The Metropolitan Spokane Region Water Resources study was accomplished by the Seattle District, U.S. Army Corps of Engineers assisted by Kennedy-Tudor Consulting Engineers under sponsorship of the Spokane Regional Planning Conference. Technical guidance was provided by the Spokane River Basin Coordinating Committee, with general guidance from the study's citizens committee. Major cooperating agencies include Spokane City and County, and the Washington State Department of Ecology. The study was coordinated with appropriate Federal and State agencies and with the general public within the metropolitan Spokane area.

PREFACE

5 . 9 Q 8.7.

With the enactment of the Federal Water Pollution Control Act Amendment of 1972 (Public Law 92-500), new national goals have been established for the elimination of pollution discharges into our streams and lakes. This appendix is a part of the report prepared to assist local government in satisfying State and Federal Requirements relating to Public Law 92-500. The suggestions contained in this report are for implementation by local interests with available assistance from other local, State and Federal agencies. The study suggests a regional wastewater management plan for the metropolitan Spokane urban area and provides major input to Washington State Department of Ecology Section 303e plans for the Spokane River Basin in Washington State. Also included in the study are planning suggestions for urban runoff and flood control, and the protection of the area's water supply resources.

As listed on the inside front cover, documentation for this study consists of a Summary Report and a Technical Report with supporting Appendices A through J.

The Technical Report summarizes Appendices A through J, which contain 58 individual task section reports prepared during the study. These task sections are listed by title in Attachment I of the Technical Report. Generally, the numbering of appendix task sections reflects the following system:

Study Task Sections	Type of <u>Study Activity</u>
300's	Data Collection
400's	Data Evaluation and Projection
500's	Identification of Unmet Needs
600's	Development of Alternative Plans
700's	Evaluation Comparison and Selection of Plans
800's	Institutional Arrangements

Pages within each appendix are numbered by task section, as illustrated below:

SURFACE WATER

Introduction

The Study Area represents the downstream portion of the hydrologic basin of the Spokane River and its tributaries. The hydrologic basin covers 6,640 square miles above the mouth of the Spokane River where it empties into the Franklin D. Roosevelt Lake impoundment of the Columbia River. The Study Area, which includes that part of the hydrologic basin that lies in the State of Washington, occupies approximately 2,295 square miles. The remainder of the hydrologic basin, approximately 4,345 square miles in area, is in the State of Idaho. Refer to Plate 308-1. Obviously, the surface water supply of the Study Area is dominated by considerations of the hydrologic basin in Idaho.

Hydrologic Basin in Idaho

The hydrologic basin in Idaho forms three tributary systems which enter the Study Area separately. The first and largest is the river system tributary to Coeur D'Alene Lake which is the source of the Spokane River. Secondly, there is another area topographically tributary to the Spokane River between the outlet of Coeur D'Alene Lake and the Washington border from which only part of the runoff reaches the river as surface supply. This second area lies mostly north of the Spokane River extending up the valley known as Rathdrum Prairie and includes the mountain slopes on

the east and west sides of the valley. The floor of this valley consists of deep deposits of highly permeable glacial outwash gravel which becomes a groundwater repository for most of the runoff from this area. Thirdly, the tributary areas of Hangman Creek and its tributary kock Creek extend into Idaho.

The tributary area of Coeur D'Alene Lake is approximately 3,700 square miles, thus occupying approximately 86 percent of the hydrologic basin in Idaho. This drainage area extends eastward to the crest of the Bitterroot Mountains that form the Montana-Idaho border. Two river systems drain the srea. The northern portion is drained by the Coeur D'Alene River, with its tributaries, which enters the Lake near Harrison, Idaho. The southern portion is drained by the St. Joe and St. Maries Rivers which enter the southern end of the lake.

Both the Coeur D'Alene and St. Joe-St. Maries systems drain mountainous, forested country which rises from elevation 2120 feet at Coeur D'Alene Lake to elevation 6500 feet at the crest of the Bitterroot Mountains. The Coeur D'Alene River has a tributary area of 1488 square miles and the St. Joe River and its tributary, the St. Maries River, have a combined tributary area of 1886 square miles. A large proportion of the drainage basin of Coeur D'Alene Lake is in national forest land. To the north of the Coeur D'Alene River, the tributary area of the river is in Coeur D'Alene National Forest. East of Calder, the St. Joe River watershed is in St. Joe National Forest.

As noted in the section on climate, there is a west to east

trend of increasing average annual precipitation caused by the rising terrain facing the predominant eastward moving marine air masses. This pattern gives further importance to the watershed of Coeur D'Alene Lake as the primary source of Spokane River waters. Except for the local condition at Mt. Spokane, the rainfall in the Washington portion of the hydrologic basin ranges from 15 inches in the west to about 25 inches at the Idaho border. From the Idaho border eastward, the annual rainfall increases from 25 inches to 50 inches in the headwaters of the Coeur D'Alene River and 70 inches at the headwaters of the St. Joe.

There are no existing impoundments of any significance on either the Coeur D'Alene system or the St. Joe system above Coeur D'Alene Lake. The rivers are unregulated and free discharging.

Coeur D'Alene Lake is a natural lake that has a natural outlet to the Spokane River. The Post Falls Dam on the Spokane River, nine miles below the outlet from Coeur D'Alene Lake, was constructed by Washington Water Power Company (WWP) to regulate the lake level to optimize water power production. A description of the operating philosophy of WWP for the Post Falls outlet works is given later in this section.

Coeur D'Alene Lake is approximately 24 miles long with widths in the range of 1 to 2 miles. The lake has a general northsouth orientation with the major entering rivers at the south end and the Spokane River outlet at the north end. The fact that the lake is long and narrow and that the water has to flow through its

length has important consequences for water quality which are discussed in other sections.

In addition to its physical properties, the flow regulation of Coeur D'Alene Lake is a consequence of the interaction between Idaho law and the requirement for power production in Washington Water Power Company's six installations on the Spokane River. The legally useable storage in Coeur D'Alene Lake is significantly less than what would be required to retain surplus natural flows of the peak runoff season for release during periods of natural low flow. For the same reason, the lake storage effect on flood flows is insufficient to prevent moderately large flows in the Spokane River. In the past, a number of studies have been made by the Corps of Engineers for impoundments on the Coeur D'Alene and St. Joe Rivers to optimize annual flow and reduce flood flows. None of these possibilities are currently being considered for implementation. The possibilities of implementation are presently so remote that the potential for any additional regulation above Coeur D'Alene Lake will not be considered in this study.

The Washington Water Power Company owns certain flowage rights associated with various levels of Coeur D'Alene Lake. Complete flowage rights are owned to elevation 2126.5, partial rights to 2128.0 and a few to 2130.0. Normal regulation of the level of Coeur D'Alene Lake for power production is restricted by Idaho law to the range between elevation 2120.5 and 2126.5. Other considerations governing the control of lake level and flow release to the Spokane

River are the lake level during the recreation season and the drainage of agricultural lands at the southern end of the lake. The present operating philosophy of Washington Water Power Company, taking the foregoing into consideraiton, is as follows*:

> The Coeur D'Alene Lake elevation is held nearly full, 2128.0 feet elevation, through the summer recreation season. Initial releases may commence in the latter part of August or first of September when Columbia River flows have receded following the summer runoff and Coeur D'Alene storage releases would be usable through the Columbia River plants downstream from the Spokane River. Draft from Coeur D'Alene normally occurs at the rate of about one to two feet per month during the months of September through January and at rates compatible with the hydraulic capability (turbine capacity) of the Spokane River plants. During this period, inflow to the lake can vary widely due to heavy rainfall and sudden "chinooks," so lowering of the lake level is seldom at a uniform rate.

Minimum 1-ke elevation usually occurs in late January or February. At this time, regulation of the outflow normally ceases and the lake is allowed to seek its minimum natural level in the interest of making the maximum amount of storage available for flood control. Minimum lake elevations are normally around the 2122.5 level, but in times of prolonged cold weather with no rainfall or snow melt, the lake level can go down as low as 2120.5.

As the runoff season begins in late winter or spring, no control over the outflow from Coeur D'Alene Lake is exercised. During periods of rapid runoff and/or heavy rainfall, the lake can rise well above the summertime control level. Over a period of nearly 80 years, this springtime flood elevation is found to average about 2131.7. During the 1948 flood, however, the lake reached 2135.95 on May 30; but during the flood of December, 1933, the lake rose to elevation 2139.05, the highest yst recorded.

Following the spring runoff, the lake level is allowed to drop to elevation 2126.5 feet. At this point, control of the lake is resumed. Most of the spill gates at Post Falls

^{*}Paraphrased from a memorandum prepared by Washington Water Power sent to Kennedy-Tudor with their letter of 15 October 1973.

Dam are closed to hold the lake at this elevation for a short period of time - usually not more than a day or two. The purpose of this operation is to allow water to drain off certain low-lying farm lands bordering on the lake. The farm lands are protected by dikes for water levels to 2128.0. Following the draining operation, the balance of the spill gates are closed to refill the lake to elevation 2128.0 feet and hold the lake near this elevation through the summer recreation season. Closure of the Post Falls gates under this method of operation, depending upon the volume of spring runoff and the timing of this runoff, can vary from late May to early July.

The available volume of storage in Coeur D'Alene Lake above the minimum elevation 2120.5 is shown in Appendix I. Post Falls Dam control devices are capable of regulating flows of up to 15,000 CFS with lake level 2128.0. When the lake level increases beyond 2128.0, control passes from Post Falls Dam to the lake outlet. The free discharge capacity of the lake outlet is shown in Appendix II. The discharge capacity of Post Falls Dam with all sector gates wide open is shown in the table Appendix III.

From the outlet of Coeur D'Alene Lake at river mile 111.1, it is 14.6 miles to the Washington-Idaho state line. Throughout this reach, the Spokane River is perched on the permeable outwash gravels of the Rathdrum Prairie and Spokane Valley. Refer to the section on geology and groundwater. The river channel is sealed by a silt deposit and the river is substantially above the groundwater table. Various estimates have been made of the amount of water percolating from the river into groundwater in this reach. Pluhoski and Thomas (1968) give values of 250 CFS for the nine miles above Post Falls Dam and 120 CFS for the section below Post Falls extending to the vicinity of Otis Orchards, four to five miles into Washington. The

308-6

うちゃくちょうというれるのがのない

outflow into the gravels is estimated to be especially high during flood flows.

As mentioned above, the watershed in Idaho north of the Spokane River and surrounding the Rathdrum Prairie makes no significant surface water contribution to the Study Area. The water from this tributary area enters the Study Area almost entirely as groundwater, joining the above described groundwater accretion from the Spokane River.

Hydrologic Basins of the Study Area

Introduction. The Study Area, with minor exceptions, is the hydrologic basin of the Spokane River within the State of Washington. The Study Area is subdivided into four Water Resource Inventory Areas as defined by the State Department of Ecology. The Water Resource Inventory Areas (WRIA) are each a natural hydrologic subbasin. The Study Area and its subdivisions are shown in Plate 308-2. The areas of its subdivision are shown in Table 1.

WRIA Number 54, Lower Spokane. This area includes the area tributary to the Spokane River from its mouth at Franklin D. Roosevelt Lake to its confluence with Hangman Creek, excluding the tributary area of the Little Spokane. The hydrologically tributary land area is 1650 square miles.

A small part of the City of Spokane is included on the east bank between the Hangman Creek and Little Spokane confluences. North of the Spokane River from the mouth of the Little Spokane to

Franklin D. Roosevelt Lake, the area included is almost entirely in Stevens County and is rolling upland with open ponderosa pine forests. The entire west half of the area north of the river is in the Spokane Indian Reservation. The largest tributary from the north is Chamokane Creek with an area of 176 square miles. Other significant streams are the little Chamokane and Sand Creek. The only population center north of the river is Wellpinit.

South of the Spokane River, the area is typically Columbia Plateau table lands cut by steep-sided ravines. The west half is in Lincoln County and the east half is in Spokane County. The area, except for the steep wooded ravines, is largely in wheat or cattle grazing. Tributary streams from the south include Coulee Creek, Deep Creek and Spring Creek. There are several population centers in addition to the suburbs of Spokane including Airway Heights, Spokane International Airport, Fairchild Air Force Base and Medical Lake.

Rainfall in WRIA 54 ranges from 15 to 20 inches per year.

WRIA Number 55. Little Spokane. This area includes the entire tributary area of the Little Spokane River, an area of 700 square miles. The Little Spokane drains a broad valley between the lower uplands to the west and the higher Selkirk Mountains to the east which culminate in Mount Spokane at an elevation of over 5000 feet. The northern part of the basin is mountainous also but has a saddle in the vicinity of Newport that opens into the valley of the Pend Oreille River.

The valley floor is largely open land devoted to agriculture,

while the surrounding uplands are forested. Most of the basin is in Spokane County but a small portion to the west is in Stevens County and most of the northern highlands are in Pend Oreille County.

The valley of the lower reach of the Little Spokane, from Dartford to the mouth, forms the boundary of the present northern suburbs of Spokane. The city limits extend into the southern part of the basin and true urban type development extends north to the river.

The Little Spokane River has a number of significant tributaries. On the east side Peone, Deadman, Deep and Deer Creeks drain the Selkirk Mountains. On the west, Dragoon Creek drains the western part of the valley and extends to the westerly mountains. Above Milan, the Little Spokane divides into east and west branches. The west branch contains a series of lakes, including Eloika, Fan, Horseshoe, Trout and Sacheen. The east branch extends through a narrow valley that includes Chain Lake and continues almost to the town of Newport.

Centers of population beyond the City of Spokane and the North Spokane suburbs include Mead, Dartford, Colbert, Chatteroy and Deer Park.

Rainfall in WRIA 55 ranges from 18 inches per year near the mouth to over 45 inches per year on the summit of Mount Spokane. For this reason, the Little Spokane River has the highest yield in the Study Area. Ground water is also significant to surface yield

in WRIA 55. Fart is due to interaction with the groundwater of the Little Spokane Valley which originates within the watershed. In addition, there is a major inflow of groundwater from outside the basin into the reach below Dartford. These groundwaters are from the main Spokane Valley aquifer and originate largely from outside the Study Area. Refer to the section on geology and groundwater.

WRIA Number 56, Hangman Creek.* This area includes that part of the Hangman Creek watershed that lies in the State of Washington. The total hydrologic basin covers 689 square miles of which 486 square miles are in Washington and the remaining 203 square miles are in Idaho.

Except for the ridges that form the basin boundary in the southeast, almost all of the tributary area of Hangman Creek is rolling open councry devoted to dry farming. The main stream and its tributaries are in steep-sided narrow canyons. The predominant soil is the Palouse which has high erosion potential. There is little prominent relief to the topography except for the steep canyon sides in the lower (northern) reaches of the river, in the boundary ridges along the northeast and southeast and a small isolated peak near Tekoa.

There are only two significant Libutaries, Rock Creek on the east and Marshall Creek on the west. Rock Creek drains an area similar to the upper reaches of Hangman Creek.

*Formerly called Latab Creek.

Hangman Creek joins the Spokane River in the City of Spokane and there is some urban type development on terraces in the lower creek canyon. Most of the suburban development is adjoining the canyon, however. Beyond the city suburbs, the population centers in the basin include Cheney, Rockford, Fairfield and Tekoa. Tensed is the only significant community in the Idaho portion of the watershed.

Rainfall ranges from 17 inches per year in the northwest to 24 inches per year in the east and southeast.

WRIA 57, Upper Spokane. This area is not a complete hydrologic unit. It is composed of two parts of an area that is topographically tributary directly to the Spokane River within Washington and an area that is tributary to the Rathdrum Prairie in Idaho. The southern part of WRIA 57, south of Shadow Mountain, drains to the Spokane River within the Study Area but includes two areas tributary to lakes that have no surface outlets. The northern part, north of Shadow Mountain, drains to the Rathdrum Prairie east across the state boundary into Idaho.

The southern part includes the floor of the Spokane Valley and the bordering slopes. T^{+} valley floor is underlain with a deep deposit of glacial outwash gravels which are a continuation of the same aquifer that underlies the Rathdrum Prairie in Idaho and which continues into WRIA 55 via the Hillyard Trough and, perhaps, into WRIA 54. Again, refer to the section, "Geology and Groundwater." The Spokane River traverses the surface of this aquifer through

WRIA 57 and experiences interchanges with the groundwater. The river loses to the groundwater between the state boundary and Otis Orchards, but gains from the groundwater below Otis Orchards.

Both Newman Lake, on the north side of the valley, and Liberty Lake, on the south side of the valley, have no surface overflow. It is also believed that the fine materials which formed at the outlet plugs of side valleys after the outwash gravels were deposited are so impermeable that there is no underground outlet from these lakes either and that they are in equilibrium with their runoff supplies.

The west portion of the valley floor is largely covered with suburban and industrial development. The eastern portion is largely devoted to irrigated agriculture. The valley area receives from 18 to 22 inches of rainfall per year.

The northern part of WRIA 57 which drains into the Rathdrum Prairie in Idaho consists of the eastern slopes of the Selkirk Mountains. Annual precipitation throughout most of this area is in excess of 40 inches per year. The area includes the headwaters of Blanchard, Brickel and Fish Creeks. All three of these streams disappear into the Rathdrum Prairie aquifer and, presumably, eventually reach the Spokane Valley as groundwater.

Streamflow Data

The available streamflow records for surface waters in the Study Area are shown in Tables 3 and 4. Table 3 shows available records from which daily or monthly flow records are available.

Table 4 shows stations for which there are available records of annual peaks or low flow measurements but no continuous type record. The locations of stations listed in both tables are shown in Plate 308-2. Refer to Table 2 for an abridged river mile index.

Spokane River. Although there have been eleven stream flow gaging stations on the Spokane River between the mouth and Post Falls, Idaho, only four are currently operating and only five have records of over twenty years length. The remaining six stations have records of 2 to 6 years length, all but one being in the period 1948-1954. The five stations added in 1948 and operated for a short period were initiated for a special study on the exchange of groundwater with the river (Broom, 1951).

The longest record, 81 years, is available from USGS gage 12-4225-00 located upstream from the Hangman Creek confluence at river mile 72.9. The next longest record, 60 years, is available from USGS gage 12-4190-00 at Post Falls, Idaho. Although this gage is not in the Study Area, its record is included herein because its record is significantly longer than that at USGS gage 12-4195-00 near Harvard Road Bridge which has a record of 43 years. The Post Falls gage is at river mile 100.7 and the Harvard Road Bridge gage is at river mile 93.9. This places the Post Falls gage 4.2 miles upstream from the state line (river mile 96.5) and the Harvard Road gage 2.6 miles downstream from the state line. There are no surface water tributary streams in the 28.3 miles between the Hangman Creek

confluence and Post Falls. However, this reach is subject to significant groundwater interchange and storm water overflow from adjoining urban development.

The only significant surface water diversion on the Spokane River at present is the cooling water diversion by the Trent works of Kaiser. There are the following impoundments on the Spokane River between Post Falls and the Hangman Creek confluence:

- 1. Spokane Dam, river mile 80.2,
- 2. Upper Falls Dam, river mile 76.2, and
- 3. Monroe Street Dam, river mile 74.24.

