**Abstract.** A "Carathéodory-Fejér method" is presented for near-best real rational approximation on intervals, based on the eigenvalue (or singular value) analysis of a Hankel matrix of Chebyshev coefficients. In approximation of a smooth function  $F$ , the CF approximant  $R^{cf}$  frequently differs from the best approximation  $R^*$  by only one part in millions or billions. To account for this we show here under weak assumptions that if  $F$  is approximated on  $[-\epsilon, \epsilon]$ , then as  $\epsilon \rightarrow 0$ ,  $\|F - R^*\| = O(\epsilon^{m+n+1})$  while  $\|R^{cf} - R^*\| = O(\epsilon^{3m+2n+3})$ . In contrast, the latter figure would be  $O(\epsilon^{m+n+2})$  for the Chebyshev economization approximant of Machly or the Chebyshev-Padé approximant of Gragg. It follows that as  $\epsilon \rightarrow 0$ , best approximation error curves approach the real parts of  $m+n+1$ -winding Blaschke products to within  $O(\epsilon^{3m+2n+3})$ . Numerical examples are given, including applications to  $e^x$  on  $[-1, 1]$  and  $e^{-x}$  on  $[0, \infty)$ . For the latter problem we conjecture that the errors in  $(n, n)$  approximation decrease with each  $n$  by a ratio approaching a fixed constant 9.28903....

## 0. INTRODUCTION

The purpose of this paper is to describe and analyze a new analytical method for nearest rational Chebyshev approximation on an interval, which we call the Carathéodory-Fejér method, that is based on an eigenvalue analysis of a Hankel matrix of Chebyshev coefficients. What is remarkable about the CF method is its extraordinary degree of optimality in approximating many smooth functions. Let  $R^*$  be the best (Chebyshev) approximation of rational type  $(m, n)$  on  $[-1, 1]$  to a continuous function  $F(x)$ , let  $R^{cf}$  be the corresponding CF approximation, and let  $E^* = \|F - R^*\|_\infty$  and  $E^{cf} = \|F - R^{cf}\|_\infty$  be the associated errors. Then Table 1 shows how close  $E^{cf}$  and  $E^*$  turn out to be for the case  $F(x) = e^x$ .

$(m, n)$	$E^*$	$E^{cf} - E^*$ (approx.)
(0,0)	1.1732	$10^{-4}$
(1,1)	2.0970(-2)	$10^{-6}$
(2,2)	8.6900(-5)	$10^{-12}$
(3,3)	1.5507(-7)	$10^{-20}$
(4,4)	1.5381(-10)	$< 10^{-27}$

Table 1. Errors in best and CF approximation of  $e^x$  on  $[-1, 1]$  by rational functions of type  $(n, n)$ ,  $0 \leq n \leq 4$ .

Such extremely strong agreement demands explanation. In this paper it is shown that if a smooth function  $F(x)$  satisfying a simple normality condition is approximated on  $[-\epsilon, \epsilon]$ , then  $\|R^{cf} - R^*\| = O(\epsilon^{3m+2n+3})$  as  $\epsilon \rightarrow 0$  (Thm. 6). As a corollary it is also shown that to the same order as  $\epsilon \rightarrow 0$ ,  $F - R^*$  equals the real part of an  $(m+n+1)$ -winding Blaschke product on the complex unit circle (Thm. 7).

Our research on CF approximation began with the study of error curves in approximation of analytic functions on the complex unit disk. If  $r^*(z)$  is the best approximation of type  $(m, n)$  to  $f(z)$  on  $|z| \leq 1$ , it turns out that the error curve  $(f - r^*)(|z| = 1)$

often approximates extremely closely a perfect circle about the origin of winding number  $m + n + 1$ . This phenomenon for polynomial approximation was discussed by Trefethen in [40], where by an analysis based on the Carathéodory-Fejér theorem [2,5], it was shown that in best approximation on the disk  $|z| \leq \epsilon$ , the error curve is circular to  $O(\epsilon^{2m+3})$  as  $\epsilon \rightarrow 0$ . By means of an extension of the CF theorem due originally to Takagi [19,37] and generalized by Adamjan, Arov, and Krein [1], this result was extended to  $O(\epsilon^{2m+2n+3})$  for rational approximation in [41]. At the same time Gutknecht found that the CF technique could be transplanted by the Joukowski map  $x = \frac{1}{2}(z + z^{-1})$  from  $|z| = 1$  to  $x \in [-1, 1]$ , and the resulting real CF method was analyzed for polynomial approximation in [21]. The present paper completes this series by presenting and analyzing asymptotically a CF method for real, rational approximation.

The Joukowski transplantation has previously been applied for near-best real approximation by Frankel, Gragg, and Johnson [14,17], who derived a Chebyshev-Padé approximation on  $[-1, 1]$  based on Padé expansions at  $x = 0$ . This Chebyshev-Padé approximation is related to, but not the same as, the earlier rational economization fraction of Maehly [6, p. 178; 17]. Our fraction might be called the *Chebyshev-CF* approximant, for it fits directly into the framework of Gragg and his colleagues. Indeed, corresponding to their Fourier-Padé and Laurent-Padé approximations, one can develop Fourier-CF and Laurent-CF approximations for real periodic and complex meromorphic functions, respectively. In general the CF approximations will be more complicated but, for smooth functions, much closer to optimal.

The history of ideas connected with the real, rational CF method is long and confused. Eigenvalues of Hankel matrices were used half a century ago for estimating the error of the best approximation and for solving certain special problems exactly by Bernstein, Achieser, and Mirakyan; see [31, p. 166] and [2, App. D] for references. The use of such a device for near-best approximation was apparently first proposed by Darlington in 1970 [10] for the real polynomial case, and the first (and only previous) extension to rational near-best approximation is due to Lam and D. Elliott in 1972-3 [12,27,28]. The connection between the CF method and approximation on the disk was first pointed out in the excellent dissertation of Hollenhorst [25] (for the polynomial case), and this was also the first work to contain error estimates. Further related contributions have also been made by C. Clenshaw, G. H. Elliott [13], A. Reddy, and A. Talbot [38,39]. One of our own contributions in previous papers [21,40,41] has been to connect CF methods with the Carathéodory-Fejér theory and the related results of Takagi and Adamjan, Arov, and Krein. This makes it possible to fill various theoretical gaps. A second innovation in our papers has been that by means of arguments related to strong uniqueness, we apply results of the CF method to get estimates on the behavior of the best approximation itself. In our view, the CF idea is not just a method for generating near-best approximations, but a theory that should reveal hitherto unrecognized properties of real and complex Chebyshev approximation and of the relation between the two.

