1. INTRODUCTION AND HISTORICAL BACKGROUND

The Binary Data Acquisition and Control System (BDACS) is a computer-controlled general-purpose instrumentation system that retrieves and stores binary logic signals generated by a system undergoing some form of testing. Simultaneously, BDACS can transmit binary logic control signals to the test system in order to initiate a specific logic state of the system or to control the sequence of operations through several logic states.

BDACS [originally called the Communications Monitor and Control System (CMCS)] was developed under the Program for Electromagnetic Pulse Testing (PREMPT), jointly sponsored by the Defense Nuclear Agency (DNA) and the Defense Communications Agency (DCA). The primary objectives of PREMPT are:

- (a) to evaluate the vulnerability/survivability of the WWMCCS/DCS Command, Control, and Communications systems (C³) subjected to a high-altitude electromagnetic pulse (HEMP) environment by using a methodology that includes both testing and analysis;
- (b) to provide hardening recommendations/fixes that insure an acceptable level of performance of the WWMCCS/DCS in a HEMP environment;
- (c) to develop the analytical tools required to analyze the WWMCCS/DCS and other critical C^3 systems.

The initial phases of PREMPT included large-scale test programs to be performed on three telephone switch centers that form a part of the continental U.S. Automatic Voice Network (CONUS-AUTOVON). As part of the data requirements for these test programs, the logic states of the switch centers had to be monitored and controlled. The development of BDACS is a result of these requirements.

A block diagram of the BDACS hardware is shown in figure 1 (a to c). The hardware is centered around a Data General Corporation (DGC) Nova-1230 minicomputer processor and peripheral system. The computer includes a 16K core memory, Teletype (TTY) control unit, card-reader input unit, line-printer output unit (to allow real-time hard-copy output of BDACS results), a 9-track magnetic-tape drive (to allow archive storage of BDACS results), and a disk-cartridge drive to store both the background operating software system (supplied by DGC) and the foreground BDACS control software system that was developed concurrently with the hardware. The special-purpose interface board supplied by the original equipment manufacturer (OEM) provides the hardware link between the computer section and the binary signal interface/multiplexer and special-purpose control boards of BDACS. These special-purpose control

BLOCK DIAGRAMS OF BDACS

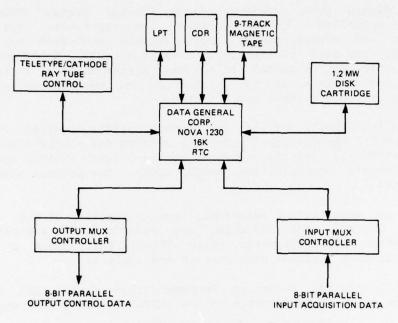

Figure 1(a). Central control and processor.

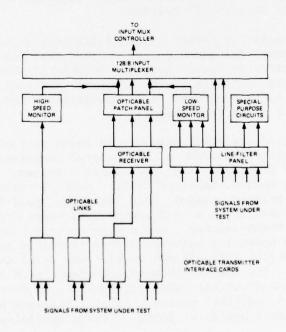

Figure 1(b). Input multiplexer unit.

BLOCK DIAGRAM OF BDACS

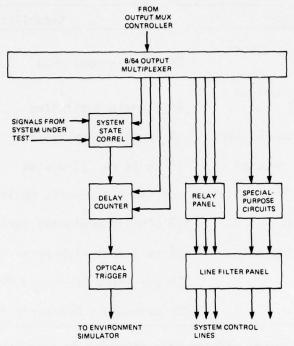

Figure 1(c). Output multiplexer unit.

boards include (1) a state correlator which generates a time-delayed trigger signal when the system under test enters a prescribed logic state (as defined by the parallel coincidence of up to eight logic signals) (2) a high-speed buffer (HSB) that allows very fast monitoring of sixteen binary signals at sample rates of two per microsecond, (3) a low-speed buffer (LSB) that allows a slow monitor and serial transfer of slowly changing logic signals, and (4) audible tone diallers and dial-tone detectors that are specific interface modules for the particular telephone switch centers which were tested under PREMPT. The present capabilities of BDACS are summarized in table I.

The heart of the BDACS consists of a software control program and several ancillary programs that provide the communications links between the BDACS operator and the system hardware. The remainder of this report describes the architecture and functions of several modules that comprise the BDACS software.

The initial BDACS software package was prepared by the OEM during the initial system development and was used during BDACS operations at Polk City, FL. During the BDACS refurbishing period in preparation of operations at Delta, UT, some minor modifications and improvements to

TABLE I. PRESENT BDACS CAPABILITIES

Feature	Capabilities						
Binary signal monitor (input MUX)	128 signals monitored						
Binary signal control (output MUX)	64 signals controlled						
System state correlator	8 signals correlated						
Trigger delay counter	O to 55 μs, simulated						
High-speed buffer	2K (16 bits) words monitored (0.5 μ s)						
Low-speed buffer	128 signals monitored serially (50 μs)						
Sampling resolution	50 μsinput high-speed MUX words (16 bits)						
	350 μsinput low-speed MUX words (112 bits)						
	1000 μs-~output MUX words (64 bits)						

the initial software package were provided by personnel of Harry Diamond Laboratories (HDL). In particular, an option was incorporated to provide the immediate on-line data printout using the TTY control unit in lieu of the line printer.

During these earlier portions of BDACS operations, the basic "background" software operating system was the Real Time Disk Operating System RDOS-REV 1.00 supplied by DGC. Following the Delta test program, an updated and improved operating system, RDOS-REV 3.01, was obtained from DGC and placed on BDACS. However, because the core resident portion of RDOS-REV 3.01 is substantially larger than that of RDOS-REV 1.00, the 16K core capacity of BDACS was insufficient to hold both RDOS-REV 3.01 and the BDACS control program concurrently. In fact, even with the earlier RDOS-REV 1.00, the concurrent loading of this operating system with the BDACS control program filled all but approximately 20 words of BDACS core. Consequently, there was no room for any substantial software additions or improvements to the BDACS control program as required for additional monitoring capability, without drastically reorganizing the control program.

Furthermore, the initial BDACS software package was not able to meet the design objective of a $50-\mu s$ minimum sample cycle time and was very inefficient both in operating time and in data storage requirements during the data reduction phase of the program.

For these reasons, a complete redesign of the control program package was initiated. The package described in the following sections has been implemented as the current BDACS control program. The control program is written in the DGC-supplied RDOS Assembly language and interfaces with the RDOS-REV 3.01 operating system.

2. BDACS CONTROL PROGRAM -- GENERAL ARCHITECTURE

The BDACS control program has been specifically designed in a "structured program" modular format that allows for future expansion or modification without complicated interactions or interdependencies among the different modules. In particular, the overall operation of the control program has been separated into major sequential tasks, with each task programmed as a separate overlay module of the control-program save file. Information exchange among the different overlay modules has been kept to a minimum and is in one of the following forms:

- (a) ZREL parameters (a very limited number)
- (b) NREL tables in the root binary
- (c) data files organized under the RDOS operating systems

Moreover, those system parameters defined within each overlay module which may be subject to change with system augmentation or expansion have been collected into a separate system parameter file, BDACS.SR, organized under RDOS. As described below, this file should be assembled with each program segment when the user constructs the control-program save file.

The BDACS control program is composed of a root binary section and six overlay modules which are common to a single overlay region. The major tasks associated with the root binary and each overlay module are summarized below and are described in detail in the subsequent sections.

Module	Name	Task
Root binary	MONTR.SR	holds ZREL parameters
		holds NREL tables
		provides overlay control
Overlay No. 1	PHAS1.SR	initializes and opens RDOS files
		reads and constructs METHOD file data acquisition and reduction tables

Module	Name	Task
		reads and constructs METHOD file data control tables
		reads and stores PREAMBLE query file
		stores the METHOD and ASSIGN files
Overlay No. 2	PHAS2.SR	controls real-time data acquisition and control sequencing
Overlay No. 3	PHAS3.SR	retrieves and stores HSB data
Overlay No. 4	PHAS4.SR	reduces and stores the MUX and LSB data
Overlay No. 5	PHAS5.SR	reads and stores POSTSCRIPT query file
		produces the on-line data printout
Overlay No. 6	ERMSG.SR	generates error messages
		provides normal or abnormal return to the RDOS-CLI

To produce the working load module (that is, the .SV save file and the .OL overlay file) of the control program, the user should first assemble the root binary and each overlay module using the RDOS-supplied assembler to produce the associated relocatable binary (.RB) file. The RDOS-CLI command strings for these assemblies are

(a) Root binary

ASM BDACS MONTR MONTR.RB/B

(b) Overlay No. 1

ASM BDACS PHAS1 PHAS1.RB/B

(c) Overlay No. 2

ASM BDACS PHAS2 PHAS2.RB/B

(d) Overlay No. 3

ASM BDACS PHAS3 PHAS3.RB/B

(e) Overlay No. 4

ASM BDACS PHAS4 PHAS4.RB/B

(f) Overlay No. 5

ASM BDACS PHAS5 PHAS5.RB/B

(g) Overlay No. 6

ASM BDACS ERMSG ERMSG.RB/B

Following assembly, the relocatable binary files are combined, and relocatable externals are resolved to produce the final save and overlay files. The RDOS-CLI command string for this loading operation is

RLDR MONTR [PHAS1, PHAS2, PHAS3, PHAS4, PHAS5, ERMSG] 10/ C .

The final result is the generation of a save file named MONTR.SV and an associated overlay file named MONTR.OL.

3. BDACS DATA FILES AND TEMPORARY FILES

The BDACS control program uses the RDOS file management routines to create and maintain a number of different data files and temporary files used during BDACS operations. A general description of the content and format of these files follows.

PREAMBLE.DA--An RDOS sequentially organized, permanent, and write-protected file containing alphanumeric text information generated and maintained by the DGC-supplied text editor (EDIT.SV) under the control of the BDACS operator. The file contains a series of alphanumeric "query" or "statement" lines which are presented to the BDACS operator line by line at the beginning of a BDACS test run. A query line requires operator response, and both the query and response are stored for later incorporation in the final data vector. A statement line (which begins with an asterick) does not require a response. It is used to incorporate information into the final data vector which does not change from one test run to the next or it is used for formatting purposes.

POSTSCRIPT.DA--An RDOS sequentially organized, permanent, and write-protected file, similar to the preamble file described above. The postscript file contains a series of query or statement lines which are presented to the BDACS operator following a BDACS test run. Again, the query/response or the statement is incorporated in the final data vector.

