1. Introduction

In this paper, we present a class of iterative descent methods for solving large, sparse, nonsymmetric systems of linear equations whose coefficient matrices have positive-definite symmetric parts. Such problems commonly arise from the discretization of non-self-adjoint elliptic partial differential equations. The methods we consider are modelled after the conjugate gradient method (CG) [14-16]. They require no estimation of parameters and their rate of convergence appears to depend on the spectrum rather than  $A_{\alpha}^T A_{\alpha}$ . Their convergence can also be accelerated by preconditioning techniques.

The methods are tested on two sample problems, and their numerical behavior is compared with that of two other methods, the nonsymmetric Chebyshev algorithm [10, 11], and the conjugate gradient method applied to normal equations [8, 9, 13]. All the methods are tested in conjunction with two preconditionings, the incomplete LU factorization [12], and the modified incomplete LU factorization [3, 6].

In Section 2, we describe the methods, outline their computational costs, and present some bounds on their convergence rates. In Section 3, we show how they can be implemented with preconditioning techniques. In Section 4, we describe two sample nonsymmetric model problems derived from a non self-adjoint elliptic equation. Finally, in Section 5, we present the results of numerical experiments with the methods. Tables and figures follow the list of

## 2. The Generalized Conjugate Descent Method, and Variants

In this section, we describe a class of descent methods for solving the linear system

卷之三

where  $A$  is a nonsymmetric matrix of order  $N$  with positive definite symmetric

Please consider four variables all of which have the following form:

THE JOURNAL OF CLIMATE

A rather than  $\mathbf{A}_P^T$ . Their convergence can also be accelerated by preconditioning techniques.

The methods are tested on two sample problems, and their numerical behavior is compared with that of two other methods, the nonsymmetric Chebyshev algorithm [10, 11], and the conjugate gradient method applied to normal equations [8, 9, 13]. All the methods are tested in conjunction with two preconditionings, the incomplete LU factorization [12], and the modified incomplete LU factorization [3, 6].

The choice of  $\alpha_1$  satisfies  $\|I - A(x_1, \alpha_1)\|_2 = \|I - \alpha_1\|_2$  as a function of  $\alpha_1$ , so that the Euclidean norm of the residual decreases at each step. The fear methods are determined by four techniques for choosing  $\beta_{k+1}$ :

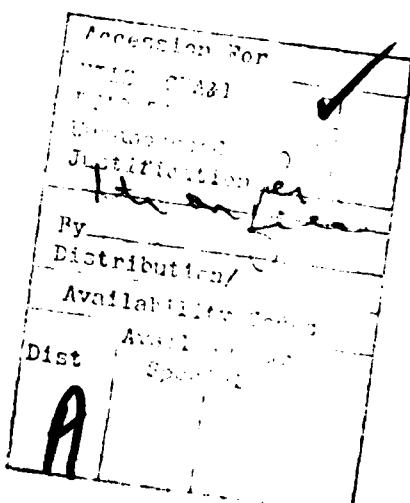

卷之三

### (11) Generalized Conjugate Residual (GCR):

$$P_{i+1} = x_{i+1} + \sum_{j=0}^i b_j^{(i)} P_j \quad . \quad (2.2)$$

三

$$b_j^{(1)} = - \frac{(\Delta x_{j+1}, \Delta p_j)}{(\Delta p_j, \Delta p_j)}, \quad j \leq 1. \quad (2.3)$$

(2) Orthomin(k) [11]:

$$\mathbf{p}_{i+1} = \mathbf{r}_{i+1} + \sum_{j=\max(0, i-k+1)}^i \frac{\mathbf{b}_j^{(i)}}{\mathbf{b}_j^{(i)}} \mathbf{p}_j$$

where  $(\mathbf{b}_j^{(i)})$  are defined by (2.3).

(3) GCR(k):

The generalized conjugate residual algorithm restarted every k+1 steps. Every k+1 steps, the current iterate,  $\mathbf{x}_i(k)$ , is taken as the new starting guess.

(4) Minimum Residual (MR):  $\mathbf{p}_{i+1} = \mathbf{r}_{i+1}$ .