The present paper also differs from the previous work of Lam and Elliott in two practical ways. First, our method applies for arbitrary  $m$  and  $n$ , rather than just  $m \geq$

$n$ ; the idea behind this extension is derived from an example by Talbot [38]. Second, its asymptotic order of accuracy on small intervals is  $O(\epsilon^{3m+2n+3})$  rather than (it appears)  $O(\epsilon^{2m+2n+3})$ .

Our arguments proceed in two steps. First, one shows that the CF method yields an error curve that nearly equioscillates (real case) or is nearly circular (complex case); this implies  $E^{cf} \approx E^*$ . Second, one shows by an argument related to strong uniqueness or Lipschitz continuity of best approximations that this behavior further implies  $R^{cf} \approx R^*$ . All of our estimates are asymptotic, pertaining only to the interval  $[-\epsilon, \epsilon]$  in the limit  $\epsilon \rightarrow 0$ . (Equivalently, one could consider increasingly smooth functions  $F(\epsilon x)$  on the fixed interval  $[-1, 1]$ .) This is effectively the same limit considered in the past in various papers on Chebyshev approximation, notably [29,34] for real polynomial, [7,20,43] for real rational, [32] for complex polynomial, and [42] for complex rational approximation. Where these papers obtain one term of an asymptotic expansion of the best approximation (two, in the case of [34]), the CF method gets many.

The CF method and related ideas are currently attracting much attention in the theories of digital filtering, control, and linear systems. This work has been mainly stimulated by the papers of Adamjan, Arov, and Krein [1], and is being carried out by (among others) M. Bettayeb, A. Bultheel, P. Dewilde, Y. Genin, S. Kung, and L. Silverman. See the book by Kailath [26] for some references, and also [20].

## 1. THE CARATHÉODORY-FEJÉR METHOD

Let the unit disk and circle be denoted  $D = \{z : |z| < 1\}$  and  $\partial D = \{z : |z| = 1\}$ , let  $\partial D^+$  be the upper semicircle  $\partial D \cap \{z : \text{Im} z \geq 0\}$ , and let  $I_\epsilon = [-\epsilon, \epsilon]$ . Let  $\|\cdot\|_{I_\epsilon}$ ,  $\|\cdot\|_{\partial D}$ , etc. be the corresponding supremum norms, but let  $\|\cdot\|$  be an abbreviation for  $\|\cdot\|_{I_\epsilon}$ . In what follows  $x$  will always denote a real and  $z$  a complex variable; upper case letters will be used for functions of  $x$  and lower case for functions of  $z$ .

We begin with a real function  $F(x)$  that is continuous on  $I_\epsilon$  and with a pair of fixed integers  $m, n \geq 0$ . Let  $V_{mn}$  be the set of rational functions of type  $(m, n)$  with real coefficients, and let  $R^*(x)$  denote the best approximation to  $F$  on  $I_\epsilon$  out of  $V_{mn}$ . ( $R^*$  exists and is unique; see [2], [6], or [31].) For any finite  $M \geq 0$ ,  $F$  possesses a partial Chebyshev expansion

$$F(x) = F_M(x) + G_M(x) = \sum_{k=0}^M a_k T_k(x/\epsilon) + G_M(x), \quad (1.1)$$

with  $T_k$  denoting the  $k$ th Chebyshev polynomial, where the prime indicates that the term with  $k = 0$  should be multiplied by  $\frac{1}{2}$ . Here  $a_k$  is defined by the inner product [6, p. 117]

$$a_k = \frac{2}{\pi} \int_{-\epsilon}^{\epsilon} F(x) T_k(x/\epsilon) \frac{dx}{\sqrt{\epsilon^2 - x^2}}.$$

Our fundamental transplantation is the map

$$x(z) = \epsilon \text{Re} z = \frac{1}{2} \epsilon (z + z^{-1}), \quad (1.2)$$

a bijection of  $\partial D^+$  onto  $I_\epsilon$ , which for  $x \in I_\epsilon$ ,  $z \in \partial D$  leads to the formula

$$T_k(x/\epsilon) = \frac{1}{2} (z^k + z^{-k}). \quad (1.3)$$

In particular, let us set  $a_{-k} = a_k$  and define

$$f_M(z) = \sum_{k=-M}^M a_k z^k, \quad f^+(z) = \sum_{k=m-n+1}^M a_k z^k, \quad (1.4a)$$

$$f^o(z) = \begin{cases} \sum_{k=n-m}^{m-n} a_k z^k & \text{if } m \geq n, \\ - \sum_{k=m-n+1}^{n-m-1} a_k z^k & \text{if } m < n. \end{cases} \quad (1.4b)$$

Then

$$F_M(x) = \frac{1}{2} f_M(z) = \frac{1}{2} [f^+(z) + f^+(z^{-1}) + f^o(z)]. \quad (1.5)$$

The idea of the CF method is to first approximate the analytic function  $f^+$  on  $\partial D$  by considering an infinite-dimensional space  $\tilde{V}_{mn}$  in which a best approximation can be found exactly, then derive from this a near-best approximation  $R^{\epsilon f}$  to  $F^*$  on  $I_{\epsilon}$ . Let  $\tilde{V}_{mn}$  be the set of functions that can be written with real coefficients in the form

$$\tilde{r}(z) = \frac{\sum_{k=-\infty}^m d_k z^k}{\sum_{k=0}^n e_k z^k},$$

where the terms of negative degree in the numerator converge to a bounded analytic function in  $|z| > 1$  and the denominator has no zeros in  $D \cup \partial D$ . Let  $H$  be the real symmetric Hankel matrix

$$H = \begin{pmatrix} a_{m-n+1} & a_{m-n+2} & \cdots & a_M \\ a_{m-n+2} & & & \\ \vdots & & & \\ a_M & & & 0 \end{pmatrix}$$