ASSIGNA.DA--An RDOS randomly organized, permanent, and write-protected file containing alphanumeric text information generated and maintained by the ASSIGN.SV program which is supplied as part of the BDACS software package. The alphanumeric text is used to describe the signals being monitored by the HSB. In particular, the textual information for each signal is contained in 16 bytes (8 words packed mode 1) null filled. Thus, information for 32 signals is held in a 256-word disk block, and the file contains as many disk blocks as required for the HSB signals.

ASSIGNB.DA--An RDOS randomly organized, permanent, and write-protected file containing alphanumeric text information similar to that described above. For the present file, the text is used to describe the signals being monitored by the BDACS MUX panels. Again, each signal text is packed in 8-word segments, with 32 signal texts per 256-word disk block.

ASSIGNC.DA--An RDOS randomly organized, permanent, and write-protected file containing alphanumeric text information similar to that described above. For this file, the text is used to describe the signals being monitored by the BDACS LSB. Again, each signal text is packed in eight-word segments, with 32 signal texts per 256-word disk block.

BDACS.DA--An RDOS contiguously organized, permanent, write- and attribute-protected file containing the binary data acquired during a BDACS test run. The binary information is written into the file space independent of and external to the RDOS operating system and file maintenance routines. However, during the data reduction phase of the test run, the data are retrieved from the file under control of RDOS routines.

TEMPA.TM--An RDOS sequentially organized temporary file, created by the BDACS control program at the beginning of each BDACS test run. The file provides temporary storage for the query/response lines and the statement lines of the preamble file described earlier. At the end of a BDACS test run, this file is transferred to the final data vector and/or the on-line data printout.

TEMPB.TM--An RDOS randomly organized temporary file, created by the BDACS control program preceding the retrieval of the HSB data. At the of a BDACS test run, this file is transferred to the final data vector and/or the on-line data printout.

TEMPC.TM--An RDOS randomly organized temporary file, created by the BDACS control program preceding the reduction of the MUX and LSB data (provided the magnetic-tape option is not in effect). At the end of a BDACS test run, this file is transferred to the on-line data printout.

TEMPD.TM--An RDOS sequentially organized temporary file, created by the BDACS control program following data reduction. The file provides temporary storage for the query/response lines and the statement lines of the postscript file described earlier. At the end of a BDACS test run, this file is transferred to the final data vector and/or the on-line data printout.

4. BDACS METHOD FILES

The BDACS operator provides information to the BDACS control program on how a test run is to be conducted (or controlled) through a "method" file. The different method files are RDOS sequentially organized files containing alphanumeric text information generated and maintained by the DGC-supplied text editor (EDIT.SV) under the control of the BDACS operator. Each method file should contain the lines of information that follow.

- (1) The <u>identification line</u> does not provide information to the control program but serves to identify the contents of the file.
- (2) The <u>sample rate line</u> should contain a single-precision, decimal integer between 50 and 4095 which represents the sample rate (in microseconds) for the BDACS MUX panels. The integer may be preceded and followed by alphabetic text strings (nonnumeric).
- (3) The test duration line should contain a double-precision, decimal integer which represents the total duration of the test run (in milliseconds). The integer may be preceded and followed by alphabetic text strings (nonnumeric).
- (4) The HSB line should contain a single-precision, decimal integer between 500 and 10000 which represents the sample rate (in nanoseconds) for the BDACS HSB. An asterisk immediately following the integer indicates that the HSB data should be transferred to the on-line data printout file following the data run. Alternatively, an integer of zero in this line indicates that the HSB data-retrieval phase will be bypassed. The integer may be preceded and followed by alphabetic text strings (nonnumeric).
- (5) The LSB line should contain a single-precision, decimal integer between 1 and 16 which represents the MUX input number (on the high-speed word) at which the LSB signal is being serially monitored. Alternatively, an integer of zero in this line indicates that the LSB is not in use. The integer may be preceded and followed by alphabetic text strings (nonnumeric).

- (6) The MUX reported points list consists of two or more lines of information representing those MUX input points which are selected for data reduction and/or inclusion in the on-line data printout following a test run. The list begins with a "header" line that is used for formatting but imparts no information to the control program. Following the header line is a series of data lines that contain one or more single-precision, decimal integers separated by non-digit characters. The integers, ranging from 1 to 128, represent those points on the input MUX panels to be included in the data-reduction phase of the control program. An asterisk immediately following an integer is a flag indicating that the specified point should also be contained in the on-line data printout. The last line of the MUX reported points list should be an alphabetic text string (for example, END OF MUX LIST.), containing no digits, which is used as an end-of-list indicator.
- (7) The LSB reported points list like that described above, consists of two or more lines of information representing those LSB input points that are selected for data reduction and/or inclusion in the on-line data printout. Again, the list consists of a header line, a series of data lines, and an end-of-list indicator line. The integers in the data lines represent those LSB input points to be included in the data-reduction phase of the control program. An asterisk immediately following an integer is a flag indicating that the specified point should be included in the on-line data printout.
- (8) The control point list consists of one or more lines of information representing the control functions to be performed by the control program during a test run. The list begins with a header line that is used for format but imparts no information to the control program. Following the header line is a series of data lines, each of which contains two single-precision, decimal integers followed by a double-precision, decimal integer. The first single-precision integer represents the state which a point on the MUX output panel is to assume, either 0 or 1. The second single-precision integer represents the point number on the MUX output panel, ranging from 257 to 318. However, a special point number of 0 may also be used. This number does not correspond to any point on the MUX output panel; instead, it indicates when the control program should begin data storage during data acquisition. The double-precision integer represents the elapsed time (in milliseconds) from the beginning of a test run at which the selected control point is to assume the indicated state. The series of data lines should be arranged in an ascending sequence with respect to time, and no two adjacent times should differ by more than 32,767 ms. Furthermore, the last time in the list and the test duration time specified earlier should not differ by more than 32,767 ms. If necessary, pseudo-control data lines, which will not affect the current state of a control point, may be placed in the data series to comply with the above limitation. As a second limitation, the total number of lines in the data list should not be greater than 128. Last, an

end-of-list alphabetic text string may optionally be included in the list and as a final line of the method file. An example of a typical method file is shown in figure 2.

IDENTIFICATION: TEST METHOD SAMPLE RATE (IN USEC): 100 DURATION (IN MSEC): 10000 HS BUFFER: 5500+ 16 LS BUFFER: REPORTED POINTS TABLE 1+2+3+4+5+6+7+6+9+10+11+12+13+14+15+16+ 17+18+19+20+21+22+23+24+25+26+27+28+29+30+31+32+ 33+34+35+36+37+38+39+40+41+42+43+44+45+46+47+48+ 49+50+51+52+53+54+55+56+57+58+59+60+61+62+63+64+ 65*66*67*68*69*70*71*72*73*74*75*76*77*78*79*80* 81+82+83+84+85+86+87+88+89+90+91+92+93+94+95+96+ 97+98+99+100+101+102+103+104+105+106+107+108+109+110+111+112+ 113+114+115+116+117+118+119+120+121+122+123+124+125+126+127+128+ END OF TABLE LS BUFFER TABLE 1+2+3+4+5+6+7+8+9+10+11+12+13+14+15+16+ 17+18+19+20+21+22+23+24+25+26+27+28+29+30+31+32+ 33+34+35+36+37+38+39+40+41+42+43+44+45+46+47+48+ 49+50+51+52+53+54+55+56+57+58+59+60+61+62+63+64+ 65+66+67+68+69+70+71+72+73+74+75+76+77+78+79+80+ 81+82+83+84+85+86+87+38+89+90+91+92+93+94+95+96+ 97+98+99+100+101+102+103+104+105+106+107+108+109+110+111+112+ 113+114+115+116+117+118+119+120+121+122+123+124+125+126+127+128+ END OF TABLE STATE SIGNAL TIME 1 . 257 258 259

5. BDACS DATA VECTOR AND ON-LINE PRINTOUT

The results of a BDACS test run may be incorporated in a final data vector written on magnetic tape and/or an immediate on-line data printout produced by the BDACS line-printer or TTY control unit.

5.1 BDACS Data Vector

If the "M" global switch option is in effect, the final data vector on magnetic-tape unit MTO contains eight files described below.

- (a) MTO:0 is the preamble file query/response lines and statement lines transferred line by line from the TEMPA.TM file. This file has the standard RDOS tape format and record length of 514 bytes.
- (b) MTO:l is the method file selected for the particular test run which is transferred line by line. Again, the file has the standard RDOS tape format and record length of 514 bytes.
- (c) MTO:2 is the ASSIGNA.DA file transferred as 256-word blocks. The record length of each block is 512 bytes.
- (d) MTO:3 is the ASSIGNB.DA file transferred as 256-word blocks. The record length of each block is 512 bytes.
- (e) MTO:4 is the ASSIGNC.DA file transferred as 256-word blocks. The record length of each block is 512 bytes.
- (f) MTO:5 is the HSB data transferred as 256-word blocks from TEMPB.TM. The record length of each block is 512 bytes.
- (g) MTO:6 is the MUX input panel data and LSB data generated during data reduction. The file consists of 768-word data blocks with record lengths of 1536 bytes. Each of the 256 data entries in the data blocks has six bytes (or three words). The first byte contains a state bit (either 1 or 0), an error-recovery bit (either 1 or 0) and a select bit (either 1 or 0). The second byte contains the MUX or LSB point number corresponding to the state. The third, fourth, fifth, and sixth bytes contain a double-precision integer representing the time from the beginning of the test run (in ms) at which the selected point changed to the prescribed state.
- (h) MTO:7 is the postscript file query/response lines and statement lines transferred line by line from TEMPD.TM file. This file has the standard RDOS tape format and record length of 514 bytes.

If the "L" global switch option is in effect, the final data vector is transferred to the BDACS line printer. Similarly, if the "T" global switch option is in effect, the final data vector is transferred to the BDACS TTY control unit. For either case, this data vector contains the following entries:

- (a) The preamble file query/response lines and statement lines transferred line by line from TEMPA.TM file.
- (b) The postscript file query/response lines and statement lines transferred line by line from TEMPD.TM file.
- (c) The method file transferred line by line from the method file selected for the test run.
- (d) The HSB data, if the printout option as described in section 4 is in effect. This printout consists of (1) the assignment table for the different HSB input signals derived from ASSIGNA.DA, and (2) a chronological list of the monitored states of the HSB input signals. The time at which each signal was monitored is derived from the HSB sample rate described in section 4.
- (e) The input MUX data and LSB data for those MUX and LSB signal points which were flagged for on-line data printout, as described in section 4. The printout consists of data lines containing (1) the new state (either 1 or 0) which a signal point assumes, (2) the time (in microseconds) at which the state change occurred, (3) the signal point number and select code (either "M" for MUX panel or "L" for LSB), and (4) the signal point mnemonic name for the signal as derived from either the ASSIGNB.DA or the ASSIGNC.DA files.