The direction vectors  $(\mathbf{p}_i)$  generated by GCR are constructed so that

$$(\mathbf{A}\mathbf{p}_i, \mathbf{A}\mathbf{p}_j) = 0 \text{ for } i \neq j.$$

As a result,  $\mathbf{x}_i$  minimizes the functional  $R(\mathbf{v}) = \|\mathbf{f} - \mathbf{Av}\|_2$  over the affine space  $\mathbf{x}_0 + \text{span}(\mathbf{p}_0, \dots, \mathbf{p}_{i-1})$ , and

$$\|\mathbf{r}_i\|_2 = \min_{\mathbf{q}_i \in \mathcal{Q}_i} \|\mathbf{q}_i(\mathbf{A})\mathbf{r}_0\|_2. \quad (2.4)$$

GCR is the analogue of the conjugate residual method (CR) [2, 15] for symmetric problems. If  $\mathbf{A}$  is symmetric and positive-definite, then (2.2) reduces to a two-term expression and the resulting algorithm is equivalent to CR.

Orthomin(k) has been proposed as an alternative to GCR that is less expensive in terms of both work per iteration and storage. The vector  $\mathbf{p}_{i+1}$  is orthogonal to only the last  $k$  ( $\geq 0$ ) vectors  $\{\mathbf{p}_j\}_{j=i-k+1}^i$ . Only  $k$  direction vectors need to be stored. The iterate  $\mathbf{x}_i$  minimizes  $R(\mathbf{v})$  over the affine space  $\mathbf{x}_0 + \text{span}(\mathbf{p}_{i-k+1}, \dots, \mathbf{p}_i)$ .

GCR(k) is also proposed as a less expensive alternative to GCR. As in Orthomin(k), at most  $k$  direction vectors have to be saved. The cost per iteration is lower, since in general fewer than  $k$  direction vectors are used to compute  $\mathbf{p}_{i+1}$ .

MR corresponds to the special case of  $k = 0$  for both Orthomin(k) and GCR(k). It has very modest work and storage requirements, and in the symmetric case resembles the method of steepest descent.

In Table 2-1, we summarize the work and storage costs (excluding storage for  $\mathbf{A}$ ) of computing  $\mathbf{x}_i$  for each of the methods. The storage for GCR includes space for the vectors,  $\mathbf{x}_i$ ,  $\mathbf{r}_i$ ,  $\mathbf{A}\mathbf{x}_i$ ,  $\mathbf{p}_0, \dots, \mathbf{p}_i$ , and  $\mathbf{A}\mathbf{p}_0, \dots, \mathbf{A}\mathbf{p}_i$ .  $\mathbf{A}\mathbf{p}_i$  is computed recursively as

$$\mathbf{A}\mathbf{p}_i = \mathbf{A}\mathbf{x}_i + \sum_{j=\max(0, i-k)}^{i-1} \mathbf{b}_j^{(i-1)} \mathbf{A}\mathbf{p}_j.$$

so that the only matrix-vector product required is  $\mathbf{A}\mathbf{x}_i$ . The entries for Orthomin(k) correspond to the requirements after the  $k$ 'th iteration. The work for GCR(k) is the average over  $k+1$  iterations.

GCR gives the exact solution to (2.1) in at most  $N$  iterations. The three variants do not in general display finite termination. In practice, however, all four methods tend to compute sufficiently accurate solutions in far fewer than  $N$  iterations.

We now present some error bounds for the four methods. Let  $\mathbf{M} := (\mathbf{A}\mathbf{A}^T)/2$  denote the symmetric part of  $\mathbf{A}$ , and let  $\mathbf{R} := -(\mathbf{A}^T\mathbf{A})/2$  denote the skew-symmetric part of  $\mathbf{A}$ , so that  $\mathbf{A} = \mathbf{M} + \mathbf{R}$ . Let  $\mathbf{J} := \mathbf{V}^T\mathbf{A}^{-1}\mathbf{V}$  denote the Jordan canonical form of  $\mathbf{A}$ . For any square matrix  $\mathbf{X}$ , let  $\mathbf{q}(\mathbf{X})$  denote the set of eigenvalues of  $\mathbf{X}$ . Let  $\lambda_{\min}(\mathbf{X})$  denote the eigenvalue of  $\mathbf{X}$  of smallest absolute

value. Let  $\lambda_{\max}(A)$  denote the eigenvalue of largest absolute value, and let  $\rho(A)$  denote the spectral radius of  $A$ . If  $\lambda_{\max}(A) = 1$ , then  $\|Ax\|_2 \leq \|A\|_2 \|x\|_2$ . Finally, let  $P_A$  denote the condition number of  $A$ , defined to be  $K(A) := \|A\|_2 \|A^{-1}\|_2$ .