These impoundments are relatively small and the associated hydro-electric works are operated on a run-of-the-river basis. For a more complete description of these structures refer to the paragraphs below on hydroelectric facilities.

There are no Spokane River gages that show the combined flow below the Hangman Creek confluence or the combined flow below the Little Spokane confluence. The next Spokane River gage below number 12-4225-00 is at Long Lake Dam. The record for USGS gage number 12-4330-00 is derived from Washington Water Power Company powerhouse records of turbine operation, periodically checked by USGS stream flow measurements below the powerhouse.

The absence of a gage between the Hangman Creek and Little Spokane confluence does not pose a serious data gap since Hangman Creek is gaged near the confluence. Other inflows in this reach are (1) the discharge of the City of Spokane sewage treatment plant which are metered except during storm water overflow and bypass con-

ditions, (2) a suspected but unevaluated groundwater inflow and (3) Deep Creek. Nine Mile Reservoir in the lower end of this reach with a surface area of 440 acres is subject to only minor regulation.

The absence of a gage below the Little Spokane confluence does pose a significa.t data gap for two reasons. The Little Spokane gage at Dartford, USGS number 12-4310-00, is 10.8 miles upstream from the confluence and there is a known significant groundwater inflow downstream from the gage. The flow record at Long Lake Dam 12-4330-00 can be used with the lake stage record 12-4325-00 and its area capacity characteristics, Appendix IV, to approximate the combined flow below the Little Spokane confluence. As presently operated, the level in Long Lake Reservoir is held as near as possible to elevation 1536 which puts the backwater upstream from the Little Spokane confluence. It was the adoption of this higher control level in 1952 that flooded out USGS gage number 12-4315-00 at river mile 3.9 on the Little Spokane.

k ;

And do not be the second

The record at USGS gage 12-4335-00, river mile 27.5, below Little Falls would provide an approximate extension of the Long Lake record prior to 1940 and back to 1912 except that Spring Creek enters the Spokane River between these gages. The tributary area of Spring Creek is only 56 square miles out of 6340 tributary at Little Falls. This would give an aggregate record of 81 years, comparable to the gage at Spokane, number 12-4225-00. The Little Falls gage has been flooded out by high water levels in Franklin D. Roosevelt Lake since completion of the Grand Coulee Dam which is the reason for its discontinuation.

Considering the foregoing facts, the following station records are selected for the purposes indicated in subsequent stages of this study:

- Spokane River at Spokane, USGS #12-4225-00, is selected for flood frequency analysis for determination of the 100 year return period flood because of length of record and because it best represents the flow in the reach from the Hangman Creek confluence to the state line for which the flood profile is to be determined.
- 2. Four gages, #12-4190-00 at Post Falls, #12-4195-00 at Harvard Road Bridge, #12-4225-00 at Spokane and #12-4330-00 at Long Lake are selected for frequency analysis for 7-day low flow with 10-year return frequency. The Post Falls gage is included, although outside the Study Area, for its longer record and what it may demonstrate about the importance of groundwater when compared with downstream gages.

These same four gages are selected as most representative of the entire Spokane River in the Study Area for presentation herein in tabular and graphical form. Refer to Table 5 for a summary tabulation of mean annual and extreme flows and to Table 6 for maximum, minimum and mean monthly discharges. The maximum, minimum and mean monthly discharges for the gage at Spokane is shown in Figure A.

3. The record from the Harvard Road Bridge gage #12-4195-00 is selected as the source of the hydrologic input of the Spokane River as it enters the Study Area for use in the simulation model. Length of record beyond 20 years is not a consideration for this purpose. The more important consideration is that it includes groundwater effects up to the state line.

Hangman Creek. There is only one gage on Hangman Creek with over twenty years of record, the gage at the mouth, USGS number 12-4240-000. The five other gages on Hangman Creek and its tributaries all apply to very small segments of its watershed. Annual peak data

are available from three of these for period of 10 to 18 years.

For the purpose of this study, there is a data gap in not having any record for Rock Creek where a flood problem exists.

Gage number 12-4240-00 is selected for frequency analysis for flood flows with 100-year return period and for 7-day low flow with 10-year return period. For this same gage, the mean annual and extreme flows are shown in Table 5, the maximum, minimum and mean monthly discharges are shown in Table 6 and Figure B.

Little Spokane River. Two gages on the Little Spokane River have records over twenty years in length, USGS number 12-4270-00 at Elk and USGS number 12-4310-00 at Dartford. The gage at Elk measures flows from 115 square miles on the headwaters of the east branch, approximately one-sixth of the total watershed. The gage at Dartford measures the flow from 665 square miles of the total 700 square miles in the watershed.

As mentioned above under the discussion of the Spokane River, the gage at Dartford is 10.8 miles upstream from the mouth and does not measure the known groundwater increment in the downstream reach. The backwater from Long Lake on the Spokane River caused the discontinuation of the downstream gage, USGS number 12-4315-00. The inability to measure the groundwater increment constitutes a data gap.

For the purpose of determination of flood flow in the reach from Chatteroy to the mouth, there is a data gap in the absence of record at Chatteroy or on the intervening tributary streams above

Dartford, namely Deadman and Peone Creeks.

There are a significant number of gages in the Little Spokane watershed devoted to annual peak and low flow measurements. There are seventeen devoted to low flow and five to peak annual flow. The gage on Deer Creek records both. Most of these records are from 1954 or 1955 to date. Dragoon Creek is the largest tributary with a watershed of 177 square miles, more than the gage on the main stream at Elk. Low flows are available for Dragoon but no peak flows. The geology and rainfall of the area east of the main stream are significantly different than the main valley and the west half. Lack of a more complete understanding of the hydrology of these streams is regarded as a data gap.

The gage at Dartford, number 12-4310-00 is selected for flood flow frequency analysis for 100-year return period. The two gages, at Dartford and at Elk are selected for frequency analysis for 7-day low flow with 10-year return. The annual mean and extreme for both the above gages is shown in Table 5 and the maximum, minimum and mean monthly discharges are shown in Table 5. The monthly data for the Dartford gage are shown graphically in Figure 6.

Other Streams. Only two streams in WRIA 54 other than the Spokane River itself have available flow records. There is a small fragment of record for USGS number 12-4255-00 on the headwaters of Deep Creek (54)*. For USGS gage number 12-4333-00 peak annual flow

*Note that there are two Deep Creeks in the Study Area. To avoid confusion the number of the WRIA in which the creek is located is included after the name.

records from 1954 to date are available for an unnamed tributary of Spring Creek near Reardon.

There were no data at all for the most significant tributary stream in WRIA 54, Chamokane Creek with a drainage area of 180 square miles, until gage number 12-4332-00 was established in February 1971. The only available record is from 1971 to date. There is no available record for Little Chamokane Creek which has a drainage area of 69 square miles.

<u>Comparison of Elements</u>. A graphical presentation comparing the three main hydrological elements of the Study Area is contained in Figure D. The annual flow patterns for the year 1972 are shown for the Spokane River at Spokane, Hangman Creek at Spokane and the Little Spokane River at Dartford.

Note the contrast in size of flows. The Spokane River flows are approximately ten tipes the flows in Hangman Creek and the Little Spokane River.

Note the contrast in character of flow pattern between Hangman Creek and the Little Spokane River. Hangman Creek exhibits a very flashy response to rainfall events which are plotted in parallel. On the other hand, the Little Spokane exhibits a very stable pattern.

The effect of low flow regulation for power production is evident in the Spokane River.

あるいがののの

Historic Floods

Spokane River. Floods on the Spokane River are generated by hydrologic events on the Coeur D'Alene and St. Joe River systems, but are limited by routing through Coeur D'Alene Lake and by the restricted outlet of Coeur D'Alene Lake. The importance of the control imposed by Coeur D'Alene Lake can be demonstrated by consideration of the inflow versus outflow for the December 1933 flood. For this flood, the highest mean daily inflow to Coeur D'Alene Lake was 101,000 CFS and the estimated crest was 130,000 CFS. The peak experienced on the Spokane River in this same flood was 47,800 CFS.

Historic floods of record on the Spokane River are shown in Table 7. The two earliest floods were before the construction of Post Falls Dam. Refer to Appendix II which shows that for lake stages above 2128 and flows of 15,000 CFS, Post Falls Dam is not controlling. Therefore, flood flows are all on the same basis.

In Davenport (1922) there is a discussion of the relationship between the control of flow from Coeur D'Alene Lake and lake stage. This water-supply paper was written primarily in response to the problems of adjudicating the differences between WWP and land owners upstream from Coeur D'Alene Lake. Its primary interest today is the demonstration of how the configuration and slope of the Spokane River channel between Coeur D'Alene and Post Falls is the determining factor in volume of flood floor for any given stage of the lake.

Water-supply paper 532 (1924) is of interest for its remarks

about the validity of flow records prior to October 1896 for the Spokane River at Spokane. This paper points out that the records prior to this date are of doubtful accuracy for several reasons. The extreme discharge of May 31, 1894 falls in this period and is given as 49,000 CFS as revised.

The following materials are abstracted from House Document No. 531 and describe the character and mechanism of floods on the Spokane River:

> Floods in Spokane River Basin usually occur in the spring as a result of the rapid melting of snow following unusual rises in temperature. Occasionally, as in April 1938, heavy rains occur simultaneously with the temperature rise, thereby increasing the flood flow to damaging proportions. Spring floods are normally of short duration. Within the 56-year period of record, the basin has experienced four damaging spring floods; i.e., in May 1893, May 1894, May 1917, and April 1938. (Subsequent to data available for Document No. 531, another spring flood of damaging size occurred in May 1948.) That of May 1894 was the greatest of the spring floods, having had an estimated maximum 24-hour discharge of 49,000 cubic feet per second at Spokane (see paragraph above quoting Water-Supply Paper #532 on accuracy of this figure) and a lake (Coeur d'Alene) elevation of 2,137.6 feet. Two severe winter floods have occurred in the period of record: in January 1918 and December 1933. The frequency of damaging floods is, therefore, about once in 9 years. The 1933 flood attained the highest recorded level, 2,139.05 feet in Coeur D'Alene Lake, but its peak discharge at Spokane was only 47,800 cubic feet per second. Winter floods are caused by unusually heavy rains in coincidence with chinook winds and consequent rapid melting of accumulated snow.

> The flood of December 1933 resulted from an unusually long period of excessive precipitation coupled with the rapid melting of accumulated snow by a chinook wind in the latter half of the month. Temperatures exceeded the normal for the month by an average of $7.7^{\circ}F$, the period of highest temperature coinciding with the periods of greatest precipitation. The melting of all snow below the 4,000 foot level and in exposed areas above that level, together with the

heavy rain, created floods in the tributary streams much larger than any previously recorded and raised Coeur D'Alene Lake to its highest known level. Weather conditions were similar throughout the upper drainage area, so that peak discharges in the tributaries occurred almost simultaneously. As a result, the crest inflow to the lake was more than double the crest outflow, the maximum 24-hour inflow being 106,000 cubic feet per second as compared with a maximum 24-hour discharge of 47,100 cubic feet per second at Spokane.

During the flood of May 1894, the rise in lake level was more gradual than that of the 1933 flood. The 1894 flood on the Spokane was part of the prolonged general flood of that year that extended over the entire Columbia River drainage area. This flood produced the highest discharge in the Columbia River that has been recorded in the 69 years of record on the gage at The Dalles, Oreg. The only records of the 1894 flood available for the Spokane River indicate that the peak discharge at Spokane was higher than that of December 1933, although the maximum level of Coeur D'Alene Lake was lower in 1894 than in December 1933.

The floods of greatest volume and highest levels in Coeur D'Alene Lake occur in the winter during short periods of high precipitation and temperature. It reasonably may be expected that, at some future date, there will occur a combination of meteorological, ground, and runoff conditions worse than those prevailing in December 1933, when the most severe flood in the past 55 years of record occurred in the basin. If the maximum probable storm predicted by the Hydrometeorological Section of the Weather Bureau were to occur at the time when the ground was covered with loosely packed snow, and if meteorological conditions were then such that rapid melting of the snow would occur simultaneously with the high rates of rainfall, there would be available for stream runoff not only the actual precipitation, but also the water released by the melting snow. It may be assumed that the increment from the melting snow would exceed water losses from absorption, percolation, evaporation, and transpiration. Then the river system would be called upon to carry all of the precipitation from the maximum 3-day storm, plus some snow melt. The runoff resulting from this maximum probable storm under these assumed conditions is shown in table 8, together with comparable data on the December 1933 flood. (The referenced table 8, not reproduced herein, shows that the maximum probable flood (MPF) would have produced flows into Coeur D'Alene Lake comparable to the December 1933 flood for the first four days, but that on the fifth and sixth day, the MPF inflows would be 320,000 and

172,000 CFS respectively compared with the December 1933 values of 101,400 and 92,300 CFS respectively.) Flood flows for the maximum probable flood have been calculated for a storm centered over the area tributary to Coeur D'Alene Lake.

Assuming an initial lake elevation of 2,126.5, which is the allowable upper limit for regulation of Coeur D'Alene Lake, and using the maximum inflows as shown in table 8, flood-routing computations indicate that the lake level would rise to elevation 2,146.9, and the mean daily discharge of the river at Spokane would be 83,600 cubic feet per second. (In other words, the MPF would produce flows in the Spokane River 70 percent greater than the greatest historical flood or the 100-year flood as shown below.)

Frequency studies were made of maximum annual stages of Coeur D'Alene Lake at Coeur D'Alene, Idaho, and observed peak discharges for the Spokane River at Spokane, Wash. The study for the lake was for the period of recrue 1905 through 1946, and for the river from 1892 throug 946. The results of these studies are as follows:

Average recurrence interval (year)	Maximum river discharge at Syokane	Maximum lake elevation
	Cubic feet	
	per second	
2	24,500	2,130.9
10	37,800	2,135.0
20	41,500	2,136.5
50	46,000	2,138.2
100	49,000	2,139.5

The House Document No. 531 concluded that the resulting benefits, both upstream and downstream from Coeur D'Alene, would be insufficient to justify improvements to the lake outlet and Post Falls Dam that would increase capacity at lower lake levels to prevent the lake from reaching high levels and the peak discharges associated with the high levels.

House Document No. 531 concludes that discharges in the Spokane River in excess of 40,000 CFS result in damage. The only flood of this magnitude since 1894 was the flood of December 1933. The historical damage from the 1933 flood, below Post Falls, is given as follows:

Kind of Damage	Dollar Value
Agricultural	1,000
Residential	8,100
Industrial	150,800
Utility .	77,000
TOTAL	237,500

The limits of the area flooded and the associated water profile for the December 1933 flood are available in several documents as follows:

- 1. Corps of Engineers Drawing File D-10-6-60.
- U.S. Geological Survey Maps, Plan and Profile of Spokane River, Spokane, Washington to Post Falls, Idaho in 4 sheets.

Reference 1 above shows the outline of the flooded area in plane at a scale of 1" = 1000' from the vicinity of Division Street to City Water Works power house.

Reference 2 includes three sheets of topographic plans at $1^{"} = 1000'$ from Cochrane St. to Post Falls but does not show flooded areas; only sheet four, a profile at $1^{"} = 2000'$ shows 1933 water surface from the falls one-third of a mile above Mission Street Bridge.

In addition to the above, there are available seven graphs by Washington Water Power Company showing the day by day water surface elevation from December 8, 1933 to January 13, 1934 at Coeur D'Alene Lake, Post Falls, Upper Falls, Monroe Street, Nine Mile Dam, Long Lake, and Little Falls Dam.
The Corps of Engineers has made a flood level determination for the immediate vicinity of the Spokane Expo 74. The results of this study are shown on a drawing at scale 1" = 80' which delineates the 100-year flood plan from Howard Street to Division Street on both sides of Havermale Island.

1

1

Andreas and a second

A levee project on the right bank of the Spokane River in the vicinity of Trent Avenue was considered in 1938 but was never implemented. Subsequent investigations revealed that foundation conditions were unsatisfactory. Refer to House Document No. 53100.841.

The Spokane River below Spokane Falls (Monroe Street) has not been subject to flood problems. The depth of the canyon and absence of development in the canyon minimize flood potential. A flood level determination was made recently in connection with the proposed enlargement of City of Spokane sewage treatment plant.

Hangman Creek. Flood control problems have been studied by the Corps of Engineers at three locations in the Hangman Creek Watershed. These are: (1) The upper portion of Hangman Creek in the vicinity of Tekoa, Washington and Tensed, Idaho; (2) in the vicinity of the town of Rockford on the Rock Creek tributary; and (3) on the lower Hangman Creek between river mile 12.5 and 15.0.

<u>Upper Hangman Creek</u>. Reconnaissance reports were made, beginning in 1966 on a number of alternatives to the flooding problem in the vicinity of Tensed and Tekoa, all of which have been found to be economically unjustified. These alternatives included the following:

308-25

「二日のの

- 1. For the area from the Washington-Idaho border upstream to two miles above Tensed (approximately 9.3 miles) a channel improvement was proposed to protect against 40-year flood recurrence.
- 2. For the area in the vicinity of Tekoa, a combination of channel enlargement and levee construction and alternatively higher levees without channel improvement.
- 3. Upstream storage, alternatively 1 mile upstream from Tekoa and 4.5 miles upstream from Tensed.

The most recent evaluation of average annual damage in the 13.2 mile stretch from Tensed to Tekoa is \$148,000 consisting of 68 percent agricultural, 22 percent roads, bridges, railroads, and streets, 7 percent residential property and 3 percent commercial property.

Vicinity of Rockford on Rock Creek. The most recent studies by the Corps of Engineers of the flood problem at Rockford indicates that floods with recurrence intervals of 20, 50 and 100years will flood areas of 10, 14, and 18 acres respectively. The area of the 100-year flood plain includes 5 public buildings, 15 commercial and 4 residences in addition to the associated streets and utilities and the fair grounds. The value of \$114,000 at 1970 price levels is estimated for damages associated with a 100-year recurrence flood and an average annual damage rate of \$4.300 from all floods.

Existing flood protection in Rockford consists of a levee on the right bank constructed by WPA after the 1933 flood. This levee protects to level of 20-year recurrence. Rockford was flooded again in 1963 and 1964. The levee was repaired by the

Corps of Engineers in 1965.

Subsequently, a preliminary plan of improvements was developed by the Corps of Engineers and found to have a benefit-cost ratio of 0.9. The plan has not been implemented. The proposed improvement consists of raising the levee 3 feet for a distance of 700 feet and rebuilding the remaining leves for a distance of approximately 1,000 feet, all to provide protection to the 100-year recurrence level.

Little Spokane River. The Little Spokane River from its mouth to the town of Chatteroy meanders through a flat valley floor with considerable potential for going overbank at high flow. The area is also now under development pressure from northward expansion of Spokane's suburbs.

There are no records of flood damages in this reach nor have there been any flood control studies made.

Hydroelectric Facilities.

Washington Water Power Company has six hydroelectric power plants on the Spokane River. All except the Post Falls facility are in the Study Area. The City of Spokane has a single hydroelectric plant on the Spokane River. Each of these seven hydroelectric facilities is associated with a dam. Table 9 lists the hydroelectric power facilities and Table 8 lists the associated dams and their characteristics.