6. ROOT BINARY SEGMENT--MONTR.SR

The root binary segment is the part of the control program that remains core resident throughout a BDACS test run. For this reason, the root binary segment was designed to require only a small amount of core, while most of the program core requirements are shared among the several overlay modules. The assembly language structure for MONTR.SR is given in appendix A, section A-1. The root binary segment is divided into the following three regions (sect. 6.1, 6.2, and 6.3).

6.1 ZREL Parameters

This region is organized in relocatable page-zero locations and contains those parameters that are common among or global to the several overlay modules. In particular, the following parameters are presently in use.

- (a) OVRTN holds the return address to the root binary from all overlay modules (except when program exit is affected in ERMSG.SR). This parameter is set in subroutine OVLOD as part of the overlay loading procedure.
- (b) RECOV provides several functions: First, it holds the system error code if an RDOS system call error occurs during processing in any of the overlay modules. Second, it holds the root binary return address, previously stored in OVRTN, if a recoverable error occurs in any overlay module.
- (c) ERRTN contains the NREL address to the root binary section labelled ERROR. This allows an abnormal exit from any overlay module to the root binary segment when specific errors occur.
- (d) ERCOD contains an error code which is returned to the root binary segment whenever an abnormal error return is affected. In particular, a code of -l is returned for an RDOS system call error. For other errors, the left-hand byte of ERCOD contains the overlay number in which the error condition occurred, and the right-hand byte of ERCOD contains the error number for that particular overlay module. ERCOD is set within each overlay module and supplies information to the error message overlay ERMSG.SR.
- (e) MAGFG provides two functions: First, it holds the first global switch word supplied from the COM.CM file generated by the RDOS-CLI. Second, it holds a nonzero value as a flag if global switch "M" is optionally set indicating a magnetic tape is required. This parameter is set in overlay module PHAS1.SR and used in PHAS1.SR, PHAS3.SR, PHAS4.SR, and PHAS5.SR.
- (f) PRINT provides two functions: First, it holds the second global switch word supplied from the COM.CM file generated by the RDOS-CLI. Second, it holds nonzero print flags if global switch "L" is set, for line printer required, or global switch "T" is set, for TTY control unit required. Bit 1B15 is set for "L" and 1B0 is set for "T." This parameter is set in PHAS1.SR and used in PHAS5.SR.
- (g) SMPRT holds the MUX panel sample rate as a single-precision binary integer. It is set in overlay module PHAS1.SR and used in PHAS2.SR and PHAS4.SR.
- (h) HSMON holds the HSB sample rate as a single-precision binary integer and the optional HSB on-line data printout flag in 1BO. It is set in overlay module PHAS1.SR and used in PHAS3.SR and PHAS5.SR.
- (i) LSMON holds the LSB signal point on the MUX panel as a single-precision binary integer. It is set in overlay module PHAS1.SR and used in PHAS4.SR during data reduction.

- (j) BLKCT contains the number of remaining track surfaces on the disk in which data from the MUX input panel are stored. The parameter is initially set to a maximum count, currently 200, and decremented during overlay module PHAS2.SR operations. The parameter is also used in PHAS4.SR during data reduction.
- (k) HLDCT contains the number of data blocks acquired but not stored on the disk preceding the onset of data storage. The parameter is initially zero and periodically incremented during data acquisition PHAS2.SR of the control program. The parameter is used in PHAS4.SR during data reduction.

6.2 NREL Input/Output Control Tables

This region of the root binary segment consists of three tables containing input and output control information.

- (a) MSKTB is divided into three parts. The first part contains mask words of those MUX input points which have been designated for data reduction (see sect. 4). The mask words are packed with 16 points per word, each bit from 1B15 to 1B0 being set if the corresponding point is reported. At present, eight such mask words corresponding to 128 input points are in use. The second part contains mask words whose bits correspond to the previous state (either 1 or 0) of the different MUX input points. As above, the words are packed with 16 points per word for a total of eight mask words. Initially, the mask words are all zero, corresponding to an assumed initial 0 or "off" state for the input points. The third part of MSKTB contains mask words of those MUX input points which have been designated for immediate on-line data printout (see sect. 4). Again, the words are packed with 16 points per word for a total of eight mask words. Thus, the total present length for MSKTB is 24 words, plus one spare.
- (b) LSBTB is the LSB equivalent to MSKTB. Again the table is divided into three parts containing mask words which correspond to the reported points, the previous state, and the points enabled for on-line printout.
- (c) CTLTB contains the information required to perform the control operations in overlay module PHAS2.SR. Currently, the table has a capacity for 128 such control functions, with each control function having a corresponding three-word entry in the table. The first word of an entry contains the elapsed time (in milliseconds) from the previous entry at which the present control function is to be activated. The second word of an entry contains a word mask specifying the corresponding bit position in the MUX output-panel buffer word which is to be activated (or altered). The third word of an entry contains both the state to be activated (in bit position 1B15) and the address of the MUX output-panel buffer word (in the remaining bit positions).

6.3 NREL Code

This region of the root binary segment contains the limited amount of instruction code which is required for overlay module initiation and loading and for overlay module entry and exit control.

The control program begins at parameter START and immediately initializes and opens the control program overlay file MONTR.OL on channel No. 7. Next, the overlay modules PHAS1.SR, PHAS2.SR, PHAS3.SR, PHAS4.SR, and PHAS5.SR are sequentially loaded into memory via the overlay load subroutine OVLOD. Following each load a branch instruction is performed into the overlay region to addresses OVST1, OVST2, OVST3, OVST4 and OVST5. Following a normal completion of these overlay module instructions, or if an error condition occurs, the last overlay module ERMSG is loaded and entered. From this overlay module a normal or abnormal return to the RDOS-CLI is performed, or the root binary segment is reentered if a recoverable error is encountered.

7. OVERLAY MODULE -- PHAS1.SR

This overlay module is the part of the control program that receives the control input data from the "method" file and constructs the control tables as described in sections 4 and 6.2. In addition, this module performs the query/response operations associated with the PREAMBLE.DA file and begins construction of the BDACS temporary files and the BDACS data vector described in sections 3 and 5.

PHASEL.SR is composed of instructions interspersed with tables and parameters. Logically, the module is divided into three main regions, the "backbone," the subroutines, and the name/test strings. These regions are described in detail in sections 7.1 to 7.4 and the assembly language listing for PHASL.SR is shown in appendix A, section A-2.

7.1 PHAS1.SR Backbone Code

The backbone code for PHAS1.SR is primarily a set of sequential initialization tasks for the control program. The main tasks performed are to

- (a) reset MUX output buffer, MUX input mask table, and the LSB input mask table.
- (b) disable RDOS spooling on \$LPT and \$TTO; open the output message unit (\$TTO).
- (c) open the RDOS-generated COM.CM file and retrieve the global switches and "method" file name; set data vector and on-line printout option flags (see sect. 6.1(f) and (h)); initialize MTO (if required).

- (d) open the prescribed "method" file and extract program control data as described in section 4; construct MUX input mask table, LSB input mask table, and MUX output control table, as described in section 6.2.
- (e) create TEMPA.TM file; open TEMPA.TM and PREAMBLE.DA files; read preamble query/statement lines and obtain operator response; construct TEMPA.TM.
- (f) transfer TEMPA.TM, the "method" file, ASSIGNA.DA, ASSIGNB.DA, and ASSIGNC.DA to the magnetic-tape data vector (if "M" option is in effect).
 - (g) check for proper sense-switch conditions.

During the process of receiving initialization parameters and data, these quantities are checked for proper value limits. If an out-of-bounds condition arises, control is transferred to an error routine.

7.2 PHAS1.SR Subroutine Code

The subroutines which comprise part of the PHAS1.SR code are accessed from the backbone code one or more times using the assembly language JSR instruction. Typically, access to the subroutine is indirect, with the subroutine starting address stored in an access word near the JSR instruction. Moreover, depending on the subroutine, one or more parameters may follow the JSR instruction. Return is made to the instruction following the last parameter, unless errors or exceptional conditions cause branching to other parts of the code. The following paragraphs briefly describe the subroutines found in PHAS1.SR.

- (a) TABLE reads the contents of the MUX or LSB-reported points list in the "method" file and constructs the MSKTB or LSBTB mask table described in section 6.2(a) and (b). Three parameters are associated with the subroutine: the first contains the beginning address of the mask table, the second contains the maximum size of a valid list entry, and the third contains offset within the table for the beginning of the on-line printout masks. Entries within the list are assumed to begin at a value of one. An exceptional return to the error routine occurs if an entry in the list is out of bounds. Normal return occurs when a line containing no digits is encountered in the list.
- (b) CKNBR checks a binary number for valid bounds. The number is contained in ACO. The lower bound is given as the first parameter and the upper bound is given as the second parameter. An exceptional return to the error routine occurs if an out-of-bounds condition occurs.

- (c) XFERF transfers ASCII data from one file to another. The two parameters that are required contain the byte pointers to the source file name and the destination file name. The files are opened on RDOS channels No. 3 and No. 4, the transfer is made on a line-by-line basis, and the files are then closed on both channels. No exceptional condition is explicitly contained in this subroutine.
- (d) XBLK transfers contents from a disk file to a magnetic-tape file block by block (256 words per block). Similar to XFERF, the files in XBLK are opened on RDOS channels No. 3 and No. 4, the transfer is made, and the files are then closed on both channels.
- (e) MVWUT transfers words to a destination storage area from the utility buffer pointed to by the byte pointer UTBPT. Two parameters are required, the first containing the address of the destination area, and the second containing the number of words to be moved.
- (f) FMMSK forms a mask (in ACl) and displacement value (in ACO) corresponding to an initial binary value in ACO. In effect, the subroutine divides ACO by 16 to form the displacement as the quotient. The remainder is used to set the associated bit position in the mask word contained in ACl (a remainder of 0 sets bit 1B15). All other bits in the mask are reset.
- (g) GTSPN reads an ASCII decimal integer text string and forms the corresponding single-precision unsigned binary integer in ACO. The byte pointer to the beginning of the text string is stored in ACI. The subroutine searches the text string until the first decimal character is encountered. Thereafter, each succeeding decimal character is folded into the binary equivalent of the number. The first non-decimal character terminates the scan, and upon exit from the subroutine AC2 contains the byte pointer to this terminating character. A jump is made to the error routine whenever a binary number overflow occurs (that is, a number greater than 65,383) or whenever no number is found within the text string.
- (h) GTDPN is similar to GTSPN except that a double-precision unsigned binary integer is formed in ACO and AC1. An overflow occurs whenever the number is greater than 4,294,967,295.
- (i) GTSPR is similar to GTSPN except that if no number is found in the text string, then exit from the subroutine is performed via the first parameter.
- (j) GTBYT retrieves a byte from a text string pointed to by a byte pointer in AC2. The byte is returned in ACO (right-hand position), and the byte pointer is left unchanged.