Finally, let  $P_A$  denote the set of real polynomials  $q_i$  of degree less than or equal to  $i$  such that  $q_i(0) = 1$ .

The following bounds for GM and GM(k) are proved using (2.4):

**Theorem 2.1:** If  $\{\mathbf{r}_i\}$  is the sequence of residuals generated by GM, then

$$\|\mathbf{r}_i\|_2 \leq \min_{q_i \in P_i} \|\mathbf{b}_{q_i}(A)\|_2 \|\mathbf{r}_0\|_2 .$$

If  $A$  has a complete set of eigenvectors, then

$$\|\mathbf{r}_i\|_2 \leq K(R) M_i \|\mathbf{r}_0\|_2 .$$

where

$$M_i := \min_{q_i \in P_i} \max_{\lambda \in \sigma(A)} |q_i(\lambda)| .$$

Moreover, if  $A$  is normal, then

$$\|\mathbf{r}_i\|_2 \leq M_i \|\mathbf{r}_0\|_2 .$$

**Theorem 2.2:** If  $\{\mathbf{r}_j\}$  is the sequence of residuals generated by GM(k), then

$$\|\mathbf{r}_j(k+1)\|_2 \leq \left[ \min_{q_{k+1} \in P_{k+1}} \|\mathbf{b}_{q_{k+1}(A)}\|_2 \right]^j \|\mathbf{r}_0\|_2 .$$

If  $A$  has a complete set of eigenvectors, then

$$\|\mathbf{r}_j(k+1)\|_2 \leq (K(T) M_{k+1})^j \|\mathbf{r}_0\|_2 ,$$

and if  $A$  is normal, then

$$\|\mathbf{r}_j(k+1)\|_2 \leq (\mathbf{b}_{q_{k+1}})^T \|\mathbf{r}_0\|_2 .$$

Finally, the following result implies that GM(k) converges, and provides another error bound for GM, GCR(k), and MN.

**Theorem 2.3:** If  $\{\mathbf{r}_i\}$  is the sequence of residuals generated by GM, Orthomin(k), GCR(k), or MN, then

$$\|\mathbf{r}_i\|_2 \leq \left[ 1 - \frac{\lambda_{\min}(R)^2}{\lambda_{\max}(A)^2} \right]^{i/2} \|\mathbf{r}_0\|_2 .$$

and

$$\|\mathbf{r}_i\|_2 \leq \left[ 1 - \frac{\lambda_{\min}(R)^2}{\lambda_{\min}(R) \lambda_{\max}(R) + \rho(R)^2} \right]^{i/2} \|\mathbf{r}_0\|_2 .$$

Proofs of these results can be found in [4].

### 3. Implementation with Preconditioning

The methods presented in the previous section can be accelerated by preconditioning techniques. Let  $Q$  be some nonsingular matrix. The solution to (2.1) can be found by solving any of the alternative problems

$$\tilde{A} \tilde{x} = \{Q^{-1}A\} \{x\} = \{Q^{-1}f\} = \tilde{f} ; \quad (3.1)$$

$$\tilde{A} \tilde{x} = \{A Q^{-1}\} \{Qx\} = \{f\} = \tilde{f} ; \quad (3.2)$$

$$\tilde{A} \tilde{x} = \{Q_1^{-1} A Q_2^{-1}\} \{Q_2 x\} = \{Q_1^{-1} f\} = \tilde{f} ; \quad (3.3)$$

where  $Q$  is (formally) factored into the product  $Q_1 Q_2$ . If systems of equations having  $Q$  as coefficient matrix can be solved easily, then the use of  $Q$  as

preconditioning may greatly speed the convergence of GMK and its variants. In this section, we discuss the implementation of preconditioned versions of the four methods.

