably not exceed a dozen or so compounds. This is far less than the known eight-hundred nitrate esters which form a distinct class of organic chemical compounds. It is thus realistic to anticipate that a large variety of nitrate ester compounds will be evaluated in future propellant formulations.

One important aspect of the chemistry and technology of nitrate esters is the number of analytical methods available for determining their purity. The nitrogen content, which reflects the substitution in nitrate groups, is usually determined by the DuPont nitrometer method (Ref. 1) or by titration (Refs 2 and 3). Both of these methods are well established and of sufficient accuracy. They have, however, shortcomings in terms of convenience of manipulation, time of handling and quantity of sample required per determination. A third method of analysis, the well-known micro Dumas, would require only a few milligrams of sample per determination. Unfortunately, this method does not appear to be applicable to the polynitrate esters, for which titration usually gives low nitrogen values (Ref. 4). Quite recently a microscopic method based on dispersion staining (Ref. 5) has been developed for determining the degree of nitration of cellulose nitrate. For cellulose nitrates ranging in nitrogen content from 12.55 to 13.5%, agreement with the standard duPont nitrometer results was excellent. However, this microscopic method is strictly limited to cellulose nitrate. A modified version of the microscopic method has been suggested for inclusion in military specifications (Ref. 6). It is our opinion that, although this method based on refractive index measurement is extremely simple and fast, it lacks in scope and can only be used for cellulose nitrates of limited range in nitrogen content.

Polarography has also been considered as a potential analytical tool for the study of nitrate esters. In principle, this technique offers very attractive features, one being the small amount of sample required. But, so far, this technique has not proven too successful as a quantitative tool for a number of nitrate esters. In the case of cellulose nitrate for example, no diffusion current is detectable because of the extremely slow diffusion of the polymer at the dropping mercury electrode. Also, nitrate esters with any degree of volatility would not be amenable to precise quantitative study by this technique because of evaporation losses which may occur under the flow of nitrogen during the deoxygenation step.

One analytical technique for nitrogen determination of nitrate esters which promises to be of wide scope is infrared spectrophotometry. This technique offers a number of interesting features: (a) it is non-destructive and safe to carry out, (b) the technique can be developed to handle samples as small as ten milligrams, and (c) it is applicable to cellulose nitrate as well as to highly volatile nitrate esters. The limited work already reported in the literature (Ref. 7 and 8) indicates that this spectroscopic technique could be made competitive in terms of accuracy and reproducibility with the best conventional methods. But most important is the realization that the infrared procedure is far superior to the other methods in terms of ease and convenience of operation and scope of application.

The work described in the present report represents an attempt to establish the scope and applicability of the infrared technique for a variety of nitrate esters. The actual procedure used differs from previous ones in that a variable path length cell is used for infrared measurements.

RESULTS AND DISCUSSION

The precision and accuracy of the micrometer scale of the variable path length cell were determined by the method of interference fringes. The true path length between the windows was calculated in accordance with the formula

$$b = \frac{n}{2 (\lambda_2 - \lambda_1)} \quad (1)$$

where b = path length in cm

n = number of fringes between starting and finishing frequency
(cm^{-1})

λ_2 = starting frequency (cm^{-1})

λ_1 = finishing frequency (cm^{-1})

The calibration data is given in Table 1. It is observed that the deviations between the cell micrometer settings and the true path length decrease with an increase in path length, from 4.56% deviation at 70 microns path length to 0.92% deviation at 600 microns. Except for the longest path (600 microns), the reproducibility of the triplicate determinations is within one percent.

The analysis of the nitrate esters chosen for this study is based on the well-known fundamental Beer's law which relates the absorption at a particular wave length of radiation to the number and type of molecules. This law states that the absorbance (A) should be a linear function of the concentration of the absorbing material among other things. It is mathematically expressed as follows:

$$A = \log \left(\frac{I_0}{I} \right) = a \times b \times c \quad (2)$$

where I_0 = incident radiation

I = transmitted radiation

a = absorptivity

b = sample thickness or internal cell length

c = concentration of the absorbing material

A = Absorbance

For measuring I_0 and I of the absorption bands, we have used the base line method.

In nitrate esters, the nitrate group gives rise to six active infrared absorption bands shown in Table 2. Of these, the most intense band is assigned to the $\text{N} = \text{O}$ asymmetric stretching mode, and its high relative intensity makes this absorption particularly attractive for quantitative study. However, this band falls in the $1620 - 1680 \text{ cm}^{-1}$ spectral region, where atmospheric water also absorbs. Even with double beam spectrometers, this moisture absorption is never completely elimi-

nated. To reduce atmospheric absorption to a minimum, all measurements were done under a dry air purge.

Our study embraces five different nitrate esters: ethyl nitrate, amyl nitrate, ethylene glycol dinitrate, glycerol trinitrate, and cellulose nitrate. Their chemical compositions are shown in Table 3. Two solvents, chloroform and tetrahydrofuran, which are transparent in the spectral region of interest, were used to prepare the solutions. The shapes of the absorption bands of the individual nitrate esters are reproduced in Figures 1 through 5. All the bands were found to be narrow with a half-band width of the order of 25 cm^{-1} . With ethylene glycol dinitrate, there is some evidence of a close doublet at the maximum of the band. The band shape for cellulose nitrate appears less symmetrical, presumably because the monomeric units have their nitrate groups distributed in three chemically different patterns.

Ethyl Nitrate

Tables 4 - 5
Figures 6 - 7

The straight line relationship found establishes the validity of Beer's law for this molecule. The average absorptivity constant, a , is calculated to be $7.23 \times 10^5\text{ cm}^2, \text{mole}^{-1}$. There is indication that a may be slightly higher in tetrahydrofuran.