- (k) STBYT stores a byte held in ACO (right-hand position) in the text string pointed to by a byte pointer in AC2. Upon return from the subroutine, the byte pointer is incremented by one count.
- (1) CREAT creates a sequentially organized disk file by using the system call .CREAT. The first parameter contains a name pointer to the name of the file to be created. If the file already exists, the old file is deleted and a new file is created; otherwise, all system errors cause a branch to the system error routine.
- (m) DELET deletes a file by using the system call .DELET. The first parameter contains a name pointer to the name of the file to be deleted. If the file does not exist, no error is initiated; otherwise, all system errors cause a branch to the system error routine.
- (n) OPFLE opens a file on an RDOS channel by using the system call .OPEN. The first parameter contains a name pointer to the name of the file to be opened. The second parameter contains the channel number. Default characteristics for the file are assumed when the subroutine is called. All system errors cause a branch to the system error routine.
- (o) CLFLE closes a file on an RDOS channel by using the system call .CLOSE. The first parameter contains the channel number to be closed. All system errors cause a branch to the system error routine.
- (p) INMTA initializes the magnetic tape until MTO by using the system call .INIT. A partial initialization is assumed when the subroutine is called, and the subroutine waits locally until the "device ready" status is achieved. All system errors cause a branch to the system error routine.
- (q) WTLUT writes a line from the utility buffer (pointed to by byte pointer UTBPT) to the file opened on channel No. 3. This subroutine uses the system call .WRL. All system errors cause a branch to the system error routine.
- (r) TYLUT is similar to WTLUT except the channel on which the system console output file (\$TTO) is opened is No. 1.
- (s) TYPMG is similar to WTLUT and TYLUT except the byte pointer is given as the first parameter and points to a message text string.
- (t) RDSUT reads sequentially a number of bytes from the file opened on channel No. 4 to the utility buffer (pointed to by byte pointer UTBPT). The subroutine uses the system call .RDS, and the number of bytes to be read is given as the first parameter. All system errors cause a branch to the system error routine.

- (u) RDLUT reads a line from the file opened on channel No. 4 to the utility buffer (pointed to by byte pointer UTBPT). The subroutine utilizes the system call .RDL, and upon successful return, AC2 contains the byte pointer to the byte following the end of the line. All system errors cause a branch to the system error routine.
- (v) RDLUR is similar to RDLUT except that, upon detecting an end-of-file error condition, the subroutine exits via the first parameter.
- (w) RDLUA is similar to RDLUT except that the byte pointer is located in AC2 and the channel number for the file is given as the first parameter.
- (x) SPLDS disables spooling on a device whose name is pointed to by the byte pointer given in the first parameter. The subroutine uses the system call .SPDA, and all system errors cause a branch to the system error routine.
- (y) OPMTA opens a magnetic tape file for free format I/O on an RDOS channel by using the system call .MTOPD. The first parameter contains a byte pointer to the name of the magnetic-tape file name, and the second parameter contains the channel number on which the file is to be opened. All system errors cause a branch to the system error routine.
- (z) MTAWT performs a magnetic-tape free format "write" operation to the file on channel No. 3 by using the system call .MTDIO. The data to be transferred are located in the buffer pointed to by BUFFR and include a block of 256 words. All system error conditions except "end-of-file" cause a branch to the system error routine.
- (aa) MTASR is similar to MTAWT, except a free format "space reverse" of one record is initiated.
- (bb) MTAEF is similar to MTAWT, except a free format "write end-of-file" is initiated.
- (cc) RDBLK reads a disk block from the file opened on channel No. 4 using the system call .RDB. The first parameter contains the block number within the file which is to be read, and the second parameter contains a branching address for an end-of-file error condition. A single 256-word block is read from the file into the core area pointed to by BUFFR. All system errors except the end-of-file condition cause a branch to the system error routine.

7.3 PHAS1.SR Name/Text Strings and Buffers

The final region of PHAS1. SR is composed of a set of packed ASCII name and text strings pointed to by name or text byte pointers. These pointers are assembly language "equates" that do not generate an object code, but instead provide byte pointer values used in the "backbone" and subroutine regions of PHAS1.SR. The name and text strings are those RDOS file names and BDACS file names or messages used in PHAS1.SR and are generated with assembly packing mode 1, the normal packing mode for RDOS strings. Last, the final part of the name and text string region contains the address pointer UTBPT to a 68-word utility buffer area and the address pointer BUFFR to a 256-word block I/O buffer. These buffers are used for I/O operations for several subroutines described in section 7.2.

7.4 PHAS1.SR Error Routine

Several program error conditions can cause a branch to the PHAS1.SR error routine. This routine determines the point in the PHAS1.SR code where the error occurred and encodes an error code word which is stored in ERCOD within the root binary segment (see sect. 6.1(d)). The error code word contains in the left-hand byte the overlay module number (one in the present case) in which the error occurred and in the right-hand byte the displacement from the beginning of an error table. This error table (pointed to by the symbol ERTBL) contains as entries those addresses which immediately follow a JSR instruction to the error routine. Within the routine, the error table is scanned until a match is found between an error table entry and AC3, the latter containing the return address of that JSR instruction from which the routine was entered. Thus, the error is identified as a displacement from the start of the error table. A corresponding displacement from the start of a message pointer table in the overlay module EMMSG.SR contains a table entry which points to the associated error message. This message is subsequently printed on the system output console (that is, \$TTO).

At present, the 12 program errors detected for PHAS1.SR are

- (a) ERRI--"MONITOR POINT UNDERFLOW"--the entry in the MUX input list or LSB input list is less than unity.
- (b) ERR2--"MONITOR POINT OVERFLOW"--the entry in the MUX input list or LSB input list is greater than maximum value allowed (presently 128 and 128, respectively.
- (c) ERR3--"CONTROL TABLE OVERFLOW"--the number of control table entries exceeded the maximum value allowed (presently 128).

- (d) ERR4--"OUTPUT LIST NOT IN SEQUENTIAL ORDER"--the entries in the control table are not monotonically increasing in time.
- (e) ERR5--"OUTPUT LIST DELTA TIME OVERFLOW"--the time difference between two adjacent control list entries is greater than the maximum value allowed (32,767).
- (f) ERR6--"CONTROL POINT UNDERFLOW"--the MUX output point in a control table entry is less than the minimum value allowed (presently 257).
- (g) ERR7--"CONTROL POINT OVERFLOW"--the MUX output point in a control table entry is greater than the maximum value allowed (presently 318).
- (h) ERR8--"SP-DP OVERFLOW"--the number in a text string exceeded the single precision maximum (65,535) or the double precision maximum (4,294,967,295) in subroutines GTSPN (or GTSPR, GTSPA) and GTDPN, respectively.
- (i) ERR9--"EOL, NO NUMBER FOUND"--no number was found in a text string when subroutines GTSPN, GTSPA, or GTDPN are called.
- (j) ERR10--"SAMPLE RATE OUT OF BOUNDS"--the sample rate for the MUX panels is either less than the minimum allowed value (presently 50) or greater than the maximum allowed value (presently 4095).
- (k) ERR11--"LOW SPEED BUFFER MONITOR POINT OUT OF BOUNDS"--the point on the input MUX panel where the low-speed buffer signal is monitored is less than the minimum value allowed (presently 1) or is greater than the maximum value allowed (presently 16).
- (1) ERR12--"HIGH SPEED BUFFER SAMPLE RATE OUT OF BOUNDS"--the value specified for the HSB sample rate is less than the minimum value allowed (presently 500) or is greater than the maximum value allowed (presently 10,000).

If the error is a result of a system error returned from one of the RDOS system calls described in section 7.2, the error code ERCOD is set to -1 as a system error flag. For either type of error (program or system) return is made to the root binary section via ERRTN, as described in section 6.1(c).

8. OVERLAY MODULE--PHAS2.SR

This overlay module is the portion of the control program that initiates the start of data acquisition and supervises the operations of

the input and output MUX panels (multiplexers). This module has the complicated task of retrieving data from the input MUX and storing the data in a temporary buffer and, when the buffer is full, of transferring the data to the disk. Concurrently, the module is monitoring the real-time clock (RTC) and, at the preselected control times, updating the output MUX buffer data. These data are periodically sent to the output MUX panel to control the various BDACS operations during a test run.

Since the input and output data flow can take place at very fast rates (two input data words and one output data word can be transferred within 50 μs), the response of the standard RDOS interrupt service routine is not adequate. Thus, the main portion of the PHAS2.SR code contains a more streamlined interrupt service routine to handle the multiplexer, disk, and RTC operations. In addition, PHAS2.SR contains the test-run initiation and control loop code and data tables necessary to "set up" the multiplexer I/O controller. These three functions are described in more detail in the following sections, and the assembly language listing for PHAS2.SR is shown in appendix A, section A-3.

8.1 PHAS2.SR Multiplexer Controller Setup

The BDACS multiplexer controller contains the circuitry which provides the interface between the central processing unit (CPU) and the MUX input and output panels. Since this controller operates by direct memory access (DMA) data transfer, it must be preprogrammed with the appropriate core buffer address and word count for DMA. Furthermore, the information which controls the operation of MUX input and output panels must be supplied to the controller. These data are held in a PHAS2.SR data table and are transferred from the CPU to the multiplexer controller with the basic NOVA I/O instruction repertoire, as described below.

- (a) DMUXA holds the input and output MUX panel starting addresses and word counts. A four-bit address and a four-bit word count are associated with each type of panel. The information is supplied to the controller by a DOA instruction.
- (b) DMUXB holds the DMA input starting address for the initial DMA operation. The starting address points to a core buffer region in which the input data are stored. The address is supplied to the controller by a DOB instruction.
- (c) DMUXC holds the highspeed word option bit (1B1) and the sampling rate for the controller (in bits 1B4-1B15). Also, for proper transfer of the data, 1B0 flag bit should be "set." The data are supplied to the controller by a DOC instruction.