The philosophy and schedule of operation of the Post Falls

Dam has been discussed above in connection with the regulation of the flow from and level in Coeur D'Alene Lake. See Appendix IV for rule curves. This operation essentially sets the pattern for all of the downstream power plants with minor exceptions. The impoundments associated with the city facility, Control Works (Upper Falls), Monroe Street and Nine Mile are so small that these plants are operated as run-of-the-river plants. Long Lake reservoir capacity is utilized to operate both Long Lake and Little Falls power houses to meet both daily and weekly peaking as well as end of season drawdown. These operating possibilities are evident in the flow rating of the installed equipment. The flow capacity of the installations at Monroe Street and above are essentially matched to Post Falls. Nine Mile has peak capability about 60 percent greater than Post Falls, and Long Lake and Little Falls, which also benefits from Long Lake Storage, have capabilities almost double Post Falls.

The present method of operating Long Lake is to maintain the lake at the highest possible level consistent with the limitation imposed by flooding easements which extend to elevation 1536 and the availability of water from Coeur D'Alene. Long Lake is not normally drawn down through the summer recreation season but is drawn down in January and February to utilize the stored waters when the supply is low.

Little Falls. Little Falls Dam is a gravity concrete dam that was built by WWP in 1911. The dam is "L" shaped in plan with an uncontrolled crest on the long leg of the "L" 412 feet long and

another 185 feet of uncontrolled crest on the short leg along with two twenty-foot wide Taintor gates. The elevation of the uncontrolled crest is 1356 and the sill of the Taintor gates is 1341. The dam has a hydraulic height of 39 feet.

Capacity of the two Taintor gates wide open totals 10,000 CFS when the pool surface is 1356, the elevation of the overflow weir. Flash boards are added to the uncontrolled crest to bring the pool level to 1362. Wing wall crest is 1364. The capacity of the uncontrolled weir with flashboards removed is 60,000 CFS when the pool level reaches wing wall crest elevation 1364.

The surface area of the impoundment is 250 acres and extends 4.6 miles upstream to the toe of Long Lake Dam. Normal pool elevation is 1362 and the active storage volume above elevation 1351 is 2220 acre feet. There is no available record of dead storage below elevation 1351 which is estimated to be of the order 2000 acre feet.

The power house is located on the north bank and contains 4 units with a total nameplate rating of 32,000 kilowatts and a nameplate water rate of 6670 CFS. Peak capability is 36,000 kilowatts and 7500 CFS.

Since the available live storage is small compared with turbine capacity, operation is dependent upon releases from Long Lake power house immediately upstream.

Long Lake. Long Lake Dam is a gravity concrete dam built by WWP in 1915. The dam is "L" shaped with the penstocks descending

from the south leg of the "L" to the power house on the south bank and the spillway gates installed in the north leg. There are eight roller gates, each 25 feet wide with sill elevation 1508. The dam has a hydraulic height of 213 feet.

Discharge capacity of each gate at maximum pool elevation 1536 is 14,500 CFS making total discharge capacity 116,000 CFS.

The surface area of the impoundment is 5060 acres at maximum pool elevation 1536. Active storage between maximum pool and sill elevation of gates is 105,080 acre feet. Dead storage below sill elevation is 149,490 acre feet. The lake extends approximately 24 miles upstream to beyond the Little Spokane confluence.

The power house contains four units with a total nameplate capacity of 70,000 kilowatts and water rate of 6180 CFS. Peak capability is 72,500 kilowatts and 6300 CFS.

<u>Nine Mile</u>. Nine Mile Dam and Power House were constructed in 1908. This is a gravity concrete structure with hydraulic height 58 feet. The power house is integral with the south abutment. The overflow crest is without permanent crest control and is 364 feet long at elevation 1596.57. The crest is equipped with two removable sets of flash boards. The first set has a crest elevation of 1601.57 and the second set raises the creat to 1606.57. Normal pool elevation is 1606 with the second set of flash boards in place. When river flow exceeds 5,000 CFS, the peak hydraulic capacity of the turbines, the second set of flash boards must be removed reducing the pool level.

A discharge of 17,000 CFS is the maximum which can be passed

over the crest with the first row of flash boards in place resulting in a pool elevation of 1611. With all flash boards removed approximately 46,000 CFS can be passed at pool elevation 1611.

The impoundment storage between low pool 1590.57 and maximum pool at 1606.6 with both rows of flash board in is 4600 acre feet with a surface area of 440 acres at maximum pool. The storage volume below 1590.57 is estimated at 7,000 acre feet.

Nine Mile Power House contains four units with total nameplate capacity of 12,000 kilowatts at 3,330 CFS. Peak capability is 18,000 kilowatts at 5,000 CFS.

Monroe Street. Monroe Street Dam was the oldest dam on the river, the original structure having been built in 1890. The original structure was replaced by a new concrete structure in 1972. The new structure has the same crest elevation, 1806. There is no crest control, the structure being a simple overflow structure with a crest length of 217 feet and 25 feet hydraulic height. This structure serves both as a diversion structure for the Monroe Street Power House as well as tailwater level control for the Upper Falls Power House.

The impounded volume is negligible, estimated at less than 70 acre feet.

The Monroe Street Power House is located downstream from the dam to take advantage of the natural fall in the river below the dam. The five power units have a total nameplate capacity of 7200 kilowatts at 2,000 CFS. These old units are not given a peak rating

over the nameplate rating.

<u>Control Works (Upper Falls)</u>. The Control Works Dam is in the channel that passes north of Havermale Island and provides the overflow structure. A second dam closes the south channel and has no overflow provision but contains the inlets to the penstocks for the Upper Falls Power House which is located on the south bank at the foot of the falls. The complex of two dams and power house was built in 1922.

The Control Works Dam is a gravity concrete structure with control devices along the entire crest. Adjacent to the north bank are two 60-feet wide by 18-feet rolling sector gates with sill elevation 1854.9. The remainder of the crest to the south bank is filled with twenty lift gates each seven feet wide and all with sill elevation 1858.9. Normal operating pool level is 1870.5.

Discharge curves for the crest control devices are not available but there is a record of the upstream level at 1874.1 for the December 1933 flood, presumably with all gates open.

The sill of the sector gates at 1854.9 is essentially at river bottom so there is virtually no dead storage. The active storage between normal pool 1870.5 and low water at 1864.3 is 800 acre feet. The area of the normal pool is 1.36 acres.

The Power House is remote from the Control Works Dam being associated with the south channel closure to take advantage of the additional head provided by the natural falls. There is a single power unit with nameplate rating of 10,000 kilowatts at 2450 CFS.

Peak rating is 10,200 kilowatts at 2500 cfs.

Spokane Dam. Spokane Dam and Power House were built in 1937 by the City of Spokane to generate electrical power to drive well pumps of the city water system.

Spokane Dam is a concrete structure with eight Taintor gates fil.ing the 26 foot wide spaces between three feet thick concrete buttresses. The gate sill elevation is 1893.45.* Normal pool elevation is 1910.45, below the top of closed gates. Normal operation calls for holding the pool at 1910.45 and not overtopping the gates; flow in excess of turbine capacity is released by partial opening of one or more gates.

The bottom of the gates when open is at 1917.45 thus leaving a space 24 feet high over the sill for flood flows. Design criteria call for the ability to pass 62,000 cfs at upstream water surface 1911.13, the maximum water surface that was recorded during the 1933 flood when the old dam existed. The old dam had a crest elevation of 1889.45, four feet lower than the crest of the new dam. Stage discharge data for the gates is not available from the City.

The crest of the dam is believed to be about twenty feet above the river bed. Combined with the seventeen feet to normal pool above the sill, this gives a maximum depth of 37 feet. The City has no data on the volume of dead or live storage but the total of these quantities is estimated to be of the order of 1500 acre feet. The area of the impoundment

*USGS datum to correspond with other structures described herein. USGS = City Elevation minus 16.55.

is estimated to be 150 acres.

<u>Post Falls Dam</u>. Post Falls Dam is outside the Study Area but a brief description is necessary to the understanding of its control of Coeur D'Alene Lake.

The river is divided into three channels at Post Falls. The dam on the middle channel contains the power house and has no overflow or level control function. The structure on the north channel has all of the crest control consisting of eight Taintor gates, seven each at 21 feet wide and one at 12 feet wide, and one sector gate 102 feet wide. The sill elevation of the Taintor gates is 2114.0 and of the sector gate is 2116.5. The tops of both gates are at 2128 in the closed position corresponding to the maximum elevation at which the lake is held. The south channel dam is 127 feet wide and contains six lift gates, six feet wide by 13 feet high at sill elevation 2108.62 and an overflow spillway 37 feet long with original crest elevation 2126.52 which has been raised to 2128.0 by crest logs.

As stated above in the description of WWP operating procedure, the Post Falls control structures can control flows up to 15,000 cfs with the Lake at 2128.0. Beyond 15,000 cfs or lake elevation 2125.0, the control shifts to the outlet channel of the lake.

The normal summer pool (lake) level is 2128.0 and the winter minimum is 2120.5. The active storage between these elevations is 217,000 acre feet or 108,500 second foot days. The lake has an area of approximately 42,800 acres at summer pool level and 27,000 acres at minimum pool.

Schematic Flow Diagram and Flow Balance

A schematic diagram of the Spokane River as it passes through the Study Area is shown in Figure E. The river is shown to scale by river mile and includes the successive dams and impoundments through which the river passes, the principal tributaries, the currently active stream gages and the estimates of Broom (1951) for groundwater interchange.

A complete flow balance cannot be achieved with the available surface flow data and the Broom estimates. It must be recognized, as Broom (1951) points out, that these groundwater interchanges are only estimates based on one year of data and that the results are far from conclusive. Also, these mean values represent highly variable conditions throughout the year, the rates and even direction of flow being a function of river stage. Years with different ratios of high flow to low flow could have significantly different mean annual interchange.

Considering the reach between Post Falls gage 4190 and Harvard Road gage 4195, the long term stream flow record indicates a surface flow increment of 63 cfs whereas the Broom estimate indicates that there should be a loss of water of about the same magnitude. Since this difference is of the order of 1 percent of the mean annual stream flow, this disagreement is not surprising.

From Harvard Road gage 4195 to the Cochran Street gage 4225, the measure of mean surface flow increment is 307 cfs. In this same reach, the Broom estimate indicates a total gain of approximately 930

308-35

Ż

cfs. The 600 cfs difference here is equal to 10 percent of the mean flow and is therefore more difficult to justify.

The next reach for which a balance can be tried is between the Cochran Street gage 4225 and Long Lake gage 4330. The trial balance is as follows:

Long Lake #4330	8381 cfs	Hangman Cr	#4240	264	cfs
Cochran St #4225	6927 cfs	Little Spok	ane #4310	316	cfs
	<u> </u>	Groundwater	In	126	cfs
Difference	1454 cfs	11	11	21	cfs
		**	11	157	cfs
		**	11	218	cfs
		TOTAL		1102	cfs

The difference between the surface flow gages of 1454 cfs and the estimated inflows of 1102 cfs leaves 352 cfs to be accounted for by local tributary area and Deep Creek. The unaccounted tributary area, including Deep Creek, is approximately 340 square miles. For this area, the mean annual discharge per square mile is probably similar to Hangman Creek at 0.4 cfs per square mile. This would account for an additional 136 cfs leaving the net unaccounted at 116 cfs or 1.4 percent of the mean annual discharge at Long Lake.

The net Broom groundwater increments total 1341 cfs gain. This is higher by approximately 300 cfs than the estimates of Piper and La Rocque (1944) and Plukowski and Thomas (1968). Refer to the section on geology and groundwater.

Lakes

All of the major lakes (surface area 100 acres or more) within the Study Area can be placed in four general classifications as follows: 1. Mountain lakes that have no significant outlet.

Newman Lake Liberty Lake Diamond Lake

2. Natural lakes that are part of a stream system.

Sacheen Lake Trout Lake Horseshoe Lake Eloika Lake Chain Lake

3. Lakes in Columbia Plateau terrain.

Medical Lake West Medical Lake Silver Lake Clear Lake

4. Man-made lakes (river impoundments).

Long Lake Nine Mile Reservoir Control Works (Upper Falls) Reservoir Spokane Dam

The river impoundments have been discussed above in connection with hydroelectric facilities and will not be repeated here.

Table 10 is an inventory of lakes in the Study Area compiled from the report "Lakes Constituting Shorelines of the State Shorelines Management Act of 1971" by the State Department of Ecology. Table 11 shows the important characteristics of the major lakes from this list including the availability of lake level records. Refer to Plate 308-2 for lake locations.

A brief discussion of the major lakes follows, taken in order of the classification given in the opening above. The primary use of all lakes in the Study Area, except the man-made lakes, is recreation. The man-made lakes all have hydropower production as their primary use. Of the man-made lakes, only Long Lake has, at present, significant recreational use.

<u>Newman Lake</u> is the largest lake in the Study Area with a surface area of 1190 acres. It is located north of the Spokane Valley near the Washington-Idaho border and receives the runoff from 28 square miles in the south slopes of the Selkirk Mountains. The lake has a surface overflow that fails to reach the Spokane River and is believed to have no direct underground outlet either, the lake having been formed by a relatively impervious plug deposited in the mouth of the valley against the permeable valley fill. Refer to the Geology section. A level record is available which indicates a maximum variation of 4.24 feet. A bathymetric map of the lake is also available which shows that most of the lake is over 15 feet deep and has a maximum depth of 30 feet.

Liberty Lake is situated south of the Spokane River in a similar manner to Newman Lake and has similar outlet characteristics. Liberty Lake has an area of 711 acres and receives drainage from only 13 square miles. Level records indicate maximum variation of 4.94 feet. Bathymetric map shows most of the lake to be 25 feet deep and flat with a maximum depth of 26 feet.

Diamond Lake is located in the northern part of the Study Area in a blind watershed between the upper branches of the Little Spokane River. Diamond Take is the second largest in the Study Area with a surface area 754.5 acres. Its surface elevation of 2360 feet makes it the highest lake in the northern area. The tributary area is very small,

being only 6.1 square miles; that is, the lake covers approximately one sixth of the tributary area. A level record is available and shows a small variation of level at 1.99 feet. A bathymetric map is available which indicates that the lake is 50 feet deep throughout most of its area.

Eloika, Horseshoe, Trout and Sacheen Lakes are all part of the West Branch of the Little Spokane River. Sacheen Lake is the source and the river flows from Sacheen successively through Trout, Horseshoe and Eloika. Sacheen and Eloika are of considerable size, having areas of 282 and 659 acres respectively. Level records are available for both of these large lakes. Sacheen at the headwaters with a tributary area of 33.5 square miles, has a small range of level variation at 2.85 feet. Eloika Lake, at the lower end of the chain of lakes and with a tributary area of 101 square miles, has a level variation of 5.45 feet.

Sacheen Lake is relatively deep with a maximum of 40 feet. Eloika is very shallow for its size with a maximum depth of only 15 feet. Bathymetric maps are available for both lakes.

Trout and Horseshoe Lakes have areas of 94.8 acres and 128.0 acres respectively. Level records are not available for these lakes. Both lakes are unusually deep in spots. Trout Lake goes to 170 feet depth in its north end. The west bulb of Horseshoe Lake is 140 feet deep.

Medical Lake, West Medical Lake, Clear Lake and Silver Lake form a group in the Columbia plateau terrain southwest of the City of Spokane. The area is one of generally low relief. The tributary areas to these lakes are poorly defined and are small compared with the area of the lakes. Under overflow conditions, these lakes would not drain into the Spokane River but rather into the Palouse watershed. All four of these lakes are long and narrow and trend north-south. All are moderately deep, ranging from 35 feet in West Medical Lake to 110 feet in Clear Lake.

Notes

- 1. The discharge capacity of Post Falls Dam gates is related to the stage elevation in the Post Falls forebay which can be substantially equal to lake stage only under controlled flow conditions, that is up to elevation 2128.
- 2. For lake stages up to 2128, discharge can be controlled by Post Falls. For lake stages above 2128, the lake outlet controls. Maximum controlled flow is 15,000 cfs.
- 3. Data are from Washington Water Power Company.

*Highest observed lake stage, December 1933. **Observed stage in Post Falls Forebay, December 1933. ***Top of Post Falls gates in closed position.

SECTION 404

SURFACE WATER QUALITY SUMMARY AND EVALUATION

Scope and Objectives

Sources of water quality data for the study area are summarized in Section 307-9. These data are scattered through numerous publications, including the Storet printout, and cover a wide variety of parameters at many locations over a period of years. It is the objective of this section to summarize recent data for a limited number of parameters of primary interest in a logical order to provide a concise overview of surface water quality.

The specific locations selected for surface water quality summary are as follows:

- 1. Spokane River below Little Falls Dam (RM 29)
- 2. Spokane River below Long Lake (RM 33.3)
- 3. Spokane River at Long Lake
- 4. Spokane River at Bowl & Pitcher (RM 66.2)
- 5. Spokane River at Ft. Wright Br. (RM 69.8)
- 6. Spokane River above Hangman Creek Confluence (RM 72.9)
- 7. Spokane River at Idaho state line (RM 96.5)
- 8. Hangman Creek at Mouth
- 9. Little Spokane River at Mouth (RM 1.1)
- 10. Little Spokane River at Dartford (RM 10.6)
- 11. Liberty Lake
- 12. Newman Lake

The water quality parameters selected for summary at each of these locations, where available, are as follows:

- 1. Temperature
- 2. Dissolved oxygen
- 3. BOD
- 4. Total phosphate
- 5. Ammonia
- 6. Total nitrogen
- 7. Total coliform
- 8. Zinc

Most parameters show significant variation in concentration with the seasons of the year. Therefore, summaries are prepared as mean values for three-month periods rather than on an annual basis for river stations and on a monthly basis for the natural lakes.

In general, only data taken 1970 and later are used in computing mean values to produce a picture of current conditions. In the case of the Little Spokane River and Newman Lake where recent data was not av 11able, the data period is extended back to 1968.

It is not the purpose of this section to repeat the wide spectrum parameter data reported in sections 607.1 and 607.2 and covering only two specific dates. The purpose of this section is to show year around data for a limited number of parameters.

Sources of Data

The specific data sources from which the summaries in this section are taken are as follows (refer to List of References for complete identification of publications):

Publications

Bishop and Lee (1972)

Burkhalter et al (1970)

Condit (1972)

Funk (1973)

Lee (1969)

U.S. Geological Survey (1972)

U.S. Geological Survey (1973)

Other Sources

U.S. Environmental Protection Agency; STORET retrieval system.

- Washington Water Power Co., unpublished temperature and dissolved oxygen observations on Long Lake, June-Oct. 1973.
- Soltero, et al (1973) unpublished data supporting the published document.
- Kennedy-Tudor sampling and analysis for this study as reported in Sections 607.1 and 607.2.