At each step, the approximate solutions generated by GMK et al. minimize the Euclidean norm of the residual over some subspace. When preconditioning is used, the quantity minimized depends on the technique of applying the preconditioning. For example, if GCR is applied to (3.1), then  $\|Q^{-1}(f - Ax_i)\|_2$  is minimized at each step. The residual of (3.2) is the same as the residual of the original problem (2.1). In this paper, we restrict our attention to this version of the preconditioned problem.

GCR can be implemented to solve (2.1) using (3.2) as follows:

**Algorithm 3.1:** The preconditioned generalized conjugate residual method:

```

Choose  $A_0$ 
Compute  $r_0 = f - Ax_0$ 
Set  $p_0 = r_0$ 
FOR  $i = 0$  STEP 1 UNTIL Convergence DO
     $s_i = \frac{(r_i, Ap_i)}{(Ap_i, Ap_i)}$           (4.1)
     $x_{i+1} = x_i + s_i p_i$ 
     $r_{i+1} = r_i - s_i Ap_i$ 
     $b_j^{(i)} = \frac{(Ap_i, r_{i+1}, Ap_j)}{(Ap_j, Ap_i)} \quad j \leq i$ 
     $p_{i+1} = Q^{-1}r_{i+1} + \sum_{j=0}^i b_j^{(i)} p_i$ 

```

The work per iteration for preconditioned GMK is identical to that for the unpreconditioned version, except that the matrix-vector product is replaced by a preconditioned matrix-vector product  $Ah^{-1}r_i$ . In general, this operation is performed in two steps: a system of equations with coefficient matrix  $Q$  is solved for  $Q^{-1}r_{i+1}$ , and the result is multiplied by  $A$ . For some preconditionings based on the incomplete factorization of  $A$ , more efficient techniques for performing this operation have been developed [5].

In addition to the extra storage required for  $Q$ , preconditioned GMK requires one more vector of storage than the unpreconditioned version, for  $Q^{-1}r_i$ .

The implementations of Orthomin(k), GMK(h), and MK are analogous to

**Algorithm 3.1.** For all three methods, the work per iteration differs from the unpreconditioned versions only in the cost of the matrix vector product. Again, extra storage is required for  $Q$  and  $Q^{-1}r_i$ .

#### 4. Sample Problems

In this section, we describe two sample problems on which we tested the methods. Consider the elliptic differential equation

$$-(u_{xx} + u_{yy}) + \beta u_x = 0 \quad (4.1)$$

on the quarter plane  $x > 0, y > 0$ , with boundary conditions

$$u(x, 0) = 0 \quad u(0, y) = 1 \quad (4.2)$$

$$u(x, y) \text{ bounded as } |x| + |y| \rightarrow \infty$$

For large  $\beta$ , the solution  $u$  has a boundary layer near  $y = 0$ , and is nearly equal to 1 elsewhere [7].

For the numerical solution of (4.1) and (4.2), we restrict the domain to the unit square  $(0,1) \times (0,1)$ , and impose the additional boundary conditions

$$u(x,1) = 1 \quad , \quad u_x(1,y) = 0 \quad . \quad (4.3)$$

The effect of the outflow boundary condition is to make the boundary layer in the numerical solution nonoscillatory [7]. The exact solution to (4.1) - (4.3) is not known. A two-dimensional representation of a numerical solution for  $\beta = 100$  is shown in Figure 4-1.

For the first test problem, we discretize (4.1) using centered finite differences on a uniform  $n \times n$  grid, with  $h = \frac{1}{n^2}$  [17]. The right boundary condition is discretized by

$$u(x_n, y_j) = u(x_n, y_{j+1}) \quad .$$

Let  $u_{ij}$  denote the approximation to  $u(ih, jh)$ . The difference equations for the discretized problem are then

$$\begin{aligned} 4u_{ij} - u_{i,j-1} - (1 + \frac{\beta h}{2})u_{i-1,j} - (1 - \frac{\beta h}{2})u_{i+1,j} \\ - u_{i,j+1} = 0 \quad , \quad 1 \leq j \leq n \quad , \quad 1 \leq i < n \quad . \end{aligned} \quad (4.4)$$