- (d) DMUXD contains the (negative) word count for the initial DMA operation. As noted above, this word count in conjunction with the starting address (DMUXB) controls the storing of input data in the core buffer. When the count is decremented to zero, a MUX interrupt occurs. In contrast to (c), a 1BO flag bit should be "reset" for proper transfer of the data by a DOC instruction.
- (e) DMUXE contains the (running) starting address for the remaining DMA operations. It typically contains a core address which is one less than that specified (in DMUXB). It is used to reset the running value of the address register in the controller following a MUX interrupt and overflow. Again, the data are supplied with a DOB instruction.
- (f) DMUXF contains the (running) negative word count for the remaining DMA operations. It typically contains a count one greater (in absolute magnitude) than that specified in DMUXD. It is used to reset the running value of the word-count register in the controller following a MUX interrupt and overflow. Again, the data are supplied with a DOC instruction with 1BO "reset."

Two I/O instruction special functions should also be supplied to the controller following the general reset of the controller. First, the START function may be supplied with any of the instructions given above and causes a reset of the DONE state and a set of the BUSY state in the controller. Second, the PULSE function is supplied to the controller immediately upon receipt of the BDACS operators signal to begin the test run (via the CPU console sense switch 1BO) and causes the controller to commence I/O operations.

8.2 PHAS2.SR Test-Run Initiation and Control Loop

The sequential tasks performed in PHAS2.SR are

- (a) wait for all TTY and disk operations to end; reset the multiplexer controller, disk, and RTC,
- (b) save the RDOS interrupt service routine pointer and enable the BDACS data acquisition interrupt service routine pointer and mask,
- (c) position the disk at the beginning of the BDACS data storage file (see sect. 3.6),
- (d) set up the multiplexer controller as described in section 8.1; set the RTC for 1 ms operation, and

(e) send a "ready" message to the BDACS operation on the TTY control unit; wait for the operator to initiate the test run; then start the RTC and MUX and branch to the control loop.

These tasks are performed within the control loop:

- (a) Check the remaining time count of the current table entry (see sect. 6.2(b)); if the count is zero, update the appropriate MUX output buffer word or set the appropriate special flag (for example, HLDFG is set when the disk storage holdoff time is complete; ENDFG is set when the end of data-acquisition time is complete). Move to the next table entry.
- (b) Check the RTC counter (RTCCT); if the count is nonzero, update the remaining time count for the current control table entry. Loop back to (a).

When data acquisition is ended, the data input buffer currently being filled is completed and transferred to the disk. The final tasks involve a general reset of the multiplexer controller, disk, and RTC and a replacement of the previously saved RDOS interrupt service routine.

8.3 PHAS2.SR Interrupt Service Routine

The special BDACS interrupt service routine for PHAS2.SR processes interrupts generated by either the multiplexer controller, the disk, or the RTC. This routine uses only accumulators ACO, ACl, and CARRY; thus, only these quantities need to be stored when entering the routine. The method by which each type of interrupt is handled is

- (a) RTC interrupt is very simply handled by restarting the clock with the NIOS instruction and incrementing the RTC counter (RTCCT). Return is then made to the interrupted program.
- (b) Disk interrupt first obtains the disk status word and checks for any error condition. The status word also determines which of two possible disk conditions initiated the interrupt. First, if a disk SEEK to a new track has just been completed, the service routine determines if a core buffer is full and the data in the buffer need to be transferred. If so, the transfer (disk WRITE) operation is initiated. disk flag (DKPFG) The is updated (for example, DKPFG=0 "idle," DKPFG=-1 "seeking," DKPFG=+1 "writes deferred," DKPFG=MUXFG "writing"), and return is made to the interrupted program. Second, if a disk WRITE operation has just been completed, the block count BLKCT (see sect. 6.1(j)) is decremented; the end of acquisition flag ENDFG is checked, and final closeout is made if ENDFG has been set.

The interrupt service routine then determines if a new disk track is required. If so, the disk SEEK is initiated, the disk flag described above is updated, and return is made to the interrupted program (or to the delayed WRITE initiating section, if required).

(c) MUX interrupt first obtains the MUX status word and restarts the controller. The status word is stored as the updated MUX flag (MUXFG) and compared to the previous status word for possible errors. Next, the disk storage holdoff flag (HLDFG) is checked. If reset, buffer transfer operations to the disk are inhibited and the holdoff counter (HLDCT, see sect. 6.1(k)) is incremented. If set, the disk flag (DKPFG, described above) is checked for "idle." If the disk is idle, the disk WRITE command is initiated, the disk flag is updated, and return is made to the interrupted program. If the disk is not idle, the disk flag is placed in "write deferred" and return is made to the interrupted program.

8.4 PHAS2.SR Error Routine

The error routine operation for PHAS2.SR is almost identical to that for PHAS1.SR (see sect. 7.4). In the present case, no RDOS system calls (or errors) occur. However, four program errors are monitored at present as described below.

- (a) ERRI--"DISK ERROR"--1B15 of the disk status word was set.
- (b) ERR2--"DISK OVERFLOW"--the maximum block transfer count was reached. Presently, this count is 2400 256-word disk blocks (that is, 100 complete tracks on the disk). This is a recoverable error in which present data acquisition stops, but BDACS control program processing of the data is initiated.
- (c) ERR3--"MULTIPLEXER ERROR"--two consecutive multiplexer status words were identical.
- (d) ERR4-"INPUT BUFFER OVERRUN"--two adjacent "deferred write" requests were attempted.

9. OVERLAY MODULE--PHAS3.SR

This overlay module contains the part of the BDACS control programs that supervises the retrieval and storage of the HSB data gathered during a test run. These data are presented to the high-speed word of the input multiplexer panel on an alternate set of 16 parallel data lines, after first being transmitted serially from the remote HSB storage unit to the HSB receiver unit adjacent to the multiplexer panels. An electronic switch controlled by point No. 319 of the

multiplexer output panel selects this alternate set of input data lines when the point on the output panel is activated or "set." Alternatively, the switch selects the normal set of input data lines when the point on the output panel is deactivated or "reset." Moreover, control of the serial transmission of each HSB data word is provided by point No. 320 of the multiplexer output panel. In particular, a command is initiated to transfer a new data word when the point on the output panel changes from "reset" to "set." Following this command, a delay of 4 ms is required to allow the data to be transferred and recombined at the HSB receiver circuits. Thus, PHAS3.SR must correctly control the states of both multiplexer output points No. 319 and 320.

PHAS3.SR is constructed along the same principles as PHAS2.SR described in section 8. In particular, a special-purpose interrupt service routine is used to control the multiplexer controller operations during the HSB data retrieval and storage. Following data retrieval, the standard RDOS interrupt service routine is reinstated. The stored HSB data are then transferred to the temporary disk data file TEMPB.TM described in section 3.8. Furthermore, if the final data vector is to be written on magnetic tape, the stored HSB data are also transferred to MTO:5, as described in section 5.1(f).

As with its predecessors, PHAS3.SR is composed of three parts, the main (backbone) code, the subroutines (including the interrupt service routine), and the text strings and buffers. The main features of these units are described below, and the assembly language listing for PHAS3.SR is shown in appendix A, section A-4.

9.1 PHAS3.SR Backbone Code

The PHAS3.SR backbone code includes both instructions and tables of data used during the execution of the instructions. Of particular importance are the parameters used to initiate and control the operation of the multiplexer controller.

- (a) DMUXA = 000060 initiates the controller to accept one word from the MUX input panel at MUX address corresponding to the high-speed word. It is this word which has the alternate set of data lines to the HSB receiver. At the same time, the last word on the MUX output panel is activated. This word contains output control points No. 319 and 320 used to control HSB retrieval operations.
- (b) DMUXB = INPUT-1 contains the beginning of a two-word input buffer where HSB data are initially deposited.
- (c) DMUXC = 140144 allows the multiplexer to operate in the LS/HS mode at a 144 $_{\rm g}$ - $\mu {\rm s}$ sample time.

- (d) DMUXD = 077776 contains the (negative) number of input words (-2) received before a multiplexer controller interrupt occurs.
 - (e) DMUXE = INPUT-2 contains the running value of (b).
 - (f) DMUXF = 077775 contains the running value of (d).
- (g) DMUXG = 147777 contains the alternate data to (c). For the present value, a 7777_8 - μs sample time is sufficient for the serial data transmission from the HSB transmitter to the HSB receiver.
- (h) CNTLL = 137777 contains the control word-pattern setting control point No. 319 "on" and point No. 320 "off."
- (i) CNTLH = 037777 contains the alternate control word pattern to (h). The present value allows the setting of both point No. 319 "on" and point No. 320 "on."
- (j) INPUT represents the address of the two-word input buffer area for DMA storage of the incoming HSB data.

The sequential tasks performed by the PHAS3.SR backbone code are summarized below.

- (a) Reset the HSB output buffer pointed to by HSBUF and the MUX output buffer pointed to by MUXOB.
- (b) Wait for all TTY and disk operations to end, save the RDOS interrupt service routine pointer and mask, and install the PHAS3.SR interrupt service routine pointer and mask.
 - (c) Initialize the multiplexer controller.
 - (d) Send an "HS Buffer Retrieval" message to the TTY console.
- (e) Start the multiplexer controller, retrieve the HSB data, and store the data in the output buffer area pointed to by HSBUF. Continue operations until the buffer count (presently 2048 words) reaches zero.
- (f) Transfer the buffer to disk file TEMPB.TM and, if the magnetic-tape option "M" is in effect, transfer the buffer to the tape file MTO:5.