Appendices I through XII list the individual observations from the above listed sources which were used to compute the mean values shown in Tables 1 through 12. An exception is that unpublished data from Soltero at Spokane RM 69.8 and Little Spokane RM 1.1 are included in the calculated mean but not shown in the Appendix. There are extensive data on Long Lake presented graphically in Soltero et al 1973 and Soltero et al 1974 which are not utilized in this summary for two reasons. First, it is judged preferable to refer to the original document for the complex relationships shown in these documents which could be lost or distorted in summary. Secondly, the graphical presentation and absence of original data in tabular form make translation to tabular form difficult and uncertain.

Data Summaries

1

. .

.....

 Mean values for three-month periods for each parameter, where available, are shown for seven Spokane River locations in Tables 1 through 7, one Hangman Creek location in Table 8, and two Little Spokane River locations in Tables 9, 10. For the two natural lakes, Liberty and Newman, mean values by month at various depths are presented in Tables 11 and 12.

For the Spokane River, the tabular data are presented as quality profiles in Figures A through H. One parameter is presented on each figure, with a separate profile for each three-month time period.

Interpretation of Data

Spokane River. The quality of the Spokane River as it enters the study area from Idaho is a product of the quality of the Coeur D'Alene and St. Joe Rivers and their combined passages through Coeur D'Alene Lake. The two most significant quality changes to the incoming waters are pick-up of zinc from mine tailings on the Coeur D'Alene

River and the summer temperature increase due to passage through Coeur D'alene Lake. The entering stream does not meet colliform standards for most of the year, probably due to the treated municipal effluent from the City of Coeur D'Alene. Refer to Table 7. In general, the water is of high quality and meets drinking water standards for all parameters except colliform count.

There are four tributary sources to the Spokane River after it enters the study area which have a significant impact on quality, in addition to the inherent in-stream physical, chemical and biological processes. In the reach from the stateline at RM 96.5 to the Hangman Creek confluence at RM 72.9 there is a groundwater increment estimated at 500 to 600 cfs. This groundwater stream differs in quality from the surface flow in a number of significant ways.

- 1. The temperature is relatively constant at approximately 10° C.
- 2. Higher nitrates at 1.6 mg/1.
- 3. Lower zinc at $26 \mu g/1$.

The effect of the groundwater inflow would be expected to be a maximum when surface flows were at a minimum. The temperature reduction in July-Sept is evident in Figure A and the zinc reduction throughout most of the year as shown in Figure H. There is, however, no evidence in Figure F of an increase in nitrate at the expected time.

In addition to the groundwater inflow between RM 96.5 and 72.9, there are cooling water and industrial waste discharges and intermittant overflows from the Spokane combined sewer system. The seasonal

means tabulated herein show no significant evidence of these flows.

Hangman Creek joins the Spokane River at RM 72.9. The relative volume of this flow is very small at most times. Significant flows from Hangman Creek almost always occur when the Spokane River is also at high stage. The heavy silt load carried by Hangman Creek at flood stage is the most significant quality difference between Hangman Creek and the Spokane River. Other differences are higher ammonia throughout the year ranging from 0.104 to 0.642 mg/1, and higher total nitrogen at 1.38 to 2.61 mg/1. These ammonia and total nitrogen values are up to ten times higher than concentrations in the Spokane River. Phosphorus is also higher, at .085 to .395 mg/1; again the higher values being over ten times those in the Spokane River. As would be expected, the zinc levels are lower in Hangman Creek. The impact of these differences on the Spokane River is small in most cases due to the extreme differences in flow. Only the total nitrogen as shown in Figure F is seen to have an irregularly high impact and ammonia, as shown on Figure E actually decreases beyond the Hangman confluence. Phosphates show a small but consistent increase in Figure D.

The entrance of the existing primary treated sewage effluent from the City of Spokane treatment plant at RM 67.2 has the largest quality impact on the Spokane River. Except during the higher river flow season of April through June ammonia, total nitrogen, phosphorus and BOD show large increases below the City STP. Zinc shows a small increase.

The next stream to join the Spokane River below the City STP

is the Little Spokane River. The Little Spokane River has a stable flow pattern and contributes a significant input at all times of year. Unfortunately, there has been little data collection either of the Little Spokane at its mouth or of the Spokane River in close proximity downstream from the confluence. The Spokane River is actually a lake at the confluence and most data taken downstream from the confluence follow many miles of lake condition and reflect in-stream changes due to lake activity as well as the result of mixing with the Little Spokane. The quality of the Little Spokane River at its mouth is very similar to that of the groundwater of the Spokane Valley aquifer, which is responsible for a large fraction of the Little Spokane flow at all seasons except flood flows. The Little Spokane has relatively low phosphorus, ammonia and zinc but high total nitrogen. Coliform counts are surprisingly high. Refer to Table 9. As indicated above, the impacts of these quality differences are not reported free of lake effects.

As indicated above, it is not intended to treat Long Lake quality in detail herein but rather to report and summarize seasonal means for principle parameters. For all seasons except the winter (Jan-Mar) the lake retention results in a significant increase in temperature as represented by the surface layer. This temperature increase is not reflected to the same degree in outlet temperatures below Long Lake Dam. See Figure A. The temperature stratification of Long Lake in the June-Sept period is evident in the 7° C spread from surface to bottom as shown in Table 3. The temperatures downstream of Long Lake dam reflect release from lower levels in the lake.

The high phosphorus levels entering Long Lake, which are a major factor for the eutrophication problem in summer and fall is shown in Figure D. The capture of the phosphorus by organisms in the summer and fall is shown by the lower leaving concentrations for July-Sept and Oct-Dec. During the winter and spring there appears to be a reversal with the leaving concentrations higher than the influent. The net effect throughout the year is of phosphorus levels downstream from Long Lake being significantly higher than the Spokane River as it enters the study area and above levels of concern for eutrophic activity.

Within Long Lake the most serious quality deficiency which develops as a consequence of thermal stratification and high nutrient levels is the reduction in dissolved oxygen below the surface layers caused by the demand of dying organisms settling to the bottom. Table 3 shows that both the middle and bottom layers have low dissolved oxygen concentrations during the summer and fall seasons.

Hangman Creek. Two factors must be kept in mind in interpreting quality data for Hangman Creek at its mouth. One is that the flow is extremely variable and the other is that summer flow may be largely Spokane Valley groundwater which enters in the last downstream mile. In the absence of concurrent precipitation or snowmelt, the upstream flow approaches zero. The relatively low summer temperature as compared with the higher spring temperature is probably a measure of the increasing proportion due to low temperature groundwater in the summer. See Table 8. Also note the similarity of summer quality to Spokane Valley aquifer quality.

Little Spokane River. Two locations on the Little Spokane River are selected to show the quality which predominates in the basin upstream from Dartford as compared with the quality at the mouth after the flow increment from the Spokane Valley aquifer below Dartford. Refer to Tables 9 and 10 respectively. The Little Spokane River has unusually sustained year around flow and low peak flows, both the result of a high degree of interchange between the river and the groundwater of the basin. Consequently, the quality above Dartford is affected by the groundwater quality within the basin. Below Dartford, the quality affect is from groundwater outside the basin.

The drop in spring and summer water temperature from Dartford to the mouth clearly shows the effect of the addition of 10° C Spokane Valley groundwater.

High coliform counts at Dartford, with significant attenuation at the mouth, is the primary quality deficiency. The only point source near enough to be considered as the source is the treated sanitary wastes from Kaiser Mead which are discharged into Peone Creek which joins the Little Spokane immediately upstream from Dartford.

Liberty and Newman Lakes. Practically all of the available water quality data on these lakes is from USGS for one period March to September 1971. See USGS (1971). The data are so limited as to preclude any generalized conclusion.

Lee (1969) examined Newman Lake and several other lakes in the study area but did not include Liberty Lake. Based on one observation October 22, 1968 which included a temperature and dissolved oxygen
profile, Lee concluded as follows:

<u>Newman Lake</u> was shallow, well-mixed (isothermal), with an orthograde dissolved oxygen profile ... A moderate algal bloom was present, reflected by a low Secchi disc transparency.

Projected Water Quality

and a bill the second of the second of the second second second states of the second second second second second

The existing quality of the Spokane River as it enters the study area from Idaho is designated as a baseline condition for projection of future water quality in the study area. The primary quality deficiency at the stateline is bacteriological. Refer to Table 7. The other parameter of note is zinc. Although zinc concentration is well below drinking water standards, it is significantly higher than most natural waters. It is probable that the coliform count will be improved in the future by enforcement of effluent standards in Idaho, primarily for Coeur D'Alene. It is unlikely that a major change will be achieved in zinc concentrations which have their origin in leaching from mine tailings on the Coeur D'Alene River.

Baseline conditions on the Spokane River downstream from the stateline are being determined based on the water quality simulation model in a run with all existing point source pollutant loads removed. Projected conditions for surface water discharge of forecast year 2000 municipal flows treated to 1983 standards is the subject of another quality model simulation. Both of these results are reported in the task report on simulation model results.

SECTION 410.1

STATISTICAL ANALYSIS OF STREAMFLOW RECORDS

Purpose and Scope

The purpose of this section is to apply standard statistical methods to the available stream flow records of the study area toward determination of the magnitude and recurrence frequency of flood flows and low flows. The flood flows are used in a subsequent section to delineate the flood plain at the following locations:

- Spokane River from the Hangman Creek confluence to the Idaho boundary.
- Little Spokane River from confluence with the Spokane River to the vicinity of Chattaroy.
- 3. Rock Creek in the vicinity of Rockford.
- 4. Hangman Creek in the vicinity of potential urban developement.

The criterion for flood plain delineation is the peak flow with 100 year recurrence interval. Peak flows of lesser return frequency are also determined in the process of analysis, but the peak flows of 100 year return frequency are the critical objectives.

The low flow data are developed for the purpose of providing a basis for evaluation of critical supply for maintenance of natural stream life and for evaluation of critical assimilative and dilution potential for wastewater disposal alternatives. The criterion for low flow evaluations is the 7-day interval of lowest mean flow with recurrence interval of

ş

10 years. As with flood flow analysis, low flows of other return frequencies are developed but primary interest is for short return intervals.

Low Flow Analysis

General. The available stream gages in the study area with periods of record adequate for statistical analysis are listed in Table 1. For reasons discussed below the entire available period for each gage is not used for all gages.

Elimination of Low Flows Due to Freezing. The primary use of the resultant low flow data is to be evaluation of water quality management problems which are most critical during summer when low flows are combined with higher water temperatures. For the Little Spokane River and Hangman Creek there are winter low flow events caused by freezing. To avoid distortion of the summer lows, which are of primary interest, these winter lows are excluded from the statistical analysis by deletion of all events occurring before March 1 or after October 31. Other than the exclusion of freezing season events, the entire period of available record is utilized for the two gages on the Little Spokane River and the one on Hangman Creek. These records are twenty years in length and should give adequate results for determination of return frequencies of 10 years and less.

Regulation and Diversions. Low flow events in the Spokane River as it enters the study area are significantly affected by the controlled releases at Post Falls Dam due to Washington Water Power Companies' (WWP)

hydroelectric operations. There are relatively small interchanges between the Spokane River and groundwater between Post Falls and the study area boundary and practically none between the dam and gage number 4190. There is, however, a major groundwater interchange with the Spokane River between the study area boundary and gage number 4225 located a short distance upstream from the Hangman Creek confluence. Hence, the records for gage number 4190 reflect an almost complete dependence upon Post Falls regulation but those at gage number 4225 are only partially dependent upon regulation.

The regulation exercised by WWP is in accordance with an operating policy that has been in effect and substantially unchanged since 1946. Prior to 1946 operating policy relative to flow regulation was different due to different system capability and power requirements. Therefore, the records prior to 1946 represent a significantly different flow regime. The flow regime from 1946 to present, although fully regulated, approximates natural conditions. The current WWP operating policy is to bring Coeur D'Alene Lake to its summer level as soon as possible after the spring high flows and then to maintain that level constant throughout the summer by regulation of release rates at Post Falls.

There have been two significant irrigation diversions on the Spokane River above the streamgage near Post Falls #4190. These two irrigation diversions and the gages used to record them are: USGS Gage#

1.	Spokane Valley Farm's Company Canal at Post Falls	4185
2.	Rathdrun Prairie Canal at Huetter	4180

The Spokane Valley Farms canal began operation in 1913 and continued to supply irrigation water through the 1966 irrigation season. In 1967 the operation of the canal was suspended. Irrigation water is now being supplied from groundwater sources. The Rathdrun Prairie canal began operation in 1947 and is still an active supplier of irrigation water.

The WWP operating policy since 1946 has, in effect, been to release at Post Falls an amount of water which, combined with the irrigation diversions, is equal to the total inflow to Coeur D'Alene Lake less evaporation losses. The primary sources of inflow to Coeur D'Alene Lake are the Coeur D'Alene River and the St. Joe River. It is recognized that, at times, WWP may, for technical operating reasons, release more or less than what the natural outflow from Coeur D'Alene Lake would be, but it is believed that these occurrences are of such rare occurence and short duration as to not affect the statistical analysis.

In order that the low flow analysis best represent natural flows that could be expected to be available for water resources management, the diversions above the Post Falls Dam have been added to the flow released at the dam by Washington Water Power Company before statistical analysis. Both irrigation diversions are added back into the flow, that of the discontinued diversion and that of the continuing diversior.

There are no regulating structures on either the Little Spokane River or Hangman Creek. There are no significant diversions from Hangman Creek. A number of water rights are held for diversions from the Little Spokane River. These rights from DOE records total 111 cfs. There are, however, no records of the amounts actually diverted on seasonal basis,

let alone on a time basis, that could be correlated with stream flow records. Hence, the statistical analysis of the Little Spokane River is done on the basis of measured flow uncorrected for diversions and is, therefore, not necessarily representative of natural streamflow conditions.

In summary, the data subject to statistical analysis for low flow is as follows:

- Spokane River near Post Falls, gage 4190. Total record available 1913 to 1972. Record used 1947 to 1972. Irrigation diversions from gages 4180 and 4185 added in before analysis.
- Spokane River at Spokane, gage 4225. Total record available
 1891 to 1972. Record used 1947 to 1972. Irrigation diversions
 from gages 4180 and 4185 added in before analysis.
- Little Spokane River at Elk, gage 4270. Record available and used 1948 to 1972, except that low flows Nov. 1 to Feb. 28 (or 29) not considered.
- Little Spokane River at Dartford, gage 4310. Record available and used 1929 to 1932 and 1947 to 1973, except that low flows Nov. 1 to Feb. 28 (or 29) are not considered.
- Hangman Creek at Spokane, gage 4240. Record available and used 1949 to 1972, except that low flows Nov. 1 to Feb. 28 (or 29) are not considered.

Computation Procedure. The computation procedure for low flow analysis

using the data described above in annual series is carried out in the following steps.

- Identify the 7-day low flow event for each year included in the analysis.
- 2. Rank the data in terms of increasing discharge.
- Assign plotting positions to each piece of data from Baard, <u>Statistical Method in Hydrology</u>.
- 4. Plot the data on probability paper.
- 5. Draw a curve through the data points.
- 6. The magnitude of the 10-year event is the value where the curve intersects the probability of recurrence of 10 percent.

Frequency curves are developed graphically by plotting on logprobability paper. Refer to Figures A through E. A break in slope is an expected feature of these low flow curves, connecting two straight line plots. The location of the break in slope is clearly indicated in the plots for the Little Spokane at Dartford and for the Spokane River at Spokane in the vicinity of 25 percent. This insight is used to select the indistinct break exhibited by the data for Hangman Creek at Spokane River near Post Falls. The final fittings are made using the method of least squares. The Little Spokane River at Elk data does not exhibit any break in slope but is rather a single straight line throughout. The plotting positions for the split record on the Little Spokane River are determined by the method of Beard^{*}s Exhibit 11 in recognition of the probability that 1930 and 1931 are the lowest years in the last 45 years (and possibly the lowest since 1891). <u>Results</u>. The determined value of 7-day low flow with recurrence frequency of 10 years for the five gages is summarized in Table 1.

While the Spokane Valley Farms diversion, USGS gage #4185, and Rathdrun Prairie Canal, USGS gage #4180, were both in service from 1947 through 1966, the total of both diversions is in the range 230 to 290 cfs for most years during the critical low flow period. Beginning in 1967, with only the Rathdrun Prairie Canal in operation, the total diversion during critical low flows is approximately 50 cfs. Assuming the Rathdrun Prairie Canal continues in operation, the calculated statistical low flows which do not include these diversions are approximately 50 cfs greater than would be observed.

Discussion of Low Flow Results

Spokane River. The observed flow at Post Falls, as indicated above, is essentially equal to the inflow of the Coeur D'Alene and St. Joe river systems into Coeur D'Alene Lake less evaporation from Coeur D'Alene Lake. Since there are no significant storage structures in these rivers, the observed flow represents natural conditions. If the natural low flow condition occurs concurrently with the irrigation season for the Rathdrun Prairie Canal, the actual flow experienced below Post Falls would be about 50 cfs less than shown in Figure A due to the diversion, making net the 10 year flow approximately 145 cfs.

The tributary area at Post Falls, gage 4190, is 3840 square miles and at Spokane, gage 4225, is 4290 square miles, or 12 percent more. The

7-day low flow at Spokane is 860 compared with 195 at Post Falls or 4.4 times greater. This much larger flow is due to the groundwater increment between Post Falls and Spokane which not only affects the quantity but the quality and temperature. It should be noted that the ultimate source of most of the groundwater increment is outside of the tributary area of the river above Post Falls. The 7-day low flow is 0.05 cfs per square mile at Post Falls and 0.20 cfs per square mile at Spokane.

<u>Hangman Creek</u>. The 7-day low flow at the Hangman Creek gage 4240 is only 3.4 cfs or 0.005 cfs per square mile of tributary area. The entire watershed is essentially in the Columbia Plateau region which consists of Palouse topsoil on a base of basalt interbeded with Latah formation. There is essentially no groundwater body in the area except that which occupies the fractures in the basalt element. The topsoil has good moisture holding qualities for agriculture but stores no free water for subsequent release to groundwater. Therefore, it is to be expected that the streamflow outside the rainfall season would be very small.

The 7-day low flow with 10 year recurrence actually gives an optimistic picture of what can happen, as it actually did in the fall of 1974 when it essentially went dry. This is indicated by the steep slope of the curve to the right of the break.

Little Spokane River. The shape of the curves obtained at the Elk gage, number 4270, and the Dartford gage, number 4310, as well as the

yield per square mile of tributary area indicate different hydrologic regimes. The curve at Elk exhibits no break and shows a yield of 0.31 cfs per square mile at 7-day low flow with 10 year recurrence. The curve for Dartford shows a break and has a corresponding yield of 0.13 cfs per square mile.

As indicated above, there is an unknown effect on the Dartford yield due to the exercise of water rights for diversions of up to 111 cfs. This would tend to decrease the apparent yield at Dartford. The geology, on the other hand, indicates a more favorable groundwater condition for the Dartford gage since it includes the Deer Park basin gravels, whereas the areas above Elk are believed to have small gravel deposits on relatively impermeable base rock.

Flood Frequency Analysis

<u>General</u>. The stream gages subject to analysis and their periods of available record are shown in Table 2. The Spokane River gage with its 83 years of available record is the only gage with a record of adequate length for relatively high confidence determination of the 100 year recurrence event which is of primary interest. The Little Spokane and Hangman Creek records are both less than 30 years length and, for this reason, should be extended by interbasin correlation to increase reliability.