(A **Hankel matrix** is a matrix with  $a_{ij} = a_{|i+j|}$ .) Let

$$H = U \Lambda U^T$$

be a real orthogonal eigenvalue decomposition of  $H$  — i.e.  $U, \Lambda$  are square real matrices with  $\Lambda = \text{diag}(\lambda_1, \dots, \lambda_{M+n-m})$  and  $U$  is orthogonal ( $U^T = U^{-1}$ ). We assume the eigenvalues are ordered by absolute magnitude:  $|\lambda_1| \geq |\lambda_2| \geq \dots \geq |\lambda_{M+n-m}|$ . (If  $H$  had complex coefficients it would become clear that a singular value decomposition rather than an eigenvalue decomposition is most appropriate, but since  $H$  is real symmetric, the two are the same here except for the possibility of negative signs.) Let  $\lambda$  abbreviate  $\lambda_{n+1}$  and let  $(u_1, \dots, u_{M+n-m})^T$  be the corresponding right eigenvector, namely the  $(n+1)$ st column of  $U$ . The following result was proved by Carathéodory and Fejér in 1911 for the polynomial case  $n = 0$  [5], extended to rational approximation by Takagi in 1924 [37], and generalized further by Adamjan, Arov, and Krein in 1971 [1]. A presentation and partial proof can be found in [41]. A full discussion of degenerate cases will be given in [19].

**Theorem 1.**  $f^+$  has a unique best approximation  $\tilde{r}^*$  on  $\partial D$  out of  $\tilde{V}_{mn}$ , which is given by

$$f^+ - \tilde{r}^* = b, \tag{1.6a}$$

where

$$b(z) = \lambda z^M \frac{u_1 + \dots + u_{M+n-m} z^{M+n-m-1}}{u_{M+n-m} + \dots + u_1 z^{M+n-m-1}}. \tag{1.6b}$$

The error is

$$\|f^+ - \tilde{r}^*\|_{\partial D} = |\lambda|,$$

and the error curve  $(f^+ - \tilde{r}^*)(\partial D)$  is a perfect circle about the origin whose winding number is  $m+n+1$  if  $|\lambda_n| > |\lambda| > |\lambda_{n+2}|$ . ■

The function  $b$  is  $\lambda$  times a finite Blaschke product, which is why  $f^+ - \tilde{r}^*$  maps  $\partial D$  onto a circle, and the optimality of  $\tilde{r}^*$  for the complex approximation problem can be seen to follow from this by Rouché's theorem. Now this optimality is not of use to us. However, let us transplant to  $I_\epsilon$  by defining

$$\tilde{R}(x) = \frac{1}{2}[\tilde{r}^*(z) + \tilde{r}^*(z^{-1}) + f^o(z)], \quad (1.7a)$$

or by (1.5) and (1.6a),

$$\tilde{R}(x) = \frac{1}{2}[f_M(z) - b(z) - b(z^{-1})]. \quad (1.7b)$$

Then by (1.5) again,

$$F_M(x) - \tilde{R}(x) = \operatorname{Re} b(z), \quad (1.8)$$

and if  $b$  has winding number  $m+n+1$ , it follows that  $F_M - \tilde{R}$  equioscillates on  $I_\epsilon$  at  $m+n+2$  points  $\epsilon = x_0 > x_1 > \dots > x_{m+n+1} = -\epsilon$ :

$$\|F_M - \tilde{R}\|_{I_\epsilon} = |\lambda|, \quad (1.9)$$

$$(F_M - \tilde{R})(x_j) = (-1)^j \lambda.$$

If  $\tilde{R}$  belonged to  $V_{mn}$ , this equioscillation would imply  $\tilde{R} = R^*$  and  $|\lambda| = E^*$ , and we would have solved our original approximation problem (for  $F_M$ ) exactly. Unfortunately, this is in general not the case. (The main exception occurs when  $M = m+1$ , and this gives rise to some of the examples of Achieser, Talbot, and others mentioned in the Introduction.) But the key to the CF method is that for smooth functions  $F$ ,  $\tilde{R}$  turns out to be very close to  $V_{mn}$ .

Let  $q = \sum_{k=0}^n \tilde{e}_k z^k$  denote the normalized denominator of  $\tilde{r}^*$  — the polynomial of degree  $\partial q \leq n$  with constant term  $\tilde{e}_0 = 1$  whose zeros are the finite poles of  $\tilde{r}^*$  lying outside  $\partial D$ . Define

$$Q(x) = q(z)q(z^{-1})/\tau, \quad (1.10)$$

where  $\tau$  is the scalar  $q(i)q(-i)$ , inserted to make  $Q(x)$  have constant term 1. Note that  $Q(x) = |q(z)|^2/\tau > 0$  on  $I_\epsilon$ . Now since  $\tilde{r}^* \in \tilde{V}_{mn}$ ,

$$f^+(z) - b(z) = \tilde{r}^*(z) = O(z^{m-\partial q}) \quad \text{as } z \rightarrow \infty,$$

hence since  $\partial q \leq n$  and  $f_M - f^+ = O(z^{m-n})$ ,

$$f_M(z) - b(z) = O(z^{m-\partial q}) \quad \text{as } z \rightarrow \infty. \quad (1.11)$$

Let us consider the Laurent series with respect to  $\partial D$  of the product

$$\tilde{R}(x)Q(x) = \frac{1}{2}[f_M(z) - b(z) - b(z^{-1})]q(z)q(z^{-1})/\tau. \quad (1.12)$$