$$(3 + \frac{\beta h}{2})u_{nj} - u_{n,j-1} - (1 + \frac{\beta h}{2})u_{n-1,j} - u_{n,j+1} = 0 \quad ,$$

$$1 \leq j \leq n \quad .$$

$$(4.4)$$

$$y(\eta) = y_0' \eta + (1 - y_0')\eta^4$$

$$[16], \text{ with } y_0' = \frac{1}{\beta} \text{. Letting } v(x, \eta) := u(x, y(\eta)) \text{, equation (4.1) becomes}$$

$$- [v_{xx} + \frac{1}{\eta^2} v_{\eta\eta}]_{\eta} + \beta v_x = 0$$

with boundary conditions

$$v(x,0) = 0 \quad , \quad v(0,\eta) = 1 \quad , \quad v(x,1) = 1 \quad , \quad v_x(1,\eta) = 0 \quad .$$

If the unknowns  $u_{ij}$  are ordered in the natural row-by-row manner, then

$$u_{ij} = \begin{cases} 0 & j = 0 \\ 1 & i = 0 \text{ or } j = 1 \\ 1 & \text{otherwise} \end{cases} \quad . \quad (4.5)$$

(4.4) can be expressed as an  $N \times N$  block tridiagonal system of linear equations

$$A \cdot x := \begin{bmatrix} T_1 \cdot w_1 & & & \\ -V_2 \cdot T_2 & \ddots & & \\ & \ddots & \ddots & -w_{n-1} \\ & & -V_n \cdot T_n & \end{bmatrix} \cdot x = f \quad . \quad (4.6)$$

where for  $1 \leq i \leq n$ ,  $T_i$  is the  $n \times n$  tridiagonal matrix

$$T_i := \begin{bmatrix} 4 & -(1+\beta h/2) & & & \\ -(1+\beta h/2) & 4 & & & \\ & \ddots & \ddots & & \\ & & -(1+\beta h/2) & 4 & -(1+\beta h/2) \\ & & & -(1+\beta h/2) & 3+\beta h/2 \end{bmatrix} \quad .$$

and  $V_i$  and  $w_i$  are  $n \times n$  identity matrices. The right hand side  $f$  is determined by (4.3), and  $N = n^2$ .  $A$  is a nonsymmetric matrix, and it has complex eigenvalues for  $\frac{\beta h}{2} > 1$  [14].

For the second test problem, we resolve the boundary layer by introducing the change of coordinates

$$y(\eta) = y_0' \eta + (1 - y_0')\eta^4$$

$$[16], \text{ with } y_0' = \frac{1}{\beta} \text{. Letting } v(x, \eta) := u(x, y(\eta)) \text{, equation (4.1) becomes}$$

$$- [v_{xx} + \frac{1}{\eta^2} v_{\eta\eta}]_{\eta} + \beta v_x = 0$$

Using a uniform  $\alpha = n$  grid on the unit  $(x,y)$  square, with  $h = \frac{1}{n^2}$ , and  $y_j' = y'(jh)$ , the difference equations are

$$(2 + \frac{1}{y_j'} \frac{1}{y_{j+1/2}'} + \frac{1}{y_{j-1/2}'})v_{ij} - \frac{1}{y_j'} \frac{1}{y_{j-1/2}'} v_{i,j-1} \\ (1 + \frac{\beta h}{2})v_{i+1,j} - (1 + \frac{\beta h}{2})v_{i-1,j}$$

$$- \frac{1}{y_j'} \frac{1}{y_{j+1/2}'} v_{i,j+1} = 0, \quad 1 \leq j \leq n-1, \quad 1 \leq i < n. \quad (4.7)$$

$$(1 + \frac{1}{y_j'} \frac{(\frac{1}{y_{j+1/2}'} + \frac{1}{y_{j-1/2}'}) + \frac{\beta h}{2}}{y_j' y_{j+1/2}'})v_{nj} - \frac{1}{y_j'} \frac{1}{y_{j-1/2}'} v_{nj-1} - (1 + \frac{\beta h}{2})v_{n-1,j} \\ - \frac{1}{y_j'} \frac{1}{y_{j+1/2}'} v_{nj+1} = 0, \quad 1 \leq j \leq n.$$

same set of problems. The cost per iteration of the Chebyshev algorithm is  $2N$  multiplications plus one matrix-vector product. The overhead required by the Chebyshev algorithm for estimating eigenvalues is not included in the operation counts. The cost per iteration of CGN is  $5N$  multiplications plus two matrix-vector products.