<u>Regulation</u>. There are no regulating structures on either the Little Spokane River or Hangman Creek. The record of flood flows on these streams is a record of natural unregulated flow. The diversions noted above in the Little Spokane basin, allowed by water rights, are negligibly small when compared with flood stage flows.

The Spokane River is subject to a degree of flood flow regulation by the control of the level of Coeur D'Alene Lake by WWP. The rivers tributary to Coeur D'Alene Lake are unregulated. The area tributary to Coeur D'Alene Lake is 3700 square miles. The area tributary to the Spokane River below Coeur D'Alene Lake and upstream from gage 4225 is 4290 square miles but the flow reaching the river from this incremental area is negligible due to the permeable valley floor between the uplands and the river channel which prevent the formation of any significant surface drainage ways.

Post Falls Dam which forms the outlet regulating structure of Coeur D'Alene Lake is capable of regulating flows of up to 15,000 cfs at lake levels up to 2128 feet. Once the lake level reaches elevation 2128 feet and the quantity available for spill exceeds 15,000 cfs, the Post Falls structure no longer exercises control and control passes to the natural outlet of the lake. Refer to Section 308 for stage discharge relations of the lake outlet and the stage capacity of Coeur D'Alene Lake. Post Falls Dam was constructed in 1906.

It is theoretically possible to partially attenuate peak flood flows in the Spokane River by lowering the lake level in anticipation of a large runoff. The storage capacity of Coeur D'Alene Lake between elevation 2120.5, the lowest level, and elevation 2128, the level at very control normally passes to the natural outlet is 108,500 second foot days or 217,000 acre feet. This volume of storage is equal to 1.1 inches of runoff from the tributary area or one week's mean daily flow for the April, May, June period. The net effect of the potential Post Falls regulation on flood flow peaks is unknown without analyzing each event by a reversed routing through Coeur D'Alene Lake. Due to the large volume associated with snowmelt events compared with the potential storage, it appears unlikely that snowmelt events could be much attenuated by a planned lowering. On the other hand, rainfall events usually cannot be anticipated sufficiently in advance to make a planned lowering. Planned operations are therefore believed to have small effects on experienced peak flows. The data used herein is as recorded and reflects the net

effect of all conditions including whatever effect planned interventions may be capable of achieving.

Rainfall and Snowmelt. Examination of flood records and the causative meteorological events indicates that for the Spokane River and Little Spokane River, flood flows can result from both rainfall and snowmelt events. For Hangman Creek, significant flood flows are predominantly caused by rainfall events. Since rainfall and snowmelt form separate statistical populations, it is necessary to develop separate analysis of flood flows from these two causes for both the Spokane River and Little Spokane River where both events cause significant floods.

<u>Computation Procedure</u>. The computation procedure for flood flow analysis is as follows:

1. Identify the annual flood peak or peaks for the years of available record. For the Spokane River at Spokane, gage 4225, and the Little Spokane River at Dartford, gage 4310, flood peaks are identified with relation to their cause, rainfall or snowmelt, by the examination of concurrent climatological data for weather stations in the watershed. For Hangman Creek at Spokane, gage 4240, one peak per year is identified based on a similar climatological screening which indicates that all significant floods are a consequence of rainfall events.

2. Since the available records of peak instantaneous discharge, in general, report only one peak per year, there is a blank in one

or the other rainfall or snowmelt series, after the reported peak is categorized. It is necessary to fill these blanks by correlations between the instantaneous peaks and the corresponding daily flow. Since the entire year record is available as daily flows, the correlation provides a means of converting other identifiable daily discharges to the corresponding instantaneous peak. The method used for correlation is the single linear correlation described by Beard (1962) at paragraph 9-02. As a result of this correlation technique, complete annual series for the period of record of each station are obtained.

3. The short record stations, Hangman Creek #4240 and Little Spokane #4310, are extended by interbasin correlation with Spokane River #4225. The method used is simple linear correlation per Beard (1962). This interbasin correlation results in extended annual series for the short record stations.

4. The annual series for each station as filled in and extended by correlation are subjected to statistical analysis by the logarithmic Pearson Type III method as described in Beard (1962). The results are calculated frequency curves and the statistical coefficients which provide an indication of the degree of reliability of the analysis. Skew coefficients are calculated and compared with the regional minimum value of -0.36. Calculated skews larger than -0.36 are utilized in determination of k factors but the regional minimum is used in lieu of smaller calculated values.

5. In addition to the calculated frequency curves, the peak flow data are also plotted on log-probability paper to show the relative response of the calculated frequency curves to length of record and statistical parameters.

6. For stations with annual series for both rainfall and snowmelt events, a combined probability curve is developed using the relationship as follows:

$$\frac{P}{\text{average}} = \frac{P}{\text{rain}} + \frac{P}{\text{snow}} - \frac{P_{\text{rain}} \times P_{\text{snow}}}{100}$$

Final results for the three stations are shown graphically in Figures F, G and H which show the full range of exceedence events. The critical values shown to have a probability of exceedence of once in a hundred years are marked on these curves and recorded as figures in Table 2.

Supporting data are shown in the Appendix as follows:

For the Spokane River at Spokane, Gage 4225. Raw data for rainfall and snowmelt peaks flows 1892 to 1974 are shown in Appendix(A) VI and VII. The annual series of peak rainfall and snowmelt events filled in by correlation with one day discharges is shown in A VIII and A IX together with the statistical properties of the results. The ordered peak flows, their logarithims and plotting position are shown in A X and XI and the plotted points in A XIII and XIV. The peak flow flow frequency curve calculation for both rainfall and snowmelt events is shown in A XII together with statistical properties, calculated skew and skew factors

used in calculation. The calculated curves are plo d on A X and A XI for comparison with unadjusted points. The calculated curves are repeated in Figure F where the combined curve is developed.

For the Little Spokane River at Dartford, Gage 4310. Raw data for rainfall and snowmelt events 1930 - 1932 and 1947 - 1974 are shown in A XV and A XVI. Correlation with gage 4225 is shown in A XVII and A XVIII together with filled in peaks with the period of record from correlation within the basin. The extended record developed from interbasin correlation with gage 4225 is shown in A XIX and A XX. Ordered peak flows, their logarithims and plotting position are recorded in A XXI and A XXII and points are plotted on A XXIV and A XXV. The peak flow frequency curve calculation for both rainfall and snowmelt events is shown in A XXIII together with statistical properties, calculated skew and skew factors used in calculation. The calculated curves are plotted on A XXIV and A XXV for comparison with unadjusted points. The calculated curves are repeated in Figure G where the combined curve is developed.

For Hangman Creek at Spokane, Gage 4240. Recorded data for events which have all been identified as rainfall events for the period of record, 1949 to 1974, are shown in A XXVI. It is not necessary for this gage to fill any gaps by correlation within its own record. Extension by correlation with the rainfall events of gage 4225 is shown in A XXVII. The ordered peak flows, their logarithims and plotting position are shown in A XXVIII and points are plotted in Figure H. The peak flow

frequency curve and its statistical properties, calculated skew and adopted skew are shown in A XXIX. The calculated curve is plotted in Figure H.

Discussion of Flood Flow Results

Spokane River. The record for this gage is 82 years, which, if complete, would provide a substantial data base for determination of events with one per hundred year exceedence. Since only one peak instantaneous flow was recorded per year without regard to whether it was a rainfall or snowmelt event, the record is not complete for either. Since 87 percent of the recorded peaks are determined to have been snow- / melt events, the rainfall data is weakest. This weakness is reflected in the computed value of N at 48.8 years for the series when filled out by correlation, indicating that the reliability of the rainfall event record is equal to 48.8 years rather than 82. For all except very rare events, snowmelt peaks are more critical than rainfall.

The determined "100 year" flood of 52,000 cfs is equal to 12.1 cfs per square mile based on the gross tributary area or 13.5 cfs per square mile if only the area above Coeur D'Alene Lake is considered. The yield is dominated by the high mountain terrain in Idaho on the headwaters of the Coeur D'Alene and St. Joe Rivers.

Little Spokane River. The short record for this station and the fact that it involves both rainfall and snowmalt events requires two stages of correlation for completion of the data series, extended. The

correlations between peak events and 1-day events within the basin are very good. Therefore, the effect on reliability of the second correlation is substantially that due to the second correlation alone. The N values computed are based on that assumption and indicate an extended record equal in quality to 31.1 and 39.0 years respectively for rainfall and snowmelt.

The Little Spokane River exhibits the opposite characteristic of the Spokane River with respect to the significance of snowmelt and rainfall events. For the Little Spokane River rainfall events of the same frequency are larger than snowmelt events over the entire range. For the "100 year" flood, the peak flow of 4700 cfs is almost entirely determined by the rainfall event curve. The flood flow is equal to a runoff of 7.05 cfs per square mile. The forest cover and permeable valley fills tend to attenuate peak flows on this basin as compared with Hangman Creek. The lower overall yield due to the lower precipitation range in the Little Spokane Valley as compared with the watershed of the Spokane River accounts for the difference between these two rivers, which more than makes up for the routing effect of Coeur D'Alene Lake.

Hangman Creek. Flood flows are entirely dominated by rainfall events. The extension by correlation is not as beneficial as for the Little Spokane due to poorer interbasin correlation. The extended data has an N of only 28.8 years.

The "100 year" flood flow at 28,000 cfs is equal to a runoff of

40.6 cfs per square mile. This reflects the absence of significant forest cover and permeable soils in the tributary area. The positive skew of the calculated curve is indicative of the potential for even greater extremes of flood flow for rare events.

SECTION 410.2

FLOOD PLAIN DELINEATION

INTRODUCTION

The flood plain analysis area is composed of four reaches: the Spokane River from the confluence with Hangman Creek, RM 72.4, to the Idaho state line, RM 96.5; the Little Spokane River from the confluence with the Spokane R. er, RM 0.0, to the vicinity of Chattaroy, RM 23.2; Hangman Creek from its confluence with the Spokane River, RM 0.0 to the end of the adjacent residential development, approximate RM 4.0; and Rock Creek in the reach through Rockford. The results of the analysis are presented as follows for each of the respective reaches: for the Spokane River, a profile delineating the 100 yr flood water surface and a plan delineation of the 100 yr flood plain on 1'' = 400' orthophoto backgrounds for the entire reach; for the Little Spokane River, a profile delineating the 100 yr flood water surface for the entire reach and a plan delineation of the 100 yr flood plain on 1'' = 400' orthophoto and topographic backgrounds for the reaches between RM 0.0 and approximate RM 16 south of the town of Buckeye and on 1" = 2000' USGS maps RM 16 to Chattaroy for Hangman Creek, a plan delineation of the 100 yr flood plain on 1" = 400 orthophoto backgrounds for RM 0.0 through RM 5.0; for Rock Creek, a profile delineating the 100 yr floodwater surface for the reaches through Rockford and plan at 1" = 400'. Large scale mapping is on places which are bound at the end of this section.

The flood flows of 100 year return frequency are developed from

Gage Number	Description	Flood Flow of 100 year recurrence cfs
4224	Spokane River at Spokane	52,000
4310	Little Spokane River at Dartford	4,700
4240	Hangman Creek at Spokane	28,000

statistical analysis of available stream gage records in another section of this study. The results are summarized below:

The Spokane River and Hangman Creek gages are located at the downstream and of the study reaches and the Little Spokane River gage at approximate mid-reach.

There is no stream gage on Rock Creek, a tributary of Hangman Creek, from which the 100 year flood flow can be developed directly by statistical analysis. The 100 year flood flow for Rock Creek at Rockford is developed by area correlation as discussed below.

Limitations

The flood plain delineations made in this study are for the purpose of general planning in water management. The results are not intended for use in establishing legal flood plain boundaries or for other uses with legal implications such as flood insurance. Neither the data base on which the studies are made nor the methodology employed in the analysis meet the requirements of such specialized legal application.

It will be noted on maps delineating the flood plain that the edge of the flood plain is shown in some cases to cross and recross contour lines. This is because greater weight is given to actual observed flooding than contour shape. The contour mapping is accurate to plus or minus 1/2 an interval or 2.5 feet. This, and other considerations, is an example of the limitations cited.

The Spokane River

والمتكلفات فالمنا الملطوسة ومعناه الكلامين والالمالي فالمراكبة والمعادية

Development of the profile delineating the 100 yr high water surface, as shown in Figs G & H, is subdivided into three parts.

1. Hangman Creek to City Waterworks bridge, RM 72.4 to RM 79.6. The City of Spokane invert profile at City datum is adjusted and matched to the Corps of Engineers study of the December 1933 flood profile at USC & GS datum using the datum shift of 16.58'. Since the 1933 flood was caused by discharge of 47,800 cfs whereas the 100 yr discharge is 52,000 cfs an upward adjustment of the 1933 profile is required to describe the 100 yr flood. Modifications are made to the 1933 profile in two sections: (a) RM 72.4 to 74.0 is raised 0.6' which reflects the incremental elevation difference between the two floods as indicated by extrapolation of the rating curve of USGS gage #4225 at RM 72.9, see Figure A; (b) The water surface in the vicinity of USGS streamgage #4220 RM 77.9, is raised 1.4 ft. to reflect the elevation difference between 47,800 cfs and 52,000 cfs as determined from the extrapolated rating curve associated with this gage. See Figure B.

2. Between Green Street Bridge, RM 78.0, and Argonne Road, RM 82.6 the invert and the 100 yr high water surface are assumed to be represented by linear joining of known conditions at the two endpoints, there being no historical data for either in this subreach.

3. Argonne Road bridge, RM 82.6, to Idaho state line, RM 96.5. This is approximately a 13 mile subreach with profile elevations and corresponding cross-section data available at about 2 mile intervals. At each of these intervals a high water measurement has been recorded for the Jan. 1974 flood of 46,100 cfs. The profile for the 1974 flood in this subreach is adjusted upward to represent the 100 yr flood by + 0.75' at RM 84.8 and + 1.5' at RM 93.9 and linearally prorated to adjacent subreaches. These increases are due to the elevation difference between the 100 yr discharge

of 52,000 cfs and the Jan. 1974 discharge of 46,100 cfs as indicated by extrapolation of USGS gages #4195 and #4215 respectively. See Figures C and D. A linear slope for both the invert and high water surface profile is assumed for all subreaches between the observed data at the crosssections.

The flood plain delineation is produced on Plates 410-1 through 410-13 by plotting the high water line on 1" = 400' orthophoto maps with the basic reference for the extent of flooding being the vertical photos taken by the Corps of Engineers during the 1974 flood. Supplemental data are drawn from field observations, field photos and the water surface profile.

In general the Spokane River is well contained by its banks and control structures. Bridges provide ample clearance to pass large floods and urban development outside the city proper is not threatened by floods. In the city, three areas are subject to partial inundation by large floods. Areas of Pleasant Valley adjacent to the River downstream of Monroe St. bridge were flooded in the Jan. 1974 occurrence and this situation would be repeated for other large magnitude floods. Other urban areas which can be expected to experience moderate inundation by a 100 yr flood are reaches along Upriver Drive and the buildings located in the flats north of the river in the vicinity of East and West Trent bridges.

Little Spokane River

Same Sime

The 100 yr water surface profile as shown in Figure I is developed from a series of field measurements made by K-T. This Data includes high water observations for the Feb. 1970 flood of 3170 cfs, several cross-sections

and both aerial and ground photographs. These measurements were applied to the Corps of Engineers HEC-2 mathematical model and one run was made which yielded an approximate water surface profile. This profile is adjusted to more accurately fit the associated high water marks. The incremental depth from the observed 100 yr flood at the USGS gage #4310 at Dartford RM 10.8 is determined from the extrapolated rating curve shown in Figure E. The difference between the 1970 flood and the 100 yr flood of 4700 cfs is 1.1 ft. This increment is prorated by depth over the entire reach and added to the 1970 profile to yield the 100 yr high water surface profile. The backwater from Long Lake which is assumed to be elevation 1539 at RM 0.0 concurrent with the 100 yr flood on the Little Spokane. The estimated water surface profile of the Little Spokane at 100 year flood is also approximately 1539 at RM 0.0 matching the assumed lake backwater indicating negligible backwater effect extending into the river.

The limits of the 100 yr flood plain are presented on 1" = 400'topographic maps from the confluence of the Little Spokane and the Spokane rivers to Buckeye. Refer to Plates 410-17 through 410-24. The extent of the 100 yr flood plain is estimated by combining the elevations predicted on the 100 yr profile with oblique photos of the Dec. 1973 and Jan. 1974 flooding of the Little Spokane River.

A large magnitude flood on the Little Spokane river can be expected to inundate adjacent residential dwellings in the vicinity of Dartford and Buckey. In the lower reaches, RM 0.0 to RM 10.3, due to the flat nature of the overbank, extensive flooding occurs when the flood stage becomes higher

than the low channel banks. Even moderate occurrences tend to have this effect. These reaches contain several dwellings and a school which have a history of flood threats and damage. The upper reaches, RM 16.3 to 21.0, also have low channel banks with a wide flat overbank which are inundated with moderate to large floods. However, very few residences are presently located on this flood plain.

Hangman Creek

A flood plain delineation on Hangman Creek is presented on 1" = 400' orthophoto maps from its confluence with the Spokane River to RM 3.0. Refer to Plates 410-1 & Plates 410-14 to 410-16. The basic reference utilized to determine extent of flooding is the photo record of the January 1974 flood made by Kennedy-Tudor. The limits of flooding are adjusted to reflect the 2.6 ft difference in the water surface between the Jan. 1974 flood of 18,300 cfs and the 100 yr flood of 28,000 cfs. This incremental adjustment is obtained by comparison of the flood discharges to the extrapolated rating curve of USGS stream gage #4240, RM 0.8 as shown in Fig. F. The gage is within the reach being analysed.

Both the mapped flood area as shown on referenced plates and the oblique aerial photos of the December 1973 and January 1974 floods indicate flooding potential to several isolated residences in the reach below the railroad bridge at RM 3.1. There is also a strip about 1/2 mile long in the vicinity of RM 2.6 not presently occupied that has flooding potential. During the December '73 and January '74 floods there was some minor flood damage reported in the newspapers in the lower Hangman Creek area.

The news photos show that the primary source of damage was by undercutting of structures built on alluvium deposited by previous floods.

Analysis of oblique aerial photos of the entire length of Hangman Creek made during the Dec. 1973 and Jan. 1974 floods indicates the following locations of other potential flooding problems:

1. There is overbank flow in the vicinity of RM 11.0, however, there are no structures involved.

2. There is overbank flow in the golf course at RM 14 which encroaches on fairways and comes near the clubhouse. The reach through the present golf course site was the subject of a previous flood profile analysis by the Corps of Engineers, results of which are not reported herein.

3. Overbank flow exists between RM 23.9 and ?5.0 but there are no buildings involved.

4. There is overbank flow north of Waverly between RM 36 and RM 37 which covered the county road and threatened a bridge during the Jan. 1974 flood. There are no buildings affected.