By (1.11) and the definition of  $q$ ,  $[f_M(z) - b(z)]q(z)q(z^{-1})/\tau$  must be analytic outside  $\partial D$  except for a pole of order at most  $m$  at  $\infty$ , and therefore all terms of order greater than  $m$  in the Laurent series of (1.12) are due to  $b(z^{-1})q(z)q(z^{-1})/\tau$ . By symmetry, all terms of order less than  $-m$  are due to  $b(z)q(z)q(z^{-1})/\tau$ . Hence, if we define

$$\hat{b}(z) = b(z)q(z)q(z^{-1})/\tau = \sum_{k=-\infty}^{M+n} \hat{b}_k z^k, \quad (1.13a)$$

$$\hat{b}^T = \sum_{k=-m}^{M+n} \hat{b}_k z^k, \quad \hat{b}^R(z) = \hat{b}(z) - \hat{b}^T(z), \quad (1.13b)$$

then the function

$$P_1(x) = \frac{1}{2} \left[ f_M(z)q(z)q(z^{-1})/\tau - \hat{b}^T(z) - \hat{b}^T(z^{-1}) \right]$$

is a polynomial of degree  $m$  in  $x$ . If we further set

$$R_1^{cf}(x) = \frac{P_1(x)}{Q(x)}, \quad B^R(x) = \frac{1}{2} \left[ \hat{b}^R(z) + \hat{b}^R(z^{-1}) \right], \quad (1.14a)$$

then we obtain

$$\tilde{R}(x) = R_1^{cf}(x) + \frac{B^R(x)}{Q(x)}, \quad (1.14b)$$

hence

$$\tilde{R}(x)Q(x) = R_1^{cf}Q(x) + O(T_{m+1}(x)). \quad (1.15)$$

We will call  $R_1^{cf} \in V_{mn}$  the *type 1* or *Maehly type* CF approximation of  $F$ , because as in Maehly's generalization of Padé approximation (cf. [6], p. 118 and [17]), truncation of higher-order terms in  $\tilde{R}$  is done after multiplying through by the denominator  $Q$ . There is a second, probably superior way to truncate  $\tilde{R}$ , namely by using a Chebyshev-Padé kind of approximation with fixed denominator  $Q$ . That is, one may take the *type 2* or *Padé type* CF approximant as

$$R_2^{cf}(x) = \frac{P_2(x)}{Q(x)}, \quad (1.16a)$$

with  $P_2$  defined by the condition

$$\tilde{R}(x) = R_2^{cf}(x) + O(T_{m+1}(x)). \quad (1.16b)$$

One could go further, in complete analogy with the Chebyshev-Padé approximation defined by Gragg, and define a third type of CF approximation by permitting the denominator of  $R^{cf}$  to be free as well as the numerator. However, one might then end up with a fraction having a pole on  $I_c$ . For this reason, and on the basis of numerical experiments and the analogy with the Chebyshev-Padé situation, we believe that  $R_2^{cf}$  is the best of these three possibilities, and from now on we will drop the subscripts and assume  $R^{cf} \equiv R_2^{cf}$ .

To obtain the polynomial  $P$  ( $\equiv P_2$ ) satisfying (1.16), one proceeds as follows. Let  $\tilde{c}_k$ ,  $\beta_k$ , and  $\gamma_k$  denote the  $k$ th Chebyshev coefficients of  $\tilde{R}(x)$ ,  $P(x)$ , and  $1/Q(x)$ , respectively. Then the coefficients  $\{\beta_k\}$  satisfy the Toeplitz system of equations

$$\begin{pmatrix} \gamma_0 & \gamma_1 & \cdots & \gamma_{2m} \\ \gamma_1 & & & \vdots \\ \vdots & & & \gamma_1 \\ \gamma_{2m} & \cdots & \gamma_1 & \gamma_0 \end{pmatrix} \begin{pmatrix} \beta_m \\ \vdots \\ \beta_0 \\ \vdots \\ \beta_m \end{pmatrix} = 2 \begin{pmatrix} \tilde{c}_m \\ \vdots \\ \tilde{c}_0 \\ \vdots \\ \tilde{c}_m \end{pmatrix}. \quad (1.17)$$

Since  $1/Q(x) > 0$  on  $I_\epsilon$ , the infinite symmetric Toeplitz matrix  $(\gamma_{|i-j|})_{i,j=-\infty}^{\infty}$  is known to be positive definite [18], and hence the principal submatrix appearing in (1.17) is positive definite also, hence nonsingular. Moreover, since this submatrix is symmetric about its anti-diagonal, a symmetric right-hand-side  $(\tilde{c}_k)$  leads to a symmetric solution  $(\beta_k)$ , as indicated in (1.17). Indeed, in practice one may reduce (1.17) to a system of size  $m+1$  instead of  $2m+1$ . Consequently,  $P$  is always well defined by (1.16).

In summary, here is the real rational (type 2) CF approximation method. We have indicated four points at which a numerical implementation can naturally be based upon the Fast Fourier Transform. For further information on uses of the FFT in complex analysis, see [22]. The FFT method indicated for the polynomial factorization of Step 4 is that proposed in §3.2 of [22]; see also [41].

- Step 1.** Given  $F$ , find its Chebyshev coefficients  $a_0, \dots, a_M$  for some large  $M$  (FFT).
- Step 2.** Construct the Hankel matrix  $H$  and find its  $n+1$ st eigenvalue (in absolute value) and eigenvector.
- Step 3.** Find the Laurent series on the circle of the Blaschke product  $b(z)$  defined by (1.6b) (FFT). Subtract this plus its conjugate from  $f_M(z)$  to obtain the Chebyshev coefficients  $\{\tilde{c}_k\}$  for  $\tilde{R}(x)$  by (1.7b).
- Step 4.** Factor the denominator of (1.6b) to obtain the polynomial  $q(z)$  and construct  $Q(x)$  from (1.10) (FFT). Find the Chebyshev coefficients  $\{\gamma_k\}$  for  $1/Q(x)$  (FFT).
- Step 5.** Determine the polynomial  $P(x)$  satisfying (1.16) by solving (1.17), and define  $R^{cf} = P/Q$ .
- Step 6.** To get a bound on  $E^{cf} - E^*$ , examine how close the error curve of  $R^{cf}$  comes to equioscillating.

*Remark.* This somewhat obscure construction of  $R^{cf}$  can be made much more transparent in the case  $m \geq n$ . The theory of complex CF approximation shows that  $\tilde{r}^*$  in Theorem 1 is close to  $V_{mn}$ , and for  $m \geq n$ , (1.7a) then implies that  $\tilde{R}$  is close to  $V_{mn}$  also.