9.2 PHAS3.SR Subroutine Code

Most of the subroutines encountered in PHAS3.SR have essentially the same structure as those subroutines described in section

- 7.2 for PHAS1.SR. In particular, the following subroutines are found in PHAS3.SR.
- (a) CRRFL creates a randomly organized disk file by using the system call .CRAND. The first parameter contains a name pointer to the name of the file to be created. If the file already exists, the old file is deleted and a new file is created; otherwise, all system errors cause a branch to the system error routine.
- (b) DELET deletes a file by using the system call .DELET. It is identical to subroutine DELET found in PHAS1.SR (see sect. 7.2(m)).
- (c) OPFLE opens a file on an RDOS channel by using the system call .OPEN. It is identical to subroutine OPFLE found in PHAS1.SR (see sect. 7.2(n)).
- (d) CLFLE closes a file on an RDOS channel by using the system call .CLOSE. It is identical to subroutine CLFLE found in PHAS1.SR (see sect. 7.2(o)).
- (e) OPMTA opens a magnetic-tape file for free format I/O on an RDOS channel by using the system call .MTOPD. It is identical to OPMTA found in PHAS1.SR (see sect. 7.2(y)).
- (f) MTAWT, MTASR, and MTAEF provide free format magnetic-tape operations using the system call .MTDIO. They are identical to MTAWT, MTASR, and MTAEF found in PHAS1.SR (see sect. 7.2(z), (aa), (bb)).
- (g) RDBLK reads a disk block from a file opened on channel No. 4 using the system call .RDB. It is identical to the subroutine RDBLK found in PHAS1.SR (see sect. 7.2(cc)).
- (h) TMPOT writes a series of disk blocks to a file opened on channel No. 3 using the system call WRB. The beginning of the first block corresponds to the beginning of the HSB output buffer pointed to by HSBUF. The number of blocks to be written is given by BLKCT (presently set to eight blocks for the HSB output buffer, corresponding to 2048 words in the buffer). All system errors cause a branch to the system error routine.
- (i) INTSR contains the interrupt service routine for PHAS3.SR. In this routine, only the multiplexer controller is enabled for interrupts. When a multiplexer interrupt occurs, the controller is immediately restarted (BUSY is "set" and DONE is "cleared"), and the controller status is read and checked. Depending on the status word

flag 180, the data previously stored in the input buffer (INPUT) are valid or invalid. Thus, with 180 set, the data word is invalid and is not stored in the HSB output buffer. On the other hand, with 180 reset, the data word is valid and is stored. In either case, the alternate control data word is updated in the output MUX buffer, and the alternate sample time word is transmitted to the controller. A normal exit is made from the interrupt service routine, except after the storage of last data word of the HSB output buffer.

9.3 PHAS3.SR Error Routine

The error routine for PHAS3.SR is identical to that for PHAS1.SR (see sect. 7.4). For the present case, the error code word generated and stored in ERCOD has overlay module No. 3 coded in the left-hand byte. At present, only a single program error is detected by PHAS3.SR.

ERRI--"MULTIPLEXER ERROR"--two consecutive multiplexer words were identical.

10. OVERLAY MODULE -- PHAS4.SR

This overlay module contains the part of the control program that performs a preliminary data reduction of the MUX and LSB data gathered and stored during the PHAS2.SR operation. These raw data were acquired (sampled) on a regular periodic basis as defined by the sampling rate specified by the BDACS operator (see sect. 4). As a consequence of this periodic sampling, the data signals may have been monitored many times in the same binary state, and much of the sampled data may be redundant. Therefore, the main task in PHAS4.SR is to scan the collected data, searching for changes in state for the monitored signals (i.e., changes from "0" to "1" or from "1" to "0"). When a state change is detected for a signal, the signal point number, the new state, and the time of the state change are all written into the BDACS data vector as a reduced data entry. This data reduction operation is applied only to those signals monitored with the MUX input panels and the LSB unit. Even then, only those signals which were previously specified by the BDACS operator are enabled for data reduction (see sect. 4). The HSB raw data are retrieved and stored in the data vector without any reduction, as described in section 9.

During data reduction, PHAS4.SR also supports an error detection and correction task. This task is performed by default unless the operator specifically disables error detection and correction by setting sense switch 1Bl on the CPU panel of the BDACS central processor unit. Error detection is achieved by a hardware strapping option which codes an address into each word of the input MUX panels. In particular, the

high-speed word of the input panel has 1816 strapped "on" while the remaining low-speed words all have 1816 strapped "off." Furthermore, bits 1813 through 1815 of the seven low-speed words are strapped with a binary number pattern from one to seven. This addressing scheme, although not the most efficient in preserving data positions on the input panels, retains the most data positions for the important high-speed word. When the data words are being reduced, the address of the word is checked for proper monitoring and storage sequence. If incorrect sequencing is detected, an error flag is set, and, if possible, a resequencing correction to the computed sample time is made. However, if the error appears too severe, data reduction is terminated, and a branch to the error routine is made.

As noted above, setting sense switch IBI disables error detection and correction. For this case, all bits of the data words are considered true data and not addresses. Data reduction is performed under the assumption that proper sequencing is maintained.

As with the previous overlay modules, PHAS4.SR may be logically separated into its backbone code, its subroutine code, and its text string and buffer area. Each of these regions is described more fully in the following paragraphs. The assembly language listing for PHAS4.SR is shown in appendix A, section A-5.

10.1 PHAS4.SR Backbone Code

The sequential tasks performed by PHAS4.SR are given in the following list.

- (a) Clear the reduced data output buffer pointed to by the parameter MTABF.
- (b) Open the raw data file BDACS.DA on channel No. 4. If the magnetic-tape "M" option is in effect, open magnetic-tape file MTO:6 on channel No. 3. Otherwise, create a random file TEMPC.TM, and open the file on channel No. 3.
- (c) Determine the initial sequence time at which raw data were stored by using the data storage holdoff count HLDCT (see sect. 6.1(k)) and the sample rate SMPRT (see sect. 6.1(g)). Store the initial time in the buffer pointed to by TIMER.
- (d) Determine the initial value of the previous low-speed word offset on the input MUX panels by using the data storage holdoff count HLDCT. The word offset is stored as PRADD.
- (e) Read the sense switches. Branch to address LO if IBl is "set" (i.e., if error detection and correction are suppressed); otherwise, branch to address LL1.

- (f) Read and reduce the MUX and LSB raw data. Store reduced data entries in the buffer area pointed to by MTABF. When the buffer is full, transfer the buffer to the file opened on channel No. 3 (i.e., either MTO:6 if the magnetic tape is enabled, or TEMPC.TM temporary disk file). Continue until the number of data blocks specified by BLKCT (see sect. 6.1(j)) has been reduced.
- (g) Close the files previously opened on channels No. $3\,$ and 4, and return to the root segment program.

10.2 PHAS4.SR Subroutine Code

Many of the subroutines used in PHAS4.SR--especially those associated with file I/O which use RDOS system calls--are identical to those already described in sections 7 and 9 and will not be repeated here. Other subroutines unique to PHAS4.SR are described below.

- (a) INTMR increments the present value of the sequence time (pointed to by TIMER). The incremental value is given by the sample rate SMPRT. Typically, the subroutine is called from the backbone code or from the subroutine RDBWD following the proper reduction of a high-speed word/low-speed word pair. This conforms to the actual sampling sequence which was performed in the data acquisition. Thus, the contents of TIMER contain the elapsed time from start of data acquisition to the time the datum (currently being reduced) was monitored. In addition, INTMR updates the low-speed buffer point number (LSPNT), the low-speed buffer word mask (LSWMK), and the low-speed buffer word offset (LSOFF). Again, in the actual acquisition, LSB data were serially transmitted with one data bit every sample cycle.
- (b) RDBWD reduces the data word entered in accumulator ACO. Upon entry to the subroutine, accumulator AC2 contains the offset from the start of the MUX reported points mask table associated with the particular word. The mask table, located in the root binary segment, is pointed to by MSKTB and is described in section 6.2(a). positions of the data word are first checked against the corresponding positions in the mask table to determine which points are enabled for data reduction. Those enabled points are then checked against the previous state values to determine if a state change occurred. Only if a state change occurs are the point number, the new state, and the current sequence time (given by the value of TIMER) transferred to the reduced data output buffer MTABF. Reduced data transferred to MTABF consist of three-word entries. The first word contains the point number, the state, the MUX/LSB flag, and the error recovery flag. The point number is in the RH position and the current state "0" or "1" is in bit position 180. If the datum is an LSB signal, bit position 181 is "1"; otherwise, 1B1 is "0" for an input MUX signal. If a sequence error was detected, bit position 1B7 is "1." The second and third words of

the output buffer entry contain the DP binary value of the current sequence time. The output buffer can hold 256 entries (768 words). When the buffer becomes full, the information is transferred to the file opened on channel No. 3 (either MTO:6 or TEMPC.TM), and the buffer is reset.

- (c) LSBRD reduces data associated with the LSB. The subroutine is called from RDBWD whenever the LSB has been enabled for monitoring (LSMON is nonzero, see sect. 6.1(i)), and whenever the high-speed word of the input MUX panel is being reduced. The latter requirement is tested since the LSB data are received only on an input point of the high-speed word. Within the subroutine, the present LSB point number contained in LSPNT is checked against the associated bit position of the LSB mask table. The mask table, located in the root binary segment, is pointed to by LSBTB and is described in section 6.2(b). Those LSB point numbers which are enabled for data reduction are then checked against the previous state value. If a state change has occurred, the new state and the LSB point number (with lBl set to "l") is returned to the calling program (i.e., RDBWD).
- (d) GTBWD controls the retrieval of the raw data from the BDACS.DA file using the system call .RDB. A complete data block of 3072 words is read to the data input buffer pointed to by BUFFR. The individual data words are then returned to the calling program in accumulator ACO and the buffer pointer is updated each time the subroutine is called. When all data have been retrieved (as determined by the data block count BLKCT), a branch is made to address DONE to complete PHAS4.SR operations. As an added option within this subroutine, the sense switches on the CPU panel are read following the retrieval of the current data word. If sense switch 1B15 is "set," the raw data word is printed to the TTY console. Thus, the BDACS operator may selectively monitor the raw data which were acquired during a test run. This option may be useful for tracing possible error conditions.
- (e) DMPWD generates the text string for the printout of the data word just described. The printout text consists of a set of 16 ASCII binary numbers corresponding to the 16 bit positions of the data word. The text string is stored in a buffer pointed to by byte pointer DPMSG.

10.3 PHAS4.SR Name/Text Strings and Buffers

The PHAS4.SR name and text strings are constructed in a manner similar to that described in section 7.3. The buffer areas used by PHAS4.SR are pointed to by the following parameters.

(a) MTABF is 768 words long and is used to hold the reduced data output entries (256 max) before they are transferred to the BDACS data vector.

(b) BUFFR is 3072 words long and is used to hold a raw data block previously written in the BDACS.DA file during data acquisition.

10.4 PHAS4.SR Error Routine

The error routine for PHAS4.SR operates identically to that for PHAS1.SR (see sect. 7.4). At present, four program errors are monitored as described below.

- (a) ERR1--"CURRENT TIME OVERFLOW"--a double-precision overflow occurred for the number held in the current sequence time TIMER during initial timer setup.
- (b) ERR2--"CURRENT TIME OVERFLOW"--a double-precision overflow occurred for the number held in the current sequence time TIMER during sequential updating.
- (c) ERR3--"MAJOR SEQUENCE SLIP OCCURRED"--a noncorrectable sequence error was encountered. An indeterminate number of sequence step omissions occurred.
- (d) ERR4--"MAX SEQUENCE ERROR COUNT EXCEEDED"--the maximum permissible number of sequence errors was exceeded (present errors set at 100).