5. Minor road flooding and a threat to isolated farm buildings occurs in the vicinity of RM 41.0.

6. At Latah and north of Latah, RM 46.0 to RM 48.0, there is overbank inundation with road flooding. Some farm buildings are also involved at RM 48.0.

7. There is extensive overbank flooding in and around Tekoa. Farm land, farm buildings, roads and some residential areas are involved. Reconnaissance reports on the flooding problem in the Tekoa area were prepared in 1966 and 1970 by the Corps of Engineers, results of which are not

reported herein,

In general, this survey of aerial photos of recent flood flows indicates that there is essentially no urban development subject to or threatened by flooding of Hangman Creek between RM 4 and Tekoa.

Rock Creek at Rockford

A 100 yr high water surface profile is presented for the reaches of Rock Creek through Rockford in Figure J. Data for this analysis, including five cross-sections, was obtained by a joint field survey by the Corps of Engineers and K-T. The high water surface for the Jan. 1974 flood is plotted relative to the stream bed profile defined by the survey cross sections. The discharge associated with this observed flood of January 1974 is estimated to be 3100 cis based on the area discharge relationship for the Hangman Creek watershed developed from USGS gage #4240. This flow of 3100 cfs when applied to normal depth analysis of the two upstream cross sections gave close agreement with the observed 1974 high water marks and verified the basis for flow correlation. The 100 year discharge on Rock Creek at Rockford is estimated on this same basis to be 4750 cfs. The normal depth analysis for a flow of 4750 cfs yields an incremental surface elevation of 1.0 ft. at the previously analysed cross-sections. This increment is added to the observed 1974 flood profile to yield the 100 yr flood profile as shown in Figure J. The profile shown in Figure J does not include any consideration of backwater potential created by the highway bridge which abuts the downstream end of the levee. The bridge deck is at

the same elevation as the top of the levee. The bridge was close to inundation during the Jan. 1974 flood causing a substantial backwater upstream along the levee. There is a possibility that a larger flood would destroy the bridge.

The January 1974 flood did not cause any significant flood damage. The flood profile developed in this study for the 100 year recurrence without consideration of backwater from the highway bridge indicates that water surface would be within one foot of the present levee top.

Modifications to the channel downstream from the highway bridge and the end of the levee have been made since the Jan. 1974 flood which will reduce the 100 yr profile somewhat in this part of the reach. Also, a culvert without backflow prevention under the levee allows sections of the town to be flooded at high river stage.

The existing levee was constructed by WPA after the 1933 flood. The alleged protection level of the levee is for 20 year flood recurrence. Rockford was flooded again in 1963 and 1964 and the levee was repaired by the Corps of Engineers in 1965.

Subsequently, a preliminary plan of improvements was developed by the Corps of Engineers and found to have a benefit-cost ratio of 0.9. The plan has not been implemented. The proposed improvement consists of raising the levee 3 feet for a distance of 700 feet and rebuilding the levee for a distance of approximately 1,000 feet, all to provide protection for the 100 year recurrence level.

The approximate limits of the 100 year flood are shown in Figure K. These limits are from the Corps of Engineers study referred to above and are not derived from the profile in Figure J. The Rockford vicinity and relation to the flood plain are shown in Plate 410-27.

Photographic Record of Flooding

Two opportunities for photographic documentation of flooding problems occurred during the study period, one in December 1973 and another in January 1974. Kennedy-Tudor made photographic records of these two flood events, as follows:

December 1973 Event

- Oblique aerial photos, color, of the Little Spokane River from mouth to vicinity of Chattaroy, 61 photos, 12-18-73.
- Ground level photos, color, of the Little Spokane River from mouth to vicinity of Chatteroy, 77 photos, 12-17-73 to 12-21-73.
- Oblique aerial photos, color, of Hangman Creek, from mouth to Tekoa, 36 photos, 12-18-73.
- Ground level photos, black and white, Spokane River, Hangman
 Crack confluence to State Line, 40 photos, 1-17-74 to 1-20-74.

January 1974 Event

- Oblique aerial photos, black and white, of the Little Spokane River from mouth to above Chattaroy, 18 photos, 1-16-74.
- Oblique aerial photos, black and white, of Hangman Creek from . mouth to Tekoa, 86 photos, 1-16-74.
- Oblique aerial photos, black and white, Rock Creek from mouth to Idaho boundary, 31 photos, 1-16-74.
- Ground level photos, black and white, Rockford vicinity, 7 photos, 1-15-74.

In addition to the photo record made by Kennedy-Tudor as described above, vertical aerial photography was made for the Corps of Engineers as follows: Spokane River from Hangman Creek confluence to Coeur D'Alene Lake on January 19, 1974, and Hangman Creek from mouth to Tekoa on January 17, 1974.

The oblique aerial photos of the December 1973 events on the Little Spokane River and Hangman Creek are included herein as Appendices I and II respectively. Contact prints of the oblique aerial photos of the January 1974 event are included herein as Appendix III. Appendix IV provides a map index to the photos shown in Appendices I through III. Appendices I and II are arranged in order from the mouth upstream in each case. Appendix III photos are in the order indicated on the map, Appendix IV.

Ground level photos and enlargements of the oblique aerial photos shown at contact size in Appendix III are available in project files. Corps of Engineers vertical photos of the Spokane River are returned to Corps files.

The 1974 event on the Spokane River which reached a peak of 46,100 cfs on January 20, 1974 was sustained at substantially peak volume over January 19, 20 and 21 so that the verticals made for the Corps on January 19 are a record of the peak flow flooding. The 1974 event on Hangman Creek peaked at 2200 hours on January 15, 1974 at 18,300 cfs but had dropped to 12,300 cfs by January 16, 1974 between 1100 and 1300 hours when the K-T oblique color photos were made. The verticals flown for the Corps on January 17, 1974 were after the high flow period.

Scope and Objectives

The objectives of Tasks 3070 and 3090 are to inventory all available surface water and groundwater quality data within the Study Area and to analyze the inventory for data gaps. Data analysis and interpretation are not within the scope of this section.

Surface water data are to be inventoried for streams, man made on-stream impoundments and natural lakes. Groundwater data are to be inventoried for all groundwater bodies within the study area including the primary aquifer of the Spokane Valley, other alluvial aquifers and the basalt aquifers.

All kinds of water quality data are to be indentified. In addition to water temperature and the traditional chemical constituents, particular attention is directed toward inventory of data which includes parameters significant to oxygen balance, nutrients, aquatic growths, heavy metals toxicity, organic toxicity, bacterial contamination, oil contamination and évidence of detergents.

The sources of data to be explored are correspondingly broad. In addition to the basic Water Quality Papers of the U.S. Geological Survey, the canvas of data includes published reports, the Storet system, and unpublished sources.

Overview

<u>Surface Water Data</u>. There have been a succession of varied interests in surface water quality in the Study Area. The

earliest cause for concern and consequent monitoring of quality was the increase in heavy metal ions, particularly zinc, which entered the basin from Idaho due to the leaching of mine waste on the Coeur D'Alene River. Next came the concern from gross untreated sewage pollution caused by the City of Spokane sewer system. After the completion of the City primary treatment plant, the focus of interest has been on eutrophication of Long Lake. This latter interest, which remains the primary focus to this day, was first documented in a data collection effort directed at coordination of quality parameters significant to eutrophication by Cunningham and Pine in 1966 and reported in Cunningham and Pins (1969). Since 1966, there has been an increasing concentration of investigations leading to Bishop and Lee (1972) and, finally, Soltero (1973). The Soltero investigation is ongoing and is scheduled to report again in 1974. In addition to individual investigations, the Department of Ecology is maintaining five monitoring stations on the Spokane River and one on the Little Spokane River which are normally sampled twice a month.

The concern for water quality in natural lakes is increasing as the few lakes within commuting distance of Spokane are subjected to residential development. There was little data prior to the Department of Ecology efforts which began in 1968. There are unpublished data on identification of lake biota from the 1930's that may prove useful for estimating water quality prior to lakeside development.

The fundamental basic source of water quality data since

1941 has been the annual publication of the U.S. Geological Survey. For the Study Area, the available USGS records for three stations go back to 1959.

<u>Groundwater Data</u>. There has not been the impetus for intensive new quality studies of groundwater in the Study Area similar to those for surface water. Recognition of the fact that there could be a potential for pollution from surface waste disposal in the highly permeable primary aquifer lead to the report by Crosby (1971). However, this report does not contain additional groundwater quality data since the investigation employed another approach to the problem. There is currently under way a study of the potential for contamination of groundwater in the basalt aquifer by Ernest Gilmore of Eastern Washington State.

Consequently, the available groundwater data are largely of the routine type which report the chemical constituents normally associated with a public health evaluation of drinking water. There has not been specific wide ranging programs for parameters which might be indicative of pollution from senitary, industrial or agricultural waste sources. Bacteriological data have been gathered routincly under the requirements of state law for sampling public water systems. Unfortunately, these data are not summarized or published.

The STORET System

<u>General</u>. In an effort to make all water quality data readily available, the Environmental Protection Agency has established

the STORET data storage and retrieval system. When fully implemented this system is proposed to be the repository of all significant water quality data, continuously kept up-to-date. At present, the system is too new to be fully implemented and its utility must be supplemented by additional data searches. The system is, however, a major repository of data organized for retrieval and is selected as the basic source for this search.

Two printouts from STORET have been obtained. The first printout is the inventory of stations and parameters. The second printout is of selected raw data based on the indicated availability in the inventory.

Other sources of data canvassed to supplement and check the STORET data are:

- 1. Published Reports.
- 2. Request to Department of Social and Health Services for unpublished data.
- 3. Request to Washington Water Power for unpublished data.
- 4. Request to USGS for data not yet put in STORET.
- Request to DOE for data from their ongoing monitoring program.
- 6. Request to Inland Empire Paper for records of their effluent quality and quantity.
- 7. Request to City of Spokane for records of sewage treatment plant effluent quality and quantity.

The STORET Data Source. The Station Inventory Printout

lists the points at which water quality data are available, the parameters measured and the period of record. In addition to listing the parameters measured, the inventory also gives the number of observations, their mean, variance, standard deviation, coefficient of variability, standard error, and the maximum and minimum value. See

sample page, Appendix I.

The location is identified in several ways:

- 1. There are station numbers assigned by the agencies which entered the data. There appear to be only three agencies which have inserted data, namely USGS, DOE and EPA. Each has its own numbering system.
- 2. The latitude and longitude are given.
- 3. There is a word description.
- 4. And for stations on rivers and streams, the river mile is generally given.

More than one agency can and does put in the same data as another agency. The printout is categorized by originating agency and there is one page or group of pages per station per agency which has put in data. There has been no attempt to eliminate duplicate data. And, in spite of all the alternative station identifiers used, it is frequently very difficult to identify duplications by inspection of the inventory. Except where the identifying numbers of both agencies are given and are identical, it may not be possible to identify a duplication because the word descriptions, latitude and longitude and river mile identifications used by the various agencies may not be identical. Only a line by line comparison of the analytical data will confirm the identity in some cases.

There is no sorting program available that will give the consolidation of data from all agencies for any particular point and eliminate duplications. The data is available only as input by each agency.

The primary source of duplications appears to be between

assignment at an about of a the street of a street and

USGS and DOE. USGS policy is to put in only data that they have analyzed including joint operations with other agencies like DOE. DOE also puts in data from their joint operations with USGS, usually at a much earlier date than USGS. The Corps of Engineers apparently has made no input to STORET in Washington or Idaho. There are a very few special inputs.

After examination of the Storet inventory printout, it is possible to make a selective order of raw data.

One of the physical limitations of the raw data printout is that it is arranged to print on each page not more than 10 columns across, one per parameter, with the date of observation and parameter values vertically. See sample page, Appendix II. This limitation of 10 parameters per sheet requires either a bulky printout or a limited selection of parameters. There are large numbers of parameters because of the variations in methods of reporting some parameters in addition to the fact that a very broad spectrum of constituents have been sampled.

Surface Water Data from STORET. A faw data printout in river mile order was obtained for the parameters listed in Table 1. Table 2 lists the other available parameters that were not ordered. Table 3 lists the surface water stations for which water quality is available in STORET and the period of record. Table 3 includes identification of common stations from various input agencies.

<u>Groundwater Data from STORET</u>. For groundwater quality, a raw data printout was ordered organized by the geographical areas shown in Figure A. The purpose of this arrangement is to collect those wells and the second of the second states and the second s

in the Study Area which are in the primary Spokane Valley aquifer within the designated areas 2, 3 and 4 and to collect all other wells in the Study Area in designated area 1. Similarly, designated area 5 is to collectuall the wells in the extension of the primary aquifer into Idaho's Rathdrum Prairie and other Idaho wells in area 6. The data received indicates that no groundwater quality data for areas 1, 5, and 6 has been placed into the STORET data files. The parameters requested for groundwater are shown in Table 4.

STORET Printouts. The above described water quality data from STORET is available as computer printout and is made a part of this report by reference. The documents are as follows:

Kennedy-Tudor File Number	Description
D-367-19	STORET DATA, Inventory
D-307-16	STORET DATA, Ground Water Quality Data, Springs and Wells
D-307-17	STORET DATA, Spokane River from Mouth to Post Falls, Idaho
D-307-18	STORET DATA, Surface Waters above Post Falls Dam
D-307-19	STORET DATA, Surface Waters within Washington other than Sockape River.

Data from Published Reports

Tables 5 and 6 list published reports studied to see if the water quality data contained therein was already in STORET or whether it was supplemental to STORET. Table 5 concerns surface water data

and Table 6 covers groundwater data. Where supplemental data are indicated in Tables 5 and 6, this data is incorporated into the summary Tables 8 and 9 and the stations are mapped on Plate 307-1 except where otherwise noted.

ر مايند المرين الماين المريخ المريخ

Since certain of these published reports contain, in addition to the referenced water quality data, interpretive data of significance, abstracts for selected reports have been prepared for reference.

All published USGS data is in STORET.

Data from State Department of Social and Health Services (DHSH)

The request to DSHS revealed that they have two primary sources of unpublished data. One is a file of chemical quality data and the other is a file of bacteriological test data. Neither of these files has been summarized for the Spokane study area. The data are in a completely raw state.

The chemical quality data for Spokane County consists of approximately 500 laboratory report sheets, each for a single sample. The sheets are unorganized as to location or date. The locations or systems to which the sample applies are difficult to identify in many cases. The paramete s tested for typically are as follows:

а.	Silica .	h.	рН
b.	Iron	i.	Conductance
с.	Manganese	j.	Color
d.	Calcium	k.	Odor
8.	Magnesium	1.	Taste
f.	Sodium	m .	Free CO ₂
g.	Potassium	Π.	Bicarboñate

nr ĊА a CO, arboñate

).	Carbonate	
).	Sulfate	
•	Chloride	
	Fluoride	
3.	Nitrate	

t. Nitrite
u. Phosphate
v. Total Solids
w. Total Hardness
x. Alkalinity

Copies of the DSHS chemical analysis reports for the years 1970, 1971 and 1972 for Spokane County have been obtained by making copies of the unsorted file in the Seattle Office of DSHS. These data are available in Kennedy-Tudor files. None of these data are in STORET. No attempt has been made at this time to classify or analyze this mass of data. The locations of the wells for which the data exists are not included in the plot on Plate 307-1.

A sample of the chemical analysis report sheet is included as Appendix III.

Similar chemical water quality data are available, sorted by counties, for Whitman, Lincoln, Stevens and Pend Oreille Counties. There are a total of about 400 sheets for these four counties together, only part of which would be in the Study Area.

Since the sources of these samples taken by DSHS are the public water systems, and since practically all public water supply systems in the area are from wells, these data are all essentially of groundwater quality.

The DSHS file of bacteriological tests are likewise from public water systems and, as stated above, are essentially groundwater samples. The samples may be taken from any location in the public water system and may or may not be indicative of the bacteriological quality of the groundwater source. Only samples taken at or in the

immediate vicinity of the well head prior to chlorination, if any, could be considered as exclusively representative of groundwater quality.

The bacteriological tests are made in numbers and frequencies called for in WAC 248-54-430 which range from 2 per month for systems serving less than 2400 persons to 150 per month for systems serving 200,000 persons. Since there are 84 water systems in Spokane County listed in the DSHS Water Facilities Inventory, these bacteriological tests are extremely numerous.

The results are reported as "satisfactory" or "unsatisfactory." Unsatisfactory is broken down into the levels represented by the five test dilutions and are given as 2.2, 4.4, 8.8 or 16. A positive indicator for dilutions beyond 2.2 is classified as unsatisfactory. Refer to sample analysis report sheet included as Appandix IV.

Neither a record nor a summary of results of bacteriological tests is maintained at State level. The tests are all run at the State laboratory in Seattle. It is our understanding that there is no record of these results except in the form of the individual slips of paper reporting each test result. There is no register or file of letters notifying the operating agency of an unsatisfactory test. There are three copies of the test result, one is returned to the area DSHS office, one is returned to the system operator and one is sent to the County or District Health Department. The DSHS laboratory keeps a record only of the test number and result without regard to system

identification or location. The file is by test number only.

The only level at which a summary or analysis can be made is at the local level DSHS office or the County Health District, each of which receives a copy. A copy of such a tabulation has been obtained from Spokane County Health District for the year 1972. A copy of this table is included as Appendix V. Those systems that provide chlorination have been marked. Where the systems are not chlorinated, a lack of "unsatisfactory" results may be interpreted as satisfactory with regard to source. Where there are "unsatisfactory" results, there is no way of knowing whether this was due to source contamination, system contamination or sample contamination.

None of this bacteriological data is in STORET and none is plotted in Plate 307-1.

Note that the definition of a "public water system" apparently does not include schools with an individual well supply system since no bacteriological tests are routinely taken of these systems of which there are a significant number. Refer to the section reporting existing water systems.

Data from Washington Water Power (WWP)

At an interview with WWP employees on September 10, 1972, a request was made for water quality data held by WWP and not available elsewhere. The request was answered as follow.

- 1. WWP has some data for 1972 on Long Lake that is available. WWP is continuing the monitoring in 1973.
- 2. WWP has some bottom sediment samples from spring of

1973 for Nine Mile Reservoir.

3. The power house log at Long Lake Dam records water temperature each day. These temperature data are not summarized anywhere. To get them would mean recording each day from a separate log sheet.

The 1972 data on Long Lake have been received and consist of dissolved oxygen and temperature data at six locations and at 5 foot depth increments at 16 different dates between June 13 and October 16. (File D-307-2)

It is not proposed to abstract the daily temperature records from the Long Lake power plant records except to the extent that it is necessary for calibration of the simulation model.

Data from USGS

A request was made to USGS for groundwater quality data that was neither on STORET nor published in a water supply paper. Three groups of data were received. The first group consists of groundwater quality analysis for 18 stations that are being monitored in an ongoing study. This data will eventually be entered into STORET. The second group of data is 1970 chemical analysis of 2 wells, numbers 24/41-23K1 and 27/41-26Q2. The two wells lie, respectively, south and north of the main aquifer.

In addition, USGS has supplied a partially completed inventory of wells located within the main aquifer. USGS is updating their inventory at wells as a part of their ongoing project with DOE to hydraulically model the Spokane Valley Aquifer.