## 2. ASYMPTOTIC RESULTS FOR SMALL INTERVALS

The basis of our results for small intervals is the theory worked out in [41] for complex approximation on small disks. For these results a normality assumption is needed. Let  $F$  be given, and let  $M \geq 3m + 2n + 2$  be a fixed integer.

**Assumption A.** The  $M$ th derivative of  $F(x)$  exists and is Lipschitz continuous at  $x = 0$ . Moreover, if  $F(x) = \sum_{k=0}^M \alpha_k x^k + O(x^{M+1})$ , with  $\alpha_k \equiv 0$  for  $k < 0$ , then

$$\det \begin{pmatrix} \alpha_{m-n+1} & \alpha_{m-n+2} & \cdots & \alpha_m \\ \alpha_{m-n+2} & & & \vdots \\ \vdots & & & \alpha_{m+n-2} \\ \alpha_m & \cdots & \alpha_{m+n-2} & \alpha_{m+n-1} \end{pmatrix} \neq 0.$$

Equivalently, the Padé approximation of  $F$  of type  $(m, n)$  has a full  $n$  finite poles—see [23], Thms. 7.5e-f and [16], §3.

The nonvanishing of this Hankel determinant is a standard assumption that appears also, for example, in [42], [43], and [31, p. 170]. For many functions, including  $e^x$ , it is satisfied for all  $(m, n)$ .

Here is the main result from [41] that we require:

**Theorem 2.** Let  $F$  satisfy Assumption A, and for each  $\epsilon > 0$ , let  $\tilde{r}^*$  be the extended best approximation in  $\tilde{V}_{mn}$  of the function  $f^+$  defined by (1.4a). Then for all sufficiently small  $\epsilon$ ,  $b = f^+ - \tilde{r}^*$  has winding number exactly  $m + n + 1$  on  $\partial D$ , it approximates a monomial according to

$$(f^+ - \tilde{r}^*)(z) = \lambda z^{m+n+1} (1 + O(\epsilon)) \quad (2.1)$$

uniformly on  $\partial D$ , and its Laurent coefficients on  $\partial D$  satisfy

$$b_k = [O(\epsilon)]^{2m+2n+2-k} \quad \forall k \leq m + n + 1 \quad (2.2a)$$

uniformly in  $k$ . In addition, the coefficients of the denominator  $q$  of  $\tilde{r}^*$  satisfy

$$\tilde{e}_k^* = O(\epsilon^k) \quad (0 \leq k \leq n). \quad (2.2b)$$

**Proof.** It can be seen that as  $\epsilon \rightarrow 0$ ,  $\{\alpha_k\}$  and  $\{a_k\}$  are related by

$$a_k = \alpha_{|k|} 2^{1-|k|} \epsilon^{|k|} + O(\epsilon^{|k|+1}) \quad -M \leq k \leq M$$

(cf. [21], Lemma 3.3), hence since  $\alpha_k = 0$  for  $k < 0$ ,

$$a_k = \alpha_k 2^{1-k} \epsilon^k + O(\epsilon^{k+1}) \quad -M \leq k \leq M. \quad (2.3)$$

Now if the  $O(\epsilon^{k+1})$  term were zero, the extended approximation problem for  $f^+$  would be that of approximating  $\sum_{k=0}^M \alpha_k 2^{1-k} (\epsilon z)^k$ , and for this the theory of [41] applies. From

Lemmas 4.1, 4.3 and 4.4 of [41] one would obtain (2.2b), (2.2a), and (2.1), respectively, on the basis of Assumption A. In fact the term  $O(\epsilon^{k+1})$  is not zero, but it is of size  $O(\epsilon)$  relative to the terms just considered. This is enough to make the arguments of [41] still go through; we omit the details. In particular, Assumption A and (2.3) imply that for all sufficiently small  $\epsilon$ , the corresponding Hankel matrix made up of coefficients  $a_k$  will also have nonzero determinant. ■

We will need a lemma on the behavior of the denominators of  $R^{\epsilon f}$  and  $R^*$ . Let us write

$$R^{\epsilon f} = P/Q, \quad R^* = P^*/Q^*,$$

where  $P$  and  $P^*$  are polynomials of degree at most  $m$ , and  $Q$  and  $Q^*$  are polynomials of degree at most  $n$  with constant terms 1.

**Lemma 3** (cf. [41], Lemma 6.1). As  $\epsilon \rightarrow 0$ ,

$$Q = 1 + O(\epsilon), \tag{2.4a}$$

$$Q^* = 1 + O(\epsilon), \tag{2.4b}$$

and hence

$$QQ^* = 1 + O(\epsilon) \tag{2.4c}$$

uniformly on  $I_\epsilon$ .

*Proof.* Equation (2.4a) follows from (2.2b). Equation (2.4b) is a corollary of the known fact [7,43] that as  $\epsilon \rightarrow 0$ ,  $R^*$  approaches coefficientwise the Padé approximant  $R^p \in V_{mn}$ , whose normalized denominator, having coefficients independent of  $\epsilon$ , obviously satisfies  $Q^p = 1 + O(\epsilon)$  uniformly on  $I_\epsilon$  as  $\epsilon \rightarrow 0$ . (In fact [7] and [43] show  $R^* \rightarrow R^p$  for  $[0, \epsilon]$ , not  $[-\epsilon, \epsilon]$ . However, C. Chui of [7] assures us that the result also holds for the latter problem (private communication, September 1981).) ■

We now show that from Theorem 2 it follows that  $F - R^{\epsilon f}$  equioscillates at  $m+n+2$  points on  $I_\epsilon$  to within  $O(\epsilon^{3m+2n+3})$ . Let  $\{z_j^T\}$  be the set of  $(2m+2n+2)$ th roots of unity on  $\partial D^+$ , and let  $\{x_j^T\}$  be the corresponding set of Chebyshev abscissae for  $I_\epsilon$ ,  $x_j^T = \epsilon \operatorname{Re} z_j^T$ .