11. OVERLAY MODULE -- PHASS.SR

This overlay module contains the part of the control program that performs the query/response operations associated with the POSTSCRIPT.DA file and completes construction of the BDACS data vector. In addition, PHAS5.SR provides the on-line data printout, if this printout is required.

As with the preceding overlay modules, PHAS5.SR is logically divided into three main regions: the "backbone" code, the subroutines, and the name/text strings and buffer area. These regions are described in detail in the following paragraphs, and the assembly language listing for PHAS5.SR is shown in appendix A, section A-6.

11.1 PHAS5.SR Backbone Code

The PHAS5.SR backbone code is primarily a set of sequential tasks designed to complete the BDACS data vector and generate the BDACS on-line printout. The main tasks are given in the following list.

(a) Open the console input file (\$TTI) on channel No. 2; create the temporary file TEMPD.TM and open this file on channel No. 3.

- (b) Open the POSTSCRIPT.DA file on channel No. 4; read the postscript query/statement lines and obtain the BDACS operator response; construct TEMPD.TM.
- (c) Transfer TEMPD.TM to the magnetic-tape file MTO:7 (if the "m" option is in effect). Close the files on channels No. 2, 3, and 4.
- (d) Open the on-line printout file on channel No. 2 (\$TTO if "T" option is in effect, or \$LPT if "L" option is in effect).
- (e) Print the BDACS on-line "header" information; print the preamble and postscript information (obtained from TEMPA.TM and TEMPD.TM); print the "method" file which was employed for the current test run. See figures 3 and 4 for an example of these printouts.
- (f) If the HSB unit was enabled, print the HSB assignment list (obtained from ASSIGNA.DA, see sect. 33). Print the HSB data obtained during the current test run (obtained from TEMPB.TM). See figure 5 for an example of these printouts.
- (g) If either or both of the input MUX panels or the LSB unit contain signals which have been enabled for on-line printout, then open the assignment list files ASSIGNB.DA for the MUX signals and ASSIGNC.DA for the LSB signals on channels No. 4 and 5, respectively. Open the reduced data file on channel No. 3 (either MTO:6, if the "M" option is in effect, or TEMPC.TM).
- (h) Read the entries in the reduced data file; construct a printout line consisting of the entry data and the signal mnemonic obtained from the appropriate assignment list file; continue processing the signals enabled for on-line printout until all data entries have been scanned. See figure 6 for an example of these printout lines.
- (i) Close the files on channels No. 1, 2, 3, 4, and 5 and return to the root binary segment.

11.2 PHAS5.SR Subroutine Code

Many of the subroutines used in PHAS5.SR, especially those associated with file I/O which use RDOS system calls, are identical to those already described in sections 7 and 9 and will not be repeated here. Other subroutines unique to PHAS5.SR are described below.

- (a) GTDAT retrieves the reduced data entries for the MUX or LSB data previously stored during PHAS4.SR operations. Initially, the subroutine reads an entire block of 256 data entries into a buffer area pointed to by BUFFR. As succeeding subroutine calls are made, the current entry pointer is updated until all entries in the buffer have been scanned. The buffer is then refilled with new entries and the scanning is continued. Upon exit from the subroutine accumulator AC2 contains the pointer to the current entry being processed.
- (b) OPEN retrieves an assignment list entry from from one of the assignment files ASSIGNA.DA, ASSIGNB.DA, or ASSIGNC.DA. The first parameter for the subroutine call contains the point number of the

signal whose assignment mnemonic text is required. The second parameter contains the pointer to the buffer containing part of the associated assignment file. In particular, files ASSIGNA.DA, ASSIGNB.DA, and ASSIGNC.DA are read into buffer areas pointed to by BUFRA, BUFRB, and BUFRC, respectively. These buffers are 256 words long and, thus, contain 32 assignment mnemonic text strings, each being 8 words (16 bytes) long. If the required assignment text string is not among the current set of 32 strings presently in the buffer, the subroutine performs a disk-block read operation using system call .RDB to retrieve the required text string from the appropriate assignment file. A normal exit is made from the subroutine with accumulator AC2 containing a byte pointer to the required text string within the assignment file buffer. An abnormal exit is made to the error routine for all system errors.

- (c) PRFLE prints the contents of an ASCII data file on the on-line printout device. The one parameter required for the subroutine is the name pointer to the ASCII data file to be printed. The data file is opened on RDOS channel No. 4; the file is read line by line, and each line is printed using subroutine PRLNE (described next); channel No. 4 is then closed. No exceptional condition is explicitly contained in this subroutine.
- (d) PRINE is the basic code for controlling and directing the on-line printout for BDACS. Two parameters are required for this subroutine. The first parameter contains a byte pointer to the message to be printed. The second parameter contains (in absolute magnitude) the number of lines that the message will require for printing. If the second parameter is a negative number, a top-of-form operation is performed before the printing. A maximum of 30 lines per page may be printed before an automatic top-of-form operation occurs. The subroutine maintains a current line count (LNCNT) and page count (PGCNT), and, when a top-of-form operation is performed, a new page number is printed. The BDACS operator may suppress printing by setting the sense switches on the CPU panel to all "1's." This suppression will continue until either the sense switches are reset (i.e., one or more to "0") or until a programmed top-of-form operation is initiated. The BDACS operator must then reapply the sense switches if suppression of the current phase of the on-line printout is to continue.
- (e) CHKPM determines if the on-line printout mask portion of MUX or LSB mask tables contains on-line printout requests. Two parameters are necessary for this subroutine. The first parameter contains the points to the mask table, either MSKTB or LSBTB for the MUX or LSB, respectively. The second parameter contains the offset count for the different parts of the mask table (see sect. 6.2(a) and (b)). Upon entry to the subroutine, accumulator ACO contains the on-line printout request flag, initially set to zero. If any on-line printout mask word in the mask table is nonzero (indicating that at least one signal requires printing), the accumulator ACO is incremented.

- (f) MVBYT transfers a text string from a source region to a destination region. The one parameter required for this subroutine contains the maximum number of bytes to be transferred. Upon entry to the subroutine, accumulators ACO and AC2 contain the byte pointers to the destination text string and the source text string, respectively. Transfer of bytes continues until either a null byte is detected in the source string or else the maximum number of bytes, as specified by the input parameter, has been transferred. Upon exit from the subroutine, accumulator AC2 contains the byte pointer to the byte following the end of the destination text string.
- (g) FMSPN creates an ASCII decimal integer text string corresponding to the single-precision unsigned binary integer contained in accumulator ACO. Upon entry to the subroutine, accumulator AC2 contains the byte pointer to the start of the text area where the string is created. Leading zeros in the generated text string are suppressed to blanks. Upon exit from the subroutine, accumulator AC2 contains the byte pointer to the byte following the generated text string.
- (h) FMDPN creates an ASCII decimal integer text string corresponding to the double-precision unsigned binary integer contained in accumulators ACO and ACl. The operation is similar to that in FMSPN.
- (i) MTAIN performs a magnetic-tape free format "read" operation from the magnetic-tape file opened on channel No. 3. The single parameter required by the subroutine contains an address to branch to when an "end-of-file" is detected. The data are transferred to the buffer pointed to by BUFFR in blocks of 768 words each. Except for "end-of-file," all system errors cause a branch to the system error routine.
- (j) TMPIN retrieves a block of data from the disk file opened on channel No. 3. The single parameter required by this subroutine contains an address to branch to when an "end-of-file" is detected. The data are transferred to the buffers pointed to by BUFFR in blocks of 768 words each. Except for the "end-of-file," all system errors cause a branch to the system error routine.

11.3 PHAS5.SR Name/Text Strings and Buffers

The PHAS5.SR name and text strings are constructed in a manner similar to that described in section 7.3. Particular strings, unique to PHAS5.SR, are those used for "headers" and standard line formats for the on-line printout. The buffer areas used by PHAS5.SR are pointed to by the following parameters.

(a) UTBPT defines a region of 68 words used for utility byte transfer operations.

- (b) BUFRA is divided into two parts. The first part contains a 256-word data storage area. The second part is a three-word buffer "header," which has a negative offset from BUFRA. The first word of the "header" (at offset -3) contains the starting signal point number for the HSB. The second word of the "header" (at offset -2) contains the RDOS channel number (in the RH part) and the I/O block count (in the LH part) associated with the HSB assignment file (ASSIGNA.DA). The third word of the "header" (at offset -1) initially contains 177777. During PHAS5.SR operation, this word will contain the block number of the current ASSIGNA.DA block contained in the data part of the buffer. This current block number is updated under control of subroutine OPEN (see sect. 11.2(b)).
- (c) BUFRB is similar to BUFRA, except that the present buffer is associated with the MUX assignment file (ASSIGNB.DA).
- (d) BUFRC is similar to BUFRA, except that the present buffer is associated with the LSB assignment file (ASSIGNC.DA).
- (e) BUFFR contains a data area sufficient to hold 256 LSB or MUX reduced data entries (presently 768 words). Entry blocks of this size are read into the buffer either from magnetic-tape file MTO:6 (if the "M" option is in effect) or from disk file TEMPC.TM, under control of subroutines MTAIN or TMPIN, respectively (see sect. 11.2(i) and (j)).

11.4 PHAS5.SR Error Routine

The error routine for PHAS5.SR operates identically to that for PHAS1.SR (see sect. 7.4). At present, four program errors are monitored:

- (a) ERR1--"ASSIGN FILE READ ERROR OCCURRED"--a system error occurred during the "read" operation in subroutine OPEN (see section 11.2(b)).
- (b) ERR2--"ASSIGN FILE SEQUENCE ERROR OCCURRED"--the signal point number for a requested assignment file text string was less than the starting-signal number specified in the "header" of the associated assignment file buffer (see sect. 11.3(b)).
- (c) ERR3--"LINE COUNT ERROR"--the updated line count in subroutine PRLNE is negative.
- (d) ERR4--"MUX OR LSB POINT # OUT OF BOUNDS"--the signal point number contained in a MUX or an LSB reduced data entry is less than the starting-signal point number.

12. OVERLAY MODULE ERMSG.SR

This overlay module contains the part of the control program that performs an orderly closing of BDACS functions and returns control to the RDOS-CLI. The overlay module can be entered from the root binary segment in one of two modes. The "normal" mode is entered when all BDACS control tasks have been successfully performed and a normal exit has been made from the preceding overlay modules. Under these conditions, the error code word (ERCOD, see sect. 6.1(d)) contains zero as a flag to immediately branch to the address NORML in ERMSG.SR. Closeout is then achieved by performing the following tasks.