Shine Marine and

Data from Inland Empire Paper Company

Inland Empire Paper Company monitors their effluent waste flow daily. In addition to the average daily flow, the following water quality parameters are reported:

<u>Parameter</u>

<u>Units</u>

Pounds Per Day

Biochemical Oxygen Demand Suspended Combustible Solids pH

Pounds Per Day Maximum, Minimum and Average

Temperature

Degrees F, Maximum, Minimum and Average

Files of these data have been obtained for the period January 1972 to June 1973. Subsequent to April 1972, periodic tests were made for zinc content of the plant raw water supply, plant effluent and the Spokane River.

Data from City of Spokane on Sewage Treatment Plant

As part of the normal operation of the City of Spokane Sewage Treatment Plant, certain water quality parameters of the plant effluent are monitored. The parameters monitored are as follows:

Parameter	Frequency of Observation
Dissolved Oxygen	5-10 Day Intervals
Biochemical Oxygen Demand	2~5 Day Intervals
рH	Daily
Suspended Solids	Work Days
Chlorine Residual	Daily
Fotal Coliform	4 Per Month, Average
ecal Coliform	4 Per Month, Average

Also available is the total daily discharge in millions of gallons per day.

These flow and quality data for the period April 1972 to April 1973 are shown in the section of this report on waste source. The data for other time periods are available in the treatment plant records.

The City does not make any observation of receiving water quality either upstream or downstream from the sewage treatment plant outfall.

None of the City data are in STORET.

Summarization of Available Surface Water Quality Data

All locations for which surface water quality data are available are listed in Table 8 and shown in Plate 307-1. This listing includes all sources found and assigns to each location a number, described in Table 8 as the K-T number, which is used as the identifier in Plate 307-1.

The kind of data and the span of time represented by these data are shown for each location in Table 8. Rather than identify each individual quality parameter, these numerous parameters and their variation have been grouped into seven categories as shown in Table 7. If a minimum number of parameters from a category as shown in Table 7 are available for a location, that category is listed as covered for that location in Table 8. Coverage is indicated by listing two dates covering the span of time from the earliest to latest reporting of

the covered parameters. Note that the two dates do not imply a continucus record between the dates indicated, or that all parameters are available over the indicated span.

The order of location listing in Table 8 is by river mile, first for the Spokane River, followed by the Little Spokane River, Hangman Creek and Chamokane Creek. Lakes and waste sources are shown last.

The sources of water quality data are shown in Table 8 in several ways. In the first column after the description, there is a numerical reference to the list of sources included at the end of Table 8. The column to the right of the quality categories headed "Total Indicated Record in STORET" provides a quick indication of whether all the data indicated for a particular location is in the STORET source or whether supplemental sources must be consulted. Where there is a "NO" in this column, the space to the right headed "Source of Elements Not in STORET" indicates the source that should be consulted for the elements not in STORET. For example, at K-T 24, the time span dates are 12-16-65 to 9-13-72 for three categories and 3-26-66 to 9-13-72 for another; followed by the indication that all data are not in STORET and the note "Soltero 5-6-72/3-15-73." This means that the older deta are on STORET but that the data between 5-6-72 and 3-15-73 must be sought from the Soltero reference.

The most important published sources not represented in STORET are Bishop and Lee (1972), Condit (1972), Cunningham and Pine (1969), Funk (1973) and Soltero (1973). Cunningham and Rothwell (1971)

and Todhunter and Cunningham (1972) are all in STORET.

1 22 34 Barren Barren San and Barren Barren Barren Barren Barren Barren Barren Barren Barren Barren Barren Barr

Under remarks, the most common information shown is a cross reference of the location and description shown in Table 8 to the identification used in the applicable reference. Using the same example above of K-T 24, the note "Soltero # Seven Mile" means that the station identified as K-T 24 on Seven Mile Bridge is the same location as Soltero's "Seven Mile" or S.M. as he abbreviates in his tables.

Also under "Remarks," locations corresponding to the sampling and analysis program for simulation model calibration are shown by the station number with the identifier K-T S&M. The data being produced by this... program are not indicated in Table 8. Refer to the section of this report devoted to reporting the results of this sampling and analysis program.

The dita availability indicated by reference to Soltero (1973) require special explanation. The published report, Soltero (1973), contains a Table V on pages 17 and 18 that lists the range and mean values for 24 parameters at six river locations for the period May 6, 1972 to March 15, 1973. The referenced report does not contain the individual observations on which Table V is based, these data being unpublished to date. Table 8 herein indicates Soltero (1973) as the source of this data whereas the raw data is actually unpublished. It is our understanding that specific requests for the raw data may be addressed to Dr. Soltero at Eastern Washington State University.

From a geographic standpoint, there is intensive coverage of the Spokane River from Long Lake Dam to Post Falls, Idaho. Gaps between sampling points are three miles or less. From Long Lake Dam to the Columbia River confluence, the spacing is 4 to 10 miles.

The Little Spokane River is well covered from the confluence with the Spokane upstream to Mead. Above Mead there are only four sampling points. Hangman Creek is devoid of water quality sampling except for two stations near the mouth. There are no sampling points on any other branch of the three main streams except for one on Chamokane Creek near Ford, Washington.

Only three natural lakes are significantly sampled, Newman Lake, Liberty Lake and Diamond Lake. Minor data for one date are available on Medical and Silver Lakes. There are no data for other lakes, the most significant of which are the chain of lakes on the west branch of the Little Spokane River.

Considering the water quality categories in combination with geographical location, the availability of data are summarized as follows:

On the Spokane River:

A DATE AND AND A DATE

Standard Tests: None available below Long Lake Dam. Well covered from Long Lake to Post Falls.

Nutrients: Well covered with 1971 and 1972 data for full length.

Oxygen Balance: Well covered for full length.

Heavy Metals: None available below Long Lake Dam. Light recent coverage from Long Lake Dam to Spokane Dam. Good recent coverage from Spokane Dam to Post Falls.

Bacteriological: Thin coverage for entire length. None below City STP until Nine Mile Dam.

- Biological: Only one location covered below Long Lake Dam. Long Lake well covered primarily by Soltero. Sparse in both location and intensity from Long Lake to Post Falls.
- Pollutants: Only one location below Long Lake and none in Long Lake. Sparse coverage from Nine Mile Dam to Post Falls. About half the available data is from 1966.

「ないちょう」というたいのできょう

On the Little Spokane River:

Practically all available data on the Little Spokane River is from Burkhalter, Cunningham and Tracy (1970) which reports analyses made in 1968. This report provides Standard Tests, Nutrients, Oxygen Balance and Bacteriological data for each of the Little Spokane locations and provides Biological data for all but three locations. Heavy metal data are available from other sources for three locations at and below Dartford. There are no Pollutants data.

On Hangman Creek:

Starte Barren same Bassing & Bauses

There are only two locations on Hangman Creek for which water quality data are available, one at the mouth and one five miles upstream. The station at the mouth has 1972-73 data for all categories except Biological. The upstream station has Standard Test data only for a period in 1968.

On Chamokane Creek:

There is only one location with Standard Test data only for a period in 1968.

Liberty and Newman Lakes:

Only Standard Tests and Nutrient data are available for a period in 1971. There are no Oxygen Balance, Heavy Metals, Bacteriological, Biological or Pollutant Bata.

Diamond Lake:

There are Standard Tests, Nutrients, Oxygen Balance,

and Biological data primarily from Bishop (1973). There are no Heavy Metals, Bacteriological or Pollutants data.

West Medical and Silver Lakes:

Bishop (1969) provides only temperature, pH, conductivity and Dissolved Oxygen for a single date in 1968.

Surface Water Quality Data Needs

and the second state of th

In order to evaluate data gaps, it is necessary to es-

tablish the quality data needs with respect to:

- 1. Parameters.
- 2. Geological Locations.
- 3. Distribution in Time.

First, considering parameters, the needs for this specific

water management study give highest priority to the following:

- 1. Temperature.
- 2. Elements of the oxygen balance, DO, BOD, COD.
- 3. Total dissolved solids.
- 4. Nutrients, primarily NO₃, NH₃, and Ortho-P.
- 5. Total and Fecal coliforms.
- 6. Heavy metals, primarily zinc.
- 7. pH.
- 8. Chlorides.
- 9. Surfactants.
- 10. Oil and grease.

In addition to the above, chlorophyll A and Zooplankton data

are needed for major man-made impoundments and natural lakes. Next, considering geographic location, the minimum needs are to define present quality at the following locations:

On the Spokane River:

Upon entering the Study Area and representative of the river downstream to where the first major point source

enters, in this case, upstream from Inland Paper.

Upstream from where city storm drains and sewer outflows begin; that is, approximately at the east city limits.

Immediately upstream from the confluence of Hangman Creek.

Below Hangman Creek confluence but upstream from the City of Spokane sewage treatment plant outfall.

Below the STP outfall but above the Little Spokane confluence.

In Nine Mile Reservoir. Below Nine Mile Reservoir.

In Long Lake.

Immediately below the Little Spokane Confluence. Selected locations throughout the length of the lake and at various depths.

Below Long Lake Dam.

In Little Falls Reservoir.

Below Little Falls Reservoir at entrance to the backwater formed by FDR Lake.

Cn Hangman Creek.

Immediately above the mouth.

At least one upstream location beyond the urban development area.

On the Little Spokane River.

Immediately above the mouth.

Upstream from the groundwater inflow from the primary aquifer, around Dartford.

murstell stores

One tributary from the Selkirk mountains.

One tributary from the West, Dragoon Creek.

On the major natural lakes.

Newman Liberty Diamond Eloika Sacheen Medical West Medical Silver

Finally, considering distribution in time, the primary need is for representation over a full year cycle under the most current conditions. It is also desirable to have concurrent observations of conditions throughout the basin to obtain data on the interrelationships from point to point. For lakes which have considerable pollutional inertia, it would be desirable to have long term, year long, records of such key parameters as nutrients and dissolved oxygen.

Surface Water Quality Data Gaps

Comparing the foregoing needs with the availability, the most important data gaps are as follows:

Spokane River

The presence of heavy metals, particularly zinc, is well established as the Spokane River enters the Study Area. More recent data at representative locations from Spokane Dam downriver to Long Lake Dam is needed to determine if the metal levels persist through this reach year round.

Bacteriological data at regular time intervals is needed throughout the reach from the State line to Long Lake Dam to permit a statistical evaluation of the time-duration of excessive levels. This is particularly applicable to the reach from Trent to Nine Mile Dam. Note the absence of data below the City STP to Nine Mile Dam.

Year round recent data for pollutants such as surfactant, oil and grease, pesticides is needed from Trent to Nine Mile Dam.
Little Spokane River

The primary need is for more recent data for all parameters that have been measured plus pollutants that have not been measured. An updating program could use a year round program of the parameters listed under needs above at the following locations:

- 1. Near mouth.
- 2. At Dartford.
- 3. On the Deadman Creek tributary.
- 4. On the Dragoon Creek tributary.
- 5. One each on the east and west branches near where they join.

Hangman Creek

which received which is

and the second second second second second second second

The primary need is for data upstream from the urban development area to evaluate the impact of that development. A location at or above the California or Rock Creek confluence would be appropriate.

Chamokane Creek

Although this stream drains an area with a low level of development, there is a need for at least one series of tests for a broader spectrum of pollution parameters than presently available to evaluate the stream.

Deep Creek

There are no data at all for this tributary which enters the Spokane River above Nine Mile Dam. It drains an area for which there are no representative data. A minimum program analysis for one location near the mouth would fill this gap.

Liberty and Newman Lakes

These two lakes are the two most subject to developmental pressures. The presently available data stops far short of that needed to evaluate the present condition of these lakes. The data needs to be expanded to include oxygen balance and biological parameters at various depths and locations and to include bacteriological and pollutant categories.

and a subscription of the set of a set of a set of the set of the set of the set of the set

ちょうちょう いろう いちない ちょうちょう ちょうちょう ちょうちょうちょうちょう ちょうちょう

Medical, West Medical and Silver Lakes

West Medical and Silver Lakes are described by Lee (1969) as being alkaline and eutrophic. Presumably Medical Lake is similar. These conditions require documentation beyond the minimal data shown in Lee (1969) and USGS (1971).

Diamond, Eloika and Sasheen Lakes

These lakes are less subject to developmental pressure. Only Diamond Lake has been studied significantly, Bishop (1973). Corresponding studies of Eloika and Sasheen are needed as a minimum.

Waste Sources

alite the start is additional and the show internet whether the

Spokane STP. The STORET data covers the period from 9-12-72

to 9/20/72 only. The specific parameters covered are:

<u>Parameter</u>	<u>Number of Observations</u>
Temperature	17
BOD	4
Conductivity	2
DD	17
DH	14
Total Hardness	2
Nitrata	-
Kieldebl N	± 1
Totel B	1
Ortho D	+
Posidus Dies 105	1
Restude, Diss 100	4
recar corriorms	1
	1
	1
Ladmium	Ţ
	5
Residue Total NFLT	5
Kesidue Settleable	4
lotal Coliforms	17

These data from STORET are so meagre and for such a limited time period that they provide little to supplement the City records which are far more extensive and complete for the fundamental para-

and the second

meters of BOD, DO, Temperature, Suspended Solids and Coliforms. The STORET data does not fill the gaps in city data which are the nutrients, heavy metals, oils, surfactants, and pesticides.

The Soltero (1973) data which covers a period from 5-6-72 to 3-15-73 has excellent coverage of all the parameters of interest except oils, surfactants and pesticides. Soltero (1973) does not duplicate the parameters that are routinely well covered by the City's monitoring. Therefore, between Soltero (1973) and the City there is adequate coverage for the 1972-73 period excepting oils, surfactants and pesticides.

<u>Inland Empire Paper Company</u>. The STORET data is limited to the period from 9-11-72 to 9-14-72 and covers the following parameters:

Parameter	<u>Number of Observations</u>
Temperature	3
BOD	3
Conductivity	3
DO	3
Total Hardness	2
Ammonia	1
Nitrate	3
Kjeldahl N	3
Phosphate	3
Fecal Coliform	3
Lead	3
Mercury	3
Cadmium	3

The only other data except the Company's own monitoring is from Cunningham (1968) which does not reflect current operations. The Company's daily monitoring gives complete coverage for BOD and suspended combustible solids. The primary data gaps for this waste source are COD and nutrients over an extended period. In addition,

Chine Lives

and a submission of the second s

a full broad spectrum analysis should be made to be sure there are no pollutants being overlooked. This broad spectrum should include sulfite, all of the metals, surfactants, oils and pesticides.

<u>Kaiser #1, Kaises #2, Spokane Industrial Park and Hillyard</u> <u>Processing</u>. These four major dischargers to the Spokane River are represented only by the data for 9-11-72 to 9-20-72 contained in STORET. The parameters covered are as follows:

Number of Observations

			Spokane	Hillyard
<u>Parameter</u>	<u>Kaiser #1</u>	Kaiser #2	Ind. Park	Processing
Temperature	3	3	4	3
BOD	2	2	4	3
Conductivity	2	2	3	3
DO	3	3	16	3
рH	-	-	13	-
Total Hardness	4	2	2	2
Chloride	1	-	-	1
Total Nitrate	3	2	2	3
Ammonia	-	-	1	1
Kjeldahl Nitrate	2	1	2	3
Total Phosphorus	3	2	2	3
Fecal Coliform	3	3	16	3
Ortho Phosphate	1	-	-	-
Lead	5	2	2	3
Mercury	4	2	2	3
Aluminum	4	2	-	2
Cadmium	5	2	2	3
COD	3	2	5	3
Residue Total NFLT	3	2	6	3
Total Coliform	3	3	16	3
Residue Diss 105		-	4	-
Residue Settleable	-	-	4	-

There are no other data available for these waste sources.

In addition to the gap inherent in the short period of time represented by the above listed test, there is a gap in parameters for oils, surfactants and pesticides.

Summarization of Groundwater Quality Data

A Marine Strate Barrier

לילים לי היציגלות על לעביצ לעביר איניים

Construction of the second second second second second second second second second second second second second

Divisions of the Study Area. The study area has two aquifers of major interest to present water supply, namely the primary Spokane Valley aquifer (hereafter referred to as the "primary aquifer") and the "basalt aquifer." There are a number of other aquifers of lesser importance which, for the purpose of water quality summarization are herein referred to as "other aquifers." Refer to the section Geology and Groundwater for detailed descriptions of these aquifers. A grossly simplified summary description follows.

The outline of the primary aquifer is shown on Plate 309-3. It consists of the gravel filled valley through which the Spokane River flows from the Washington-Id ho boundary to the confluence of the Little Spokane River. The flow of the groundwater through this aquifer is from east to west and the primary source of water is in Idaho. There is interchange of surface and groundwater as the Spokane River flows through the aquifer. In general, at average flow and less, the river looses to the aquifer between the Idaho border and Greenacres and gains from the aquifer throughout the remainder. At higher river stages, the section which looses to the aquifer increases in length and quantity.

The basalt aquifer covers the study area south and southwest of the Spokane River below the Hangman Creek confluence and includes much of the Hangman Creek tributary area. This area is delineated on Plates 309-1, 2 and 3. The basalt aquifer consists of horizontally bedded layers of basalt (ancient lava flows) interlayer with relatively impervious siltstone known as the Latah formation.

The major elements of the other aquifer category are the gravel deposits in the valley of the Little Spokane River and its tributaries and the Chamokane Creek. There are also isolated wells in rock formation which predominate in the highlands of the northeast parts of the study area.

The availability of groundwater quality data is discussed in terms of its availability within each of these three main aquifer classifications.

Before making the breakdown summaries by aquifer, the groundwater quality data sources for the entire study area are discussed and a total inventory of quality data for the study area is developed and presented in Table 9.

Columns indicating the location of each well relative to these three aquifer classifications are shown on the total quality inventory of Table 9. Tables separating the wells by aquifer are discussed after the description of study area sources.

STORET contains groundwater quality data for 4 springs in the area. One of these is the Fish Hatchery Springs which is included in the USGS-EPA ongoing study. STORET is the only source of data for the other three springs. These springs were all sampled once by EPA for a wide spectrum of parameters and should be classified as Group II data sources.

<u>Availability from STORET</u>. STORET contains groundwater quality data on 41 wells in the study area. Of these 41 wells, the data for 21 are significant with respect to the breadth of coverage of parameters reported and that data are available for more than one time. The remaining 20 wells

an an interestion with the set of the set

have data for only one time, with minor exception, and for a list of parameters usually limited to the "standards" list as shown in Table 7.

All of the groundwater quality data in STORET is for the primary Spokane Valley aquifer, with the exception of one well in the Little Spokane Valley aquifer near Mead. There are no data in STORET for the basalt aquifer. See discussion below on the aquifers in the study area.

Sources of Data in STORET. All data in STORET appear to be from published USGS sources, except that there are a few recent entries for which a published source has not been identified. The three published sources which provide practically all of the data in STORET are Weigle and Mundorf (1952), Van Denburgh and Santos (1965), and Cline (1969). Discussions below will show that not all the data available in these publications has been transferred to STORET. There are some entries that do not have the USGS well identifier number.