**Theorem 4.** Let  $F$  satisfy Assumption A, and for each  $\epsilon > 0$ , let  $R^{\epsilon f}$  be its CF approximation out of  $V_{mn}$ . Then for all sufficiently small  $\epsilon$ , there is a set of points  $\epsilon = x_0 > x_1 > \dots > x_{m+n+1} = -\epsilon$  satisfying

$$x_j = x_j^T(1 + O(\epsilon)) \tag{2.5}$$

at which

$$\|F - R^{\epsilon f}\| - \operatorname{sgn} \lambda(-1)^j (F - R^{\epsilon f})(x_j) = O(\epsilon^{3m+2n+3}). \tag{2.6}$$

*Proof.* Let  $\{z_j\}$  be the set of  $m+n+2$  points on  $\partial D^+$  at which  $f^+ - \bar{r}^*$  is real, numbered in counterclockwise order from  $z_0 = 1$  to  $z_{m+n+1} = -1$ , and take

$x_j = \epsilon \operatorname{Re} z_j$ . The bound (2.5) follows from (2.1). By (1.9),  $F_M - \bar{R}$  exactly equioscillates on the set  $\{x_j\}$  with error  $|\lambda|$ , so to prove (2.6), it is enough to show

$$\|F - F_M\| = O(\epsilon^{3m+2n+3}) \quad (2.7)$$

and

$$\|\bar{R} - R^{cf}\| = O(\epsilon^{3m+2n+3}). \quad (2.8)$$

The first bound follows from the Lipschitz continuity statement of Assumption A. To establish (2.8), we observe that from (1.13a) and (2.2a, b), we have

$$\hat{b}_k = [O(\epsilon)]^{2m+2n+2-k} \quad \forall k \leq m+1.$$

This implies by (1.13b),

$$\hat{b}^R = O(\epsilon^{3m+2n+3}).$$

From this and (1.14) and (2.4a) it follows that the analog of (2.8) holds for type 1 CF approximation:

$$\|\bar{R} - R_1^{cf}\| = O(\epsilon^{3m+2n+3}). \quad (2.9)$$

Now  $\hat{b}^R$  has terms only of degree  $\leq -m-1$ , each of order  $O(\epsilon^{3m+2n+3})$ , and from (1.10) and (2.2b) it is straightforward to see further that the Chebyshev coefficients of  $1/Q(x)$  satisfy

$$|\gamma_k| = [O(\epsilon)]^{|k|} \quad \forall k.$$

From these facts and (1.14) it follows that the degree- $m$  part of the Chebyshev series of  $\bar{R} - R_1^{cf}$  has magnitude  $O(\epsilon^{3m+2n+4})$ . In other words, if the  $\beta$ -coefficient vector for  $P_1$  is inserted in the left hand side of (1.17), then that system is satisfied up to an error of magnitude  $O(\epsilon^{3m+2n+4})$ . But as  $\epsilon \rightarrow 0$ , the matrix in (1.17) approaches the identity, so it follows that the coefficients of  $P_1$  agree with those of  $P$  up to  $O(\epsilon^{3m+2n+4})$ . By a final application of (2.4a), this implies

$$\|R_1^{cf} - R^{cf}\| = O(\epsilon^{3m+2n+4})$$

and with (2.9) this yields (2.8). ■

Thus the error curve of  $R^{cf}$  equioscillates up to  $O(\epsilon^{3m+2n+3})$ . By the de la Vallée Poussin theorem for rational approximation [31, Thm. 98], this implies

**Corollary.** As  $\epsilon \rightarrow 0$

$$\|F - R^{cf}\| - \|F - R^*\| = O(\epsilon^{3m+2n+3})$$

and

$$|\lambda| - \|F - R^*\| = O(\epsilon^{3m+2n+3}). \quad \blacksquare$$

We wish to show further that  $\|R^{cf} - R^*\| = O(\epsilon^{3m+2n+3})$ . Now by definition  $\|F - R^*\| \leq \|F - R^{cf}\|$ , so (2.6) implies that at the  $m+n+2$  points  $\{x_j\}$ ,  $R^{cf} - R^*$  must satisfy an alternating sequence of constraints

$$-\operatorname{sgn} \lambda (-1)^j (R^{cf} - R^*)(x_j) \leq \eta, \quad (2.10)$$

where  $\eta = O(\epsilon^{3m+2n+3})$ . Does this imply that  $R^{cf} - R^*$  is small? In fact it does, and this question was taken up directly in the paper on rational approximation on small intervals by Machly and Witzgall [30, Lemma 4.6]. However, for our needs (2.10) can be reduced to a similar set of constraints on a polynomial instead of a rational function, which will be easier to deal with. Let us write

$$R^{cf} - R^* = \frac{P}{Q} - \frac{P^*}{Q^*} = \frac{PQ^* - P^*Q}{QQ^*},$$

and let  $S$  denote  $PQ^* - P^*Q$ , a polynomial of degree at most  $m+n$ . Then by (2.4c),

$$R^{cf} - R^* = S(1 + O(\epsilon)) \quad (2.11)$$

uniformly on  $I_\epsilon$  as  $\epsilon \rightarrow 0$ . Therefore (2.10) leads to the sequence of  $m+n+2$  constraints

$$-\operatorname{sgn} \lambda (-1)^j S(x_j) \leq \eta \quad (2.12)$$

for some new  $\eta = O(\epsilon^{3m+2n+3})$ . We want to deduce that  $\|S\| = O(\epsilon^{3m+2n+3})$ .

This is a commonly occurring problem in approximation theoretic proofs. If  $\{x_j\}$  were a fixed set of points (i.e. not dependent on  $\epsilon$ ), then the argument that would be required is the key step in proofs of strong uniqueness or Lipschitz continuity for polynomial Chebyshev approximation. Essentially the same reasoning for this has appeared in (at least) papers of Freud [15], Machly and Witzgall [29], and Cline [8]; Machly and Witzgall even give a figure illustrating (2.12) graphically. For a general discussion see [6]. In our application the near-alternation points are not fixed, but by (2.5) they are close to Chebyshev abscissae for small  $\epsilon$ , hence uniformly separated from each other. This uniform separation is what is needed to make the argument go through, and the same is the case for applications to strong uniqueness and Lipschitz continuity [11,24].