- (a) Reset all RDOS channels using the system call .RESET.
- (b) Release the magnetic-tape drive using the system call .RLSE. Ignore any system errors, since the magnetic tape may not have been initialized.
 - (c) Return to the CLI by using the system call .RTN.

The "exceptional" mode of entering ERMSG.SR occurs when an error has been detected during the operation of an earlier overlay module. The error code word (ERCOD) contains the error code as described in section 7.4.

Two types of errors are recognized: program and system. For a system error, ERCOD contains 177777 as a flag, and the recovery parameter (RECOV, see sect. 6.1(b)) contains the system-generated error code. Closeout during a system error condition is achieved in a manner similar to that described in (a), (b), and (c) above for "normal" closeout. However, instead of an exit to the CLI by the normal return (i.e., .RTN), for the present situation the system error code from RECOV is retrieved and stored in accumulator AC2, and return is made to the CLI using the system call .ERTN.

When a program error occurs, ERCOD contains the program error code as described in section 7.4. For this case the following tasks are performed within ERMSG.SR.

- (a) Decompose the program error code into the module number and error number; determine the error message byte pointer associated with the error number and the recoverable error bit.
 - (b) Type the module message to the output console:

"ERROR IN PHASE n"

where n is replaced by the overlay module number in which the error occurred.

- (c) Type the error message describing the associated error number. These messages are discussed in the preceding sections describing the different overlay modules.
- (d) Determine if a recoverable error occurred by checking the recoverable error bit processed in (a) above. If the error is recoverable, return to the root-binary segment. Otherwise, close out the BDACS control program in the "normal" mode as described above.

The tables that are used in ERMSG.SR are described below.

- (a) TBLPT contains a list of pointers to the beginning of the message pointer tables. One such message-pointer table is associated with each of the preceding overlay modules (i.e., PHAS1, PHAS2, PHAS3, PHAS4, PHAS5).
- (b) PHAS1 contains a list of error-message pointers for overlay module PHAS1.SR. A one-to-one correspondence exists between these error-message pointers and the error table entries described in section 7.4.
- (c) PHAS2, PHAS3, PHAS4, and PHAS5 are similar to PHAS1 but are associated with overlay modules PHAS2.SR, PHAS3.SR, PHAS4.SR, and PHAS5.SR, respectively. Note: If bit 1B0 is set to "1" for any message pointer, the associated error is considered "recoverable" and is processed as described in (d) above.

The error messages are RDOS ASCII text strings with mode 1 packing. The assembly language listing for ERMSG.SR is shown in appendix A, section A-7.

13. CONTROL PROGRAM SYSTEM PARAMETERS--BDACS.SR

This file contains those BDACS control parameters which may be modified or extended as the BDACS hardware system is changed or augmented to meet future requirements. As mentioned in section 2, BDACS.SR should be assembled along with the appropriate root binary segment or overlay module files to reflect the present value of these system parameters. A brief description of these parameters along with their present value (in octal) is given below, while an assembly language listing for BDACS.SR is given in appendix A, section A-8.

(a) NOP=000401 provides a mnemonic "no operation" instruction (i.e., JMP .+1). This parameter is not expected to change if the system is augmented.

- (b) CLK=054 contains the RTC device interrupt code. Note: this clock interrupt code is not the standard RDOS code.
- (c) MUX=032 contains the multiplexer controller device interrupt code which is hardwire strapped at the controller.
- (d) MUXOB=000300 contains the output multiplexer panel buffer address. This address is hardwire strapped within the multiplexer controller.
 - (e) IMCLK=000004 contains the interrupt mask bit for the RTC.
- (f) IMMUX=001000 contains the interrupt mask bit for the multiplexer controller.
- (g) IMDKP=000400 contains the interrupt mask bit for the moving-head disk controller.
- (h) BDACA=200 contains the number of signal points located on the input MUX panels (128 decimal).
- (i) BDACB=100 contains the number of signal points located on the output MUX panel (64 decimal).
- (j) BDACD=144 contains the starting cylinder (track) number for the BDACS raw data file BDACS.DA (see sect. 3.6).
- (k) BDACE=144 contains the number (100 decimal) of complete cylinders used for file BDACS.DA. Thus, the size of this file is 2400 disk blocks. This size should be reflected in the UFT entry of the RDOS system directory SYS.DR and in the RDOS map directory MAP.DR. If a full initialization of the BDACS disk cartridge is required, the BDACS operator must insure that this file information is properly supplied (e.g., by using the RDOS disk editor DSKED.SV).
- (1) BDACF=1 contains the minimum or starting input MUX panel signal number.
- (m) BDACG=200 contains the maxium or last input MUX panel signal number (128 decimal).
- (n) BDACH=401 contains the minimum or starting output MUX panel signal number (257 decimal).
- (o) BDACI=476 contains the maximum or last output MUX panel signal number (318 decimal). Note: this number does not include the two special-purpose control points No. 319 and 320 used to control HSB data-retrieval operations (see sect. 9).

- (p) BDACJ=200 contains the maximum number of entries in the output control list (128 decimal).
- (q) BDACK=03 contains the number of words per entry in the output control list.
- (r) BDACL=03 contains the number of words per entry in the MUX and LSB reduced data file entry.
- (s) BDACM=6000 contains the number of words per data block used during data acquisition and reduction (3072 decimal).
- (t) BDACN=144 contains the maximum number of sequence errors allowed (100 decimal).
- (u) BDACO=4000 contains the number of words in the HSB unit (2048 decimal).
- (v) BDACP=200 contains the number of signal points located on the LSB unit (128 decimal).
- (w) BDACQ=1 contains the minimum or starting signal number for the LSB.
- (x) BDACR=200 contains the maximum or last signal number for the LSB (128 decimal).
- (y) BDACS=1 contains the minimum or starting bit number for the HSB unit.
- (z) BDACT=20 contains the maximum or last bit number for the HSB unit (16 decimal). Note: the number of bits per word in the HSB cannot be changed from the present value of 20_8 (16 decimal) without major changes in the overlay module responsible for HSB data retrieval.
- (aa) BDACU=60 contains the minimum MUX sample rate (in μs , 50 decimal).
- (bb) BDACV=7777 contains the maximum MUX sample rate (in $\mu \text{s}\text{, 4095}$ decimal).
- (cc) BDACW=764 contains the minimum HSB sample rate (in ns, 500 decimal).
- (dd) BDACX=23420 contains the maximum HSB sample rate (in ns, 10,000 decimal).
- (ee) BDAC1=10 contains the number of 16-bit input MUX words (8 decimal).

- (ff) BDAC2=4 contains the number of 16-bit output MUX words (4 decimal).
 - (qq) BDAC3=10 contains the number of 16-bit LSB words (8 decimal).
- (hh) BDAC5=600 contains the number of words required for the MUX output control list buffer (384 decimal).
- (ii) BDAC6=20 contains the number of words offset between the start of the MUX or LSB mask table and the on-line printout part of the table (16 decimal).
- (jj) BDAC7=7 contains the number of input MUX low-speed words (7 decimal).
- (kk) BDAC8=3000 contains the number of high-speed/low-speed word pairs per raw data block (1536 decimal).
- (11) BDAC9=1400 contains the number of words in the MUX and LSB reduced data block (768 decimal).

14. RECOMMENDATIONS FOR FUTURE SOFTWARE AUGMENTATION

A major shortcoming of the present BDACS control program is the inability of the program to provide a real-time analysis of and response to the incoming data during data acquisition. Presently, the control functions to be provided by the program are prearranged and occur independently of the data being monitored.

It is possible to provide real-time data analysis/response for BDACS. However, several basic adjustments and changes to the BDACS software package would be required. These changes are outlined in the following paragraghs.

- (a) Presently, during PHAS2.SR data acquisition and control, program control switches between the interrupt service routine (when a device interrupt occurs) and the control loop which continually monitors and updates the control output list for the next control point change (see sect. 8.2 and 8.3). If the real-time analysis/response option is to be implemented, then an additional branch must be provided to the program code controlling this analysis/response action.
 - (b) A specific example and possible implementation:

EXAMPLE

- Allow a single low-speed word to be available for analysis. Thus, the individual bits or a pattern of several bits in combination within this word will be recognized as a request for specific control or response actions.
- Let the 1B0 bit for the word be strapped as a "1." Thus, when the word is monitored and stored in the memory buffer, bit 1B0 will be set.
- Provide a circular buffer pointer which will point to the current word to be analyzed and, upon updating, will point to the succeeding word.
- When a current word has been retrieved for analysis, the storage area in memory will be reset.
- With the current word as data, a branch is made to the analysis/response control subroutine for appropriate action. Upon return from this subroutine, a control loop is entered and scanning is continued until the word is again monitored and becomes "set."
- The interrupt service routine would be essentially unchanged, except, upon exit from the RTC service, a special branch to the predefined control operations control loop would be made. The exit would then be from this loop to the control loop specified above.
- (c) In the example, timing considerations must be made to insure proper operation. In particular, the analysis/response subroutine must be efficiently constructed so that the words to be analyzed do not "stack up." This condition may also require the minimum allowable sample rate to be longer than the present minimum (50 μs).
- (d) The particulars of the analysis/response subroutine depend in detail upon the specific real-time control tasks to be performed. These tasks may possibly change from test to test and, if this occurs, either several control programs must be individually assembled and linked or several separate PHAS2.SR types of overlay modules must be assembled and linked in a universal control program. If the latter choice is made, additional provisions must be made in the root-binary segment of the universal control program to choose one of the several PHAS2.SR overlay modules to load in at runtime.
- (e) One final modification to the present control program may be required. Presently, the BDACS control program resides in memory with the RDOS executive program. The controlling factor in the expansion of the BDACS control program is primarily the size of the PHAS2.SR overlay module, since this module contains the twin data blocks—each 6000_8 words in length. If the PHAS2.SR module must be greatly expanded to

include the analysis/response subroutine code, an incompatibility may arise in which the core storage is insufficient to contain both the BDACS control program and RDOS executive program. Since PHAS2.SR does not require any RDOS system calls, if this incompatibility arises, the executive program can be temporarily transferred to disk, and the core storage used by the executive may be made available to the control program. Before an exit from PHAS2.SR, the executive program would, of course, be returned to core storage. If this action is necessary, it is recommended that tracks No. 201, 202, and 203 (decimal) on the disk be reserved in the RDOS MAP.DR for the executive program storage.

APPENDIX A.--ASSEMBLY-LANGUAGE LISTING FOR BDACS CONTROL PROGRAM

This appendix contains the assembly-language listing for the BDACS control program. The control program is composed of a root-binary section, six overlay modules, and a table of system parameters. Each of these parts is presented in the following sections of the appendix.