Availability of Data from Published Sources. The publications listed in Table 6 were canvased for groundwater quality data. Only the three publications referred to above as sources for STORET were found to contain data. These three published sources contain water quality data for 226 wells in the study area, including wells that are inside the primary aquifer and wells in basalt and other aquifers. These 226 wells and the available data and source are listed in Table 9 in order of the USGS identification number which, inherently, also gives location.

The availability of water quality data is shown in terms of the parameter categories defined in Table 7 except that the inapplicable categories are omitted and a new category is added to describe a special limited group of parameters as discussed below.

Earlier investigations such as Weigle and Mundorf (1952) and Van Denburgh and Santos (1965) usually included nitrates in their analyses but rarely included phosphates. The category "nutrients" being used herein for these two parameters is a misnomer as far as these early investigations are concerned since they were not looking for "nutrients" but were interested in nitrate (and/or nitrite) as related to the public health concern for methemogobinemia (blue baby).

Weigle and Mundorf (1952) is the source of data on 140 wells listed in Table 9. Of these, all but 22 have water quality data limited to the following four parameters: chlorides, total hardness, conductivity and alkalinity. Furthermore, these parameters were sampled and tested only once and all were in the period May - June 1951. This limited group of parameters is placed in a special category on Table 9. For 22 wells a wider spectrum of parameters is reported, being essentially the full set of the "standard" parameters listed in Table 7 plus nitrate for most. Also the dates of analysis for these 22 are not restricted to May - June 1951. In general the wells with limited parameters are not in STORET whereas the wells with a wider spectrum of data are included.

Van Denburgh and Santos (1965) is statewide in scope. Within the study area, data are included for wells in both the primary Spokane Valley aquifer and in the basalt and other areas. Thirty-seven wells from this source are in Table 9. Twelve of these wells are the same wells covered by Weigle and Mundorf. The spectrum of parameters reported in Van Denburgh is a complete set of "standard" tests per Table 7 plus nitrates and orthophosphates. Only part of the Van Denburgh and Santos (1965) data appears to be in STORET.

Cline (1969) covers north central Spokane County and southeastern Stevens County, the coverage being entirely with the study area. Cline (1969) reports on 41 wells both inside the primary Spokane Valley aquifer and those outside in basalt or other aquifers. Twenty-three analyses are for a single date of sample collection and the parameters reported are the "standard" list per Table 7 plus nitrates and phosphates in many croses. The analyses of the remaining 18 wells are of the very limited type reporting only hardness and specific conductance. STORET appears to contain most of the Cline (1969) data for wells within the primary aquifer but none of those outside.

<u>Unpublished Sources of Data</u>. There are two sources of unpublished groundwater quality data. The first is USGS who were able to provide chemical data on a total of 16 wells and 4 springs. The data for all except two miscellaneous wells are the result of the ongoing USGS-EPA program.

The USGS-EPA ongoing groundwater monitoring program is being carried out by USGS in conformance with criteria established by EFA. The program will run from June 1973 to June 1974 and will consist of 4 samples taken at 18 locations. The samples are being analyzed for the parameters listed in Table 10. Three sampling cycles have been completed. The wells and springs to be sampled are also listed in Table 10 and are plotted on Plate 309-3.

The locations were selected to meet the goals as indicated by the categories below:

Group	Purpose	Sample	Points
A	To sample aquifer quality as it discharges from springs along the Little Spokane River	26/42 26/42 26/43 26/43	11J1 (s 12A1 (s 7B1 (s 5L1 (s
В	To sample the aquifer dis- charge to the Spokane River in the gap between the falls and Shadle Park	25/42	1 3 B1
С	To sample a cross section of the aquifer in the vicinity of Park Rd. in East Spokane	25/44 25/44 25/43 25/44	19D1 18D2 13A1 7C1
D	To sample a cross section of the aquifer as it enters Washington	26/45 26/45 26/45	35F1 36N1 36Q1
E	To sample the possible effect of the Indian Trails (City) sanitary land fill	26/42	27N1
F	To sample the demolition waste disposal sites in East Spokane	25/43	14K1
G	To sample wells in a heavy industrial area, Trentwood	25/44 25/44	1J' 2Q.
Η&Ι	To sample the possible effect of the County land disposal site at Greenacres (recently made inactive)	25/45 25/45	16K1 15D1

Both the USGS-EPA ongoing locations and the two miscallaneous locations are included in the total groundwater quality inventory of Table 9.

いたいないのないの

The second unpublished data source is the DSHS chemical and bacteriological files described previously. Neither of these files is in STORET and the data availability is not inventoried herein in Table 9.

Study Area Summary. As described above, the available groundwater

quality data are summarized for the entire study area in Table 9, arranged in order of USGS number. In addition to showing the data availability by category per Table 7, Table 9 indicates the following:

- 1. Whether the data is available on STORET
- 2. If data is not on STORET, the other data source
- 3. The location of the well by aquifer
- 4. The geographical location of the well, inherent in the USGS number
- 5. An indication of the importance of the well as a water producer by symbol identifying those producing more than 5 million gallons per year.

The locations of the wells listed in Table 9 are shown on Plates 309-1, 309-2 and 309-3.

Available Data in the Primary Aquifer. The wells within this aquifer for which significant water quality data are available are listed in Table 11 and 12 and are located on Plate 309-3. Tables 11 and 12 do not list all wells for which water quality data are available, only those regarded as significant. For example none of the wells with "limited" data are listed.

Tables 11 and 12 categorize the significant source further into Group I data and Group II data respectively. Group I data is defined as at least standard tests plus nutrients and more than one test. All of the USGS-EPA ongoing series fall in this category since they include standard, nutrient, metal and pollutant parameters. Group II is defined as having at least one parameter category other than "limited" for a single date.

Of the 37 wells and springs listed in Table 11 having Group I data,

only 12 have data prior to 1970. Wide spectrum analysis in general is represented predominantly by the more recent studies. By comparison, of the 29 wells listed in Table 12 having Group II data, 26 are prior to 1970.

The USGS-EPA ongoing program consisting of 14 wells and 4 springs provides 15 listings in Table 11 that are entirely dependent upon that source and only 3 that are represented by another data source. Therefore, approximately 40 percent of the presently available wide spectrum analysis data are dependent upon this ongoing program.

Data Gaps for the Primary Aquifer. The following factors are considered in evaluation of data gaps for the primary aquifer:

1. Parameters reported

to be the second and the second state of the second state of the second state of the second state of the second

- 2. Time period of record
- 3. Geographical location
 - a. Relative to total area of the aquifer
 - b. Relation to flow direction of the groundwater body
 - c. Relation to the interchange with surface waters
 - d. Relation to location of surface disposal of pollutants

4. Coverage of major water producing wells

5. Possible affect of rate of withdrawal on quality samples Parameters Reported

The USGS-EPA ongoing program provides the widest available spectrum of parameters. The coverage in the standard, nutrient and metals categories is adequate. Only phenols and detergents are reported in the pollutants category and no bacteriological tests are made. Since none of the other sources report pesticides from the pollutant category, this absence constitutes a data gap. Due to the unsummarized condition of bacterial testing by DSHS, bacterial testing is also a data gap.

Barren warden and have a ward a second that an ince a shore

Time Period Reported

The primary interest is in existing conditions as far as absolute values are concerned but there is also an interest in trends which the present absolute values may not indicate. Twenty-eight of the 37 Group I sources are recent data representative of current conditions. Only 11 of the Group I sources go back 10 years or more but 25 of the Group II sources are 10 years old or more. Therefore, there is good recent coverage of a broad spectrum of parameters but there is good historical coverage only of the standard tests which dominate Group I.

The high rate of flushing of this aquifer indicated in the section on Geology and Groundwater probably reduces the potential for accumulation of pollutants. Hence, the difference, if any, between historical and current observations would be a measure of transient change rather then permanent long term accumulations.

From a time standpoint the data gap is for historical data on phosphates, metals and MBAS substances.

Geographical Location

Refer to Plate 309-3 on which groundwater quality locations are plotted for the primary aquifer. Four symbols are used to indicate class of data available at the locations:

- 1. Group I data from studies other than USGS-EPA ongoing program
- 2. USGS-EPA ongoing station (some of this also has data from previous studies, see Table 11)
- 3. Group II data
- 4. Limited chemical data

Considering the aquifer as a whole, the coverage of Group I data ` (which includes USGS-EPA ongoing) is absent or thin in the following locations:

- 1. North of the river from the Industrial Park to Otis Orchards
- 2. South of the river in the Dishman Opportunity area
- 3. Throughout the service area of the City of Spokane water system and north of the City to the Little Spokane

The direction of aquifer flow, the location of surface water interchange and relation to potential percolation of pollutants are considered together. Refer to the following plates in other sections of the report for delineation of these factors.

- Plates 303-28 to 35 from the section on Geology and Groundwater for groundwater surface contours indicating direction of flow.
- 2. Figure E of the section on Surface Waters showing the location of groundwater and surface water interchanges and direction of flow under mean annual conditions.
- 3. Plates 311-1 from the section on Waste Water Sources and Systems for the location of areas presently served by septic tank and drain field disposal systems.

There are four Group I sources which span the aquifer in the vicinity of the Washington-Idaho line to measure the quality as the primary groundwater flow enters the study area. Three of these, however, are close to the river in a section where there is surface water discharge from the river into the aquifer. Comparison of the analytical data for 26/45-36N1 (Siverson) and 26/45-36Q1 (Borden) indicate that the Siverson well may be heavily influenced by the river as indicated by 560 mg/l concentration of zinc. It would appear that one or two more wells farther

from the river are needed to reinforce the data on the groundwater before it is subject to the surface water inflow.

The surface water exchange to groundwater extends approximately to Greenacres. There are no sample stations near the river in this stretch to detect the extent of this influence.

The heavy concentration of septic tanks and drainfields begins near Trentwood, speaking in terms of the direction of groundwater flow. There are no Group I wells to adequately span the cross section of the aquifer prior to entering the area of drainfields.

There is a good concentration of Group I sources spanning the aquifer in two bands just east of the City limit which should adequately represent the groundwater flow through this narrows of the aquifer. These wells are under and downstream in terms of aquifer flow from the drainfield area.

There are no Group I observations in the City area as the primary aquifer flow turns north away from the river toward the Hillyard Trough and continues through the trough to the springs along the Little Spokane, except for one Kaiser well. There is another drainfeild area beginning north of the City and extending to the Little Spokane River. All of the Group I samples as the aquifer reaches the Little Spokane River are springs. These springs probably do not fully represent the deep flow entering the Little Spokane. Lack of sampling points within the City, at the Hillyard Trough and well samples at the Little Spokane constitute data gaps.

Coverage of Major Water Producing Wells

Table 15 lists the major water producing wells in the primary aquifer abstracted from the section Water Systems and Useage. This list is marked to indicate which are represented by Group I and Group II data.

Of the 37 Group I sources, 24 correspond to major water users and 13 are not listed in Table 15. The significance of a well not being in Table 15 is that it is not part of a municipal or industrial system. Of the 13 not listed, four are private domestic wells, three are commercial/ industrial wells serving small businesses, one serves the Holiday Hills recreation area, one is owned by the Federal government and four are springs. Significantly, eleven of the unlisted wells are part of the USGS-EPA ongoing program.

Of the 24 Group I sources that are also major municipal or industrial wells, 18 have data from previous studies and 6 have the USGS-EPA ongoing program as their source.

Comparing the 29 Group II sources with Table 15 indicates that 18 coincide with listed major water users and that 11 are not in Table 15. The unlisted wells consist of 8 private, 2 Washington Water Power, and one Union Sand and Gravel. The 2 Washington Water Power wells are not in the inventory of active wells furnished to the consultant for this study. The Union Sand and Gravel well is reported as having been destroyed.

Considering the data gap in representation of major producers together with the geographical gaps discussed above, Table 18 is presented listing major users that are not represented by quality data in three geographical areas where there is weak representation.

Possible Affect of Rate of Withdrawal

The primary aquifer is unique in the volume of water flowing through its cross section. Refer to the section Geology and Groundwater. If pollution is reaching the surface of this large flow volume it probably would remain on the surface without significant vertical mixing in the aquifer. Large volume wells undoubtedly draw from lower layers as well as the surface of the aquifer as evidenced by the extremely small drawdowns observed. Therefore it is possible that large volume wells represent a smaple of the aquifer that contains proportionately less of the surface layer than might a very small volume well essentially skimming from the surface.

The fact that there are few broad spectrum samples from very small wells may constitute a data gap.

Possible Affect of Season

The availability of moisture in sufficient volume to possibly carry ground surface pollution down through the unsaturated zone of the aquifer is dependent upon the time of year. The maximum volume per unit of time would be available either at the thaw or at a heavy precipitation period following a thaw. Concentrations of surface water occuring at dry well disposal sites for streets and highways might be particularly critical.

Most of the wide spectrum data presently available is the USGS-EPA ongoing program which is for June, September and December.

The lack of data at and following the spring thaw may constitute a data gap.

Consistency in Available Data

and the second second second second second second second second second second second second second second second

Reference to Table 10 containing the USGS-EPA ongoing analytical results locations shown for these analyses on Plate 309-3 indicates the following with reference to consistency of key parameters throughout the aquifer.

- 1. The Ruth Jeffers well shows such radically different quality combined with its location at the approximate contact line of the aquifer indicate that it probably is not a primary aquifer well. The following statements are with reference to the remainder of the Table 10 list without the Ruth Jeffers well.
- 2. Conductivity, total hardness and pH show great consistency from where the aquifer enters the study area from Idaho to where it discharges into the Spokane and Little Spokane River. pH is almost constant, varying from 7.4 to 7.8. Conductivity and hardness show a slight trend of increase as the water travels through the aquifer but there are individual exceptional cases. Conductivity and hardness ranges from approximately 275 and 140 respectively to 300 plus and 150.
- 3. Except for the Borden, Siverson and Kaiser wells the zinc content is in the range 10 to 50 mg/1. These three exceptional cases show values of 120, 560 and 360 respectively. Since the river water zinc concentration ranges between 10 and 730 mg/1 with an average of 290 mg/1 and these three wells are near the river and in a reach where surface water transfer to the aquifer is suspected, these analytical results appear to confirm the interchanges.
- 4. There is a slight trend toward increased chloride content as the water progresses through the aquifer. The CID #10 well which appears to be uninfluenced by the river, shows 0.8 mg/l chloride. All other wells are higher, ranging up to 8.6 mg/l, but two major springs at the aquifer discharge are 2.3 mg/l.
- 5. MBAS was detected at 0.03 mg/l in only one well, Kaiser, MBAS was undetected at all others.

The foregoing indicates that there is a high degree of consistency throughout the aquifer and that for the standard chemical tests, little additional information will be obtained from additional locations. A search could be made through the uncatalogued files of DSHS chemical tests for the

standard tests made on the particular wells listed in Table 18 to confirm the consistency of these parameters.

Summary of Primary Aquifer Gaps

Summarizing from the foregoing paragraphs, the data gaps for groundwater quality in the primary aquifer are as follows:

- 1. Pesticide analyses for the entire area
- 2. Bacterial testing or a major cateloguing and summarization effort for existing DSHS data
- 3. Geographical areas and major users as listed in Table 18
- 4. Sampling at time of year where there is maximum percolation from the aquifer surface combined with low rate withdrawal from the surface of the aquifer.

Available Data in the Basalt Aquifer. The wells within the basalt aquifer for which significant quality data are available are listed in Table 13 and locations are shown on Plates 309-1 and 2. All except one well listed in Table 13 has Van Denburgh and Santos (1965) as its source. Therefore these data consist of standard tests plus nitrate and are for the years 1960 and earlier.

Table 16 lists the major water users of the basalt aquifer. Only four wells in Table 16 coincide with those for which data are available. The municipal wells for Tekoa, Latah, Fairfield, Cheney, Rockford, Spangle and Airway Heights are not represented by water quality data.

Since the available data spectrum is no better than the DSHS routine chemical tests, all the wells listed on Table 16 could presumably be brought up to the same data availability level as those on Table 13 by a search of the uncatalogued files of DSHS.

There are no data for this aquifer in the metals, bacteriological and

pollutant categories of Table 7.

Data Gaps for the Basalt Aquifer. This aquifer is entirely different in character than the primary aquifer which is essentially one larger continuous underground body of water. This aquifer is believed to be essentially discontinuous vertically; that is, between horizontal layers of water bearing basalt and the extent of lateral movement in each layer is unknown. Therefore, coverage must be considered on an individual well basis rather than by area. The scatter of wells for which data are available would not necessarily be a measure of the quality of relatively nearby major producers not sampled.

For the wells which produce most of the water in the area, this aquifer can be said to be without water quality data for the entire broad spectrum of parameters.

<u>Available Data in Other Aquifers</u>. The wells in other aquifers for which significant quality data are available are listed in Table 14 and locations are shown on Plate 309-1. There are only 14 wells for which standard tests or better are available. Of these only Liberty Lake Utilities and Spokane County Golf Course wells have Group I data.

Table 17 lists the major water users in the other aquifers. The Little Spokane Valley is the largest single unit in the "other aquifers" category with 15 municipal service wells. The next largest group are those bordering the Spokane River in the vicinity of Long Lake with 7 wells. The remainder are the two Bureau of Indian Affairs wells at Wellpinit and the two wells in the Liberty Lake area. Refer to Plate 314-10 for the location of these wells. Of the wells listed in Table 17, only the following four have water quality data as listed in Table 14:

A. 4 CAN NEWS

Washington Water Power Riverview Hills in Little Spokane area Lakeridge Water Co. in the Long Lake area

Liberty Lake Utilities and Spokane County Golf Course, both in Liberty Lake area

Data Gaps for the Other Aquifer

There are no wells in the Little Spokane Valley area, the Wellpinit area and the Long Lake area for which there are broad spectrum analyses. A data gap exists for these three areas essentially for all parameters.

There are two wells in the Liberty Lake area with Group I data. The data gap for this area consists of bacteriological data.

Notes for Table 9

(1) A 5 in this column indicates that the well produces 5 million gallons per year or more.
(2) Data sources are identified as follows:

Yan Denburgh and Santos (1965)
Yan Denburgh and Santos (1965)
Cline (1969)
Cline (1969)
Heigle and Hundorf (1952)
Valge and Hundorf (1952)
Valge and Hundorf (1952)

S - Entire indicated record in STORET
\$ - Portion of record in STURET
\$ - Phillips (1962)

The second second second to be

NG WATER

PN) is used, the following statenalysis involves five 10 ml. tubes coliform organisms (MPN), the

ence of coliform organisms, the vestigate trouble IMMEDIATE. IPLES.

and a solid have a state and

art a she

alth bacteriological standards, a to the following:

portions examined per month, show the presence of coliform sence of the coliform group in a standard sample shall not be

- oles:
- ble per month when less than er month; or
- nt of the samples when twenty er month.

(MF) is used, the arithmetic andard samples examined per 100 ml. Coliform colonies per 4/100 ml in:

- les;
- ble per month when less than er month; or
- nt of the samples when twenty er month.

ter sample was made in accorddard Methods of Water Analysis.