**Lemma 5** (cf. [21], Thm 2.1). *Let  $S(x)$  be a real polynomial of degree at most  $\mu$  on  $I_\epsilon$ . Suppose there exist  $\mu+2$  points  $\epsilon \geq x_0 > x_1 > \dots > x_{\mu+1} \geq -\epsilon$  at which*

$$(-1)^j S(x_j) \leq \eta \quad (2.13)$$

for some  $\eta \geq 0$ , and suppose that  $x_j = \epsilon \cos \phi_j$  with

$$\left| \phi_j - \frac{j\pi}{\mu+1} \right| \leq \frac{\delta}{\mu(2\mu+1)} \quad (2.14)$$

for some  $\delta < 1$ . Then

$$\|S\| \leq \frac{(2\mu+1)}{1-\delta} \eta. \quad (2.15)$$

*Proof.*  $S(\epsilon \cos \phi)$  is a trigonometric polynomial of degree  $\mu$  in  $\phi$ , so by Bernstein's inequality [6, p. 91], one has

$$\left| \frac{dS(\epsilon \cos \phi)}{d\phi} \right| \leq \mu \|S\|.$$

If  $\{x_j^T\}$  are the Chebyshev points  $x_j^T = \epsilon \cos(j\pi/(\mu+1))$ , then this bound together with (2.13) and (2.14) implies

$$(-1)^j S(x_j^T) \leq \kappa \tag{2.16}$$

where

$$\kappa = \eta + \frac{\delta \|S\|}{2\mu + 1}.$$

Now according to a computation of Cline in [8], §4, (2.16) implies

$$\|S\| \leq (2\mu + 1)\kappa. \tag{2.17}$$

Therefore

$$\|S\| \leq (2\mu + 1) \left( \eta + \frac{\delta \|S\|}{2\mu + 1} \right) = (2\mu + 1)\eta + \delta \|S\|,$$

hence (2.15). ■

Lemma 5 provides all that is needed to prove our first main theorem:

**Theorem 6.** *Let  $F$  satisfy Assumption A, and for each  $\epsilon > 0$  let  $R^{\epsilon f}$  and  $R^*$  be its CF and Chebyshev approximations in  $V_{mn}$ . Then as  $\epsilon \rightarrow 0$ ,*

$$\|R^{\epsilon f} - R^*\| = O(\epsilon^{3m+2n+3}).$$

*Proof.* Applying Lemma 5 to (2.12) with  $\mu = m + n$  gives

$$\|S\| = O(\epsilon^{3m+2n+3}).$$

The result follows from (2.11). ■

Together with (2.8) Theorem 6 implies

$$\|R^* - \tilde{R}\| = O(\epsilon^{3m+2n+3}). \tag{2.18}$$

We can interpret this as a statement about the geometry of optimal error curves, analogous to the theorems in [40] and [41] showing that error curves in complex Chebyshev approximation are close to perfect circles:

**Theorem 7.** *Let  $F$  satisfy Assumption A. Then for all sufficiently small  $\epsilon$ , there exists a function  $b(z)$  that is a constant multiple of a finite Blaschke product, is analytic in  $1 \leq |z| < \infty$  except for at most  $n$  poles, and has winding number  $m + n + 1$  on  $\partial D$ , satisfying*

$$\|(F - R^*)(x) - \text{Re } b(z)\| = O(\epsilon^{3m+2n+3}).$$

*Proof.* Follows from (1.8), (2.7), and (2.18). ■

Theorems 6 and 7 are the extensions to rational approximation of results given in Theorem 3.4 of [21]. Theorem 3.5 of that paper also proves analogous estimates for  $m \rightarrow \infty$  on a fixed interval, but we have not extended these results.

If  $F$  satisfies Assumption A, then  $\|F - R^*\|$  has size  $O(\epsilon^{m+n+1})$  but not  $o(\epsilon^{m+n+1})$  as  $\epsilon \rightarrow 0$ . Relative to this scale, therefore, our results have strength  $O(\epsilon^{2m+n+2})$ . It appears that these orders are best possible, except that in the case  $n = 0$ , a certain "bonus" cancellation makes it possible to increase  $3m + 3$  to  $3m + 4$  in Theorems 6 and 7 (but not in the estimate on  $|\lambda|$  in the corollary to Theorem 4). See the proof of Lemma 3.2 in [21] for details.

### 3. NUMERICAL EXAMPLES

The CF method is not difficult to implement numerically, and the techniques we have used are described in §7 of [41]. In outline, we rely heavily on the Fast Fourier Transform as indicated here at the end of §1, and use EISPACK routines based on Sturm sequencing for the eigenanalysis of Step 2. The bottleneck is the eigenvalue computation, which takes time  $O(M^3)$ , for unfortunately no way is known to take advantage of the Hankel structure of  $H$ . Ideally one wants  $M$  to be large enough so that the Chebyshev coefficients  $a_k$  for  $k > M$  are negligible, hence  $F_M \approx F$ . For most of the examples considered below, such as those involving  $e^x$ , this is achieved with  $M = 35$ , leading to computation times on the order of 0.1 secs. on our IBM 370/168. With  $F(x) = |x|$ , on the other hand,  $M = 120$  is only barely large enough to get approximations with  $m, n \leq 2$  accurately, and the computation time increases to 2 secs. Thus the CF method is not only more accurate, but also much faster if the function to be approximated is smooth. For certain high-precision numbers below we have resorted to quadruple precision.

In general the CF method will yield an approximation satisfying

$$|\lambda| \approx E^*,$$

and by the de la Vallée Poussin result one has

$$E_{\min}^{cf} \leq E^* \leq E^{cf}, \quad (3.1)$$

where

$$E_{\min}^{cf} = \min_j |(F - R^{cf})(x_j)|,$$

with the minimum taken over that set of  $m + n + 2$  nearly alternating points which maximizes its value. In our experiments  $R^{cf}$  and  $\lambda$  were computed to close to machine precision, and by means of a minimization routine (FMIN, by Richard Brent),  $E^{cf}$  and  $E_{\min}^{cf}$  were also found to this accuracy (Step 6). The quantity not so precisely known is  $E^*$ , for we do not have a high-accuracy rational Chebyshev approximation routine at hand. Therefore in what follows we report  $|\lambda|$  rather than  $E^*$ .