Amyl Nitrate

Tables 6 - 8
Figures 8 - 10

In general, Beer's law is obeyed for this molecule also. In chloroform, a takes an average value of $7.88 \times 10^5\text{ cm}^2, \text{mole}^{-1}$ while in tetrahydrofuran the value is $8.66 \times 10^5\text{ cm}^2, \text{mole}^{-1}$.

Ethylene Glycol Dinitrate

Tables 9 - 12
Figures 11 - 14

In general, the plots of absorbance versus either path length or concentration show some curvature. This is confirmed by the a values which are found to decrease with concentration or path length by about 10%. In chloroform, the average a is $13.53 \times 10^5\text{ cm}^2, \text{mole}^{-1}$ as compared to $14.56 \times 10^5\text{ cm}^2, \text{mole}^{-1}$ found in tetrahydrofuran. Since this molecule contains two nitrate groups, a per nitrate group becomes $7.28 \times 10^5\text{ cm}^2, \text{mole}^{-1}$ (NO_2) in tetrahydrofuran and $6.77 \times 10^5\text{ cm}^2, \text{mole}^{-1}$ (NO_2) in chloroform.

Glycerol Trinitrate

Tables 13 - 16

Figures 15 - 18

The observations for glycerol trinitrate parallel those made for ethylene glycol dinitrate. However, the values for a are reversed in order. These values are found higher in chloroform, $22.24 \times 10^5 \text{ cm}^2 \cdot \text{mole}^{-1}$ as compared to $19.40 \times 10^5 \text{ cm}^2 \cdot \text{mole}^{-1}$ in tetrahydrofuran. Since this molecule contains three nitrate groups, a per nitrate group is calculated to be $7.41 \times 10^5 \text{ cm}^2 \cdot \text{mole}^{-1} (\text{NO}_2)$ in chloroform and $6.47 \times 10^5 \text{ cm}^2 \cdot \text{mole}^{-1} (\text{NO}_2)$ in tetrahydrofuran.

Cellulose Nitrate (12.53% N)

Tables 17 - 27

Figures 19 - 29

Because of a lack of solubility, no experiment could be conducted in chloroform. While it seems established by the results that Beer's law is obeyed reasonably well with this polymer in tetrahydrofuran, deviations from the straight line relationship appear to occur at path length settings greater than 400 microns. The average a values per nitrate group in the molecule for all experiments is $4.48 \times 10^5 \text{ cm}^2 \cdot \text{mole}^{-1}$, a value substantially lower than those found in tests of the simpler nitrate ester.

EXPERIMENTAL PROCEDURES

Materials

Spectroscopic Solvents

Eastman-Kodak spectrograde chloroform and tetrahydrofuran were used as received.

Nitrate Esters

Ethyl nitrate white label was purchased from Eastman-Kodak. Attempt to establish its purity by the standard ferrous reduction method of the nitrate group yielded very low values. The average of triplicate determinations was 25.10% of theoretical. Evidently this analytical technique is unsatisfactory for volatile nitrate esters. The procedure was modified to prevent evaporation losses and, with this modification, the values were raised to 80% of theoretical.

Amyl nitrate was purchased from K & K Laboratories, Inc., Plainview, N. Y. The standard ferrous reduction method failed to yield acceptable results. The average of six determinations gave 56.6% of theoretical. However, modifications of the procedure to reduce evaporation losses was successful and the purity from triplicate determinations was shown to be higher than 99%. Ethylene glycol dinitrate was obtained from Trojan Powder Co., Allentown, Pennsylvania. Its purity, as determined by the ferrous reduction method was found to be 98.66% of theoretical.

Glycerol trinitrate was obtained from Hercules Powder Co., Kenil, N. J. By the ferrous reduction method its purity was found to be 99.94% of theoretical.

Cellulose nitrate was supplied by Hercules Powder Co. Its nitrogen content, determined by the ferrous reduction method, was found to be 12.53%, which corresponds to a degree of substitution of 2.43.

Infrared Spectra

The infrared spectra were recorded on a Perkin-Elmer model 621 spectrophotometer. The following instrumental conditions were used

Slit program	1000 x 1
Gain	4 x 2
Attenuator speed	1100
Scan time	32

Suppression	6
Scale	IX
Source Current	0.8

The system was continuously purged with dry air in order to reduce the absorption arising from atmospheric moisture. A Perkin-Elmer variable path length cell was used for scanning the solutions.

Preparation of Solutions

The nitrate ester samples were weighed to the nearest 0.1 milligram in a 25 ml volumetric flask and the solvent was then added up to the calibrated mark. In the case of cellulose nitrate, the polymer was dried at 60°C for 3 hours under vacuum before weighing.

Fig. 17 Glycerol Trinitrate - A vs b

Fig. 18 Glycerol Trinitrate - A vs Concentration.

Concentration - 1.226×10^{-5} mole $\text{NO}_2/\text{cc.}$
Solvent - Tetrahydrofuran

Fig. 19 Cellulose Nitrate (12.53%N) A vs b

Concentration - 2.380×10^{-5} mole NO_2 /cc.
Solvent - Tetrahydrofuran

FIG. 20 Cellulose Nitrate (12.53%N) A vs b_e

Fig. 21 Cellulose Nitrate (12.53% N) A vs b

Concentration: 6.827×10^{-5} mole $\text{NO}_2/\text{cc.}$
Solvent: Tetrahydrofuran