All of the methods were tested in conjunction with two preconditionings: the incomplete LU factorization (ILU) [12], and the modified incomplete LU factorization (MILU) [3, 6]. The preconditioned problems were formulated as in (3.2); this means that the variational quantity minimized by all the GCR-variants, as well by CGN, is the Euclidean norm of the residual of the original linear problem,  $\|r_i\|_2$ .

The ILU factorization is an approximate LU factorization of  $A$  into  $Q_L = L_I U_I$  that satisfies

1. if  $A_{ij} = 0$ , then  $[L_I]_{ij} = 0$  and  $[U_I]_{ij} = 0$ ;
2. if  $A_{ij} \neq 0$ , then  $[Q_L]_{ij} = A_{ij}$ .

That is, the approximate factors are as sparse as the lower- and upper-triangular parts of  $A$ , respectively, and the product  $Q_L$  agrees with  $A$  in the nonzero entries of  $A$ .

The resulting matrix equation is also of block tridiagonal form (4.6), and nonsymmetry occurs in both sets of diagonals. Because  $y_j'$  is small for  $j$  near 0, the diagonal coefficients in  $T_j', V_j'$ , and  $W_j$  are large for small  $j$ .

### 5. Numerical Experiments

In this section, we present the results of numerical experiments. We solved the discrete problems (4.4) and (4.7) with  $h = \frac{1}{32}, \frac{1}{48}$ , and  $\frac{1}{64}$ . The linear systems are of order  $N = 961, 2209$ , and  $3969$ . Three values of  $\beta$  were used,  $\beta = 10, 100$ , and  $5000$ . All computations were done in double precision on a DECSystem-20.

We tested the algorithms MR, Orthomin(1), Orthomin(5), GCR(1), and GCR(5). We also used the nonsymmetric Chebyshev algorithm [10, 11], and the conjugate gradient method applied to the normal equations (CGN) to solve the

CGN factorization is an approximate LU factorization into  $Q_M = L_M U_M$

that satisfies

1. if  $A_{ij} = 0$ , then  $[L_M]_{ij} = 0$  and  $[U_M]_{ij} = 0$ ;
2. if  $A_{ij} \neq 0$ , and  $i \neq j$ , then  $[Q_M]_{ij} = A_{ij}$ .

MILU differs from ILU in that the diagonal of  $Q_M$  is modified so that for  $1 \leq i \leq N$ ,

$$\sum_{j=0}^N (A_{ij} - [Q_M]_{ij})^2 = 0$$

The factors of  $Q_M$  are also as sparse as the lower- and upper triangular parts of  $A$ .

The preconditioned matrix vector products were implemented to take advantage of the two cyclic nature of the problems [5]. The cost of a preconditioned matrix-vector product is  $9N$  multiplications. The stopping criterion for all the tests was

$$\frac{\|r_1\|_2}{\|r_0\|_2} < 10^{-6}$$

Tables 5-1, 5-2, and 5-3 show the number of multiplications needed by each of the methods to satisfy the stopping criterion for Problem 1 (4.4).

Figures 5-1, 5-2, and 5-3 graph the residual norm  $\|r_{1/2}\|_2$  against the number of multiplications used by MR, Orthomial(1), GCR(1), CGN, and the Chebyshev method for Problem 1, with  $h = \frac{1}{48}$  and ILU preconditioning. Figures 5-4, 5-5, and 5-6 graph  $\|r_{1/2}\|_2$  against the number of multiplications for Problem 1 with  $h = \frac{1}{48}$  and NILU preconditioning.

Tables 5-4, 5-5, and 5-6 show the number of multiplications needed by each of the methods to satisfy the stopping criterion for Problem 2 (4.7). Figures 5-7 through 5-12 graph residual norm against multiplications for Problem 2, with  $h = \frac{1}{48}$ .