As a first example, let us give more details related to  $e^x$ . Table 2 shows the eigenvalue  $|\lambda|$  in approximation on  $[-1, 1]$  for  $0 \leq m, n \leq 3$ . Each digit known to agree with the corresponding digit of  $E^*$  after both are rounded has been underlined. In most cases this knowledge is based on (3.1). The agreement is excellent, and we believe that it will get steadily better as  $m, n \rightarrow \infty$  in any fashion. (The table leaves some doubt as to whether this is true for, say,  $m = 0$  and  $n \rightarrow \infty$ , but further experiments show that by type (0, 9), five significant digits can be underlined, and the number is growing with  $n$ .) This example relates to a conjecture of Meinardus [31, p. 168] which proposes that as  $m, n \rightarrow \infty$ ,

$$E_{mn}^*(e^x) = \frac{m!n!}{2^{m+n}(m+n)!(m+n+1)!}(1 + o(1)). \quad (3.2)$$

	m = 0	m = 1	m = 2	m = 3
n = 0	<u>1.1961</u> (-0)	<u>2.787994</u> (-1)	<u>4.5017 38776</u> (-2)	<u>5.5283 70108 71194</u> (-3)
n = 1	<u>2.1724</u> (-1)	<u>2.096982</u> (-2)	<u>1.7890 66755</u> (-3)	<u>1.3461 23369 20018</u> (-4)
n = 2	<u>3.5288</u> (-2)	<u>1.677017</u> (-3)	<u>8.6899 91075</u> (-5)	<u>4.3991 63371 96896</u> (-6)
n = 3	<u>4.5235</u> (-3)	<u>1.239861</u> (-4)	<u>4.2766 46704</u> (-6)	<u>1.5506 69053 97117</u> (-7)

Table 2. The eigenvalue  $|\lambda|$  in CF approximation to  $e^x$  on  $[-1,1]$  for various  $(m,n)$ . Underlined digits are known to agree with corresponding digits of  $E^*$ , after rounding. Doubly underlined digits agree with the conjectured limit formula (3.2) of Meinardus.

At this writing the conjecture is unproved, but it is known to be valid up to a constant factor [4,33] of less than 40. The double underlinings in Table 2 mark digits where (3.2) agrees with  $|\lambda|$ , and it is evident that  $|\lambda|$  is much closer to  $E^*$  than (3.2) is. This suggests that it might be possible to resolve the Meinardus conjecture by means of the CF method. (Chebyshev-Padé approximation, it turns out, is not strong enough [17].) Two key proofs would be enough to settle the issue:

- (i)  $|\lambda| = E_{mn}^*(1 + o(1))$  as  $m, n \rightarrow \infty$ ,
- (ii)  $|\lambda|$  satisfies (3.2) as  $m, n \rightarrow \infty$ .

Unfortunately, these claims are not at all easy to establish, and the Meinardus conjecture will probably be proved true before long by some simpler technique. Nevertheless, it would be very interesting to know that asymptotically, best approximation errors agree with the eigenvalues of an infinite Hankel matrix of Chebyshev coefficients.

Incidentally, we conjecture that for the problem of complex approximation of  $e^z$  on the unit disk, formula (3.2) holds with the factor  $2^{m+n}$  removed. The best approximation errors computed in [41], Table 3 by the complex CF method show that the agreement of this conjecture with exact best approximation errors for  $m, n \leq 3$  is about as close as in the real case. The disappearance of the power of 2 is natural in the light of (2.3).

Table 3 shows some results of the CF method for functions besides  $e^x$ . In each case  $|\lambda|$  is given for approximation of type (0,1), (1,1) and (2,1) on  $[-1,1]$ , with underlinings as before. Evidently CF approximation really works, even for as low a degree as (1,1). It is apparent that it performs relatively poorly for  $|x|$ , and this is not surprising in view of the nondifferentiability of this function.

Now let us confirm that the asymptotic orders of accuracy predicted in Section 2 are valid, and sharp. Table 4 shows  $|\lambda|$  and  $E^{cf} - E_{\min}^{cf}$  in (1,1) approximation of  $e^x$  on  $I_\epsilon$  for  $\epsilon = 1, \frac{1}{2}, \dots, \frac{1}{16}$ . With each factor of 2 reduction in  $\epsilon$ , we expect  $|\lambda|$  to decrease by approximately  $2^{m+n+1} = 8$ , and  $E^{cf} - E_{\min}^{cf}$  to decrease by approximately  $2^{3m+2n+3} = 256$ . The table confirms these predictions. Such asymptotic behavior,

$F(x)$	$ \lambda : (0,1)$	$ \lambda : (1,1)$	$ \lambda : (2,1)$
$ x $	4.483(-1)	4.4827(-1)	<u>1.1359</u> (-1)
$x^6$	<u>5.397</u> (-1)	<u>5.3970</u> (-1)	<u>1.9257</u> (-1)
$\sqrt{1.1-x}$	<u>2.238</u> (-1)	<u>1.6331</u> (-2)	<u>2.9709</u> (-3)
$\arctan(x)$	<u>8.312</u> (-1)	<u>4.7889</u> (-2)	<u>4.7889</u> (-2)
$1/\Gamma(x+1)$	<u>4.041</u> (-1)	<u>1.1955</u> (-1)	<u>2.1045</u> <u>75498</u> (-2)
$e^x$	<u>2.172</u> (-1)	<u>2.0970</u> (-2)	<u>1.7890</u> <u>66755</u> (-3)
$\log \frac{x+3}{2}$	<u>1.598</u> (-1)	<u>8.6079</u> <u>41336</u> (-4)	<u>4.9591</u> <u>1561392</u> (-5)

Table 3. The eigenvalue  $|\lambda|$  in CF approximation of types (0,1), (1,1) and (2,1) to various functions on  $[-1,1]$ . Underlined digits are known to agree with corresponding digits of  $E^*$ .

$\epsilon$	$ \lambda $	Ratio	$E^{cf} - E_{min}^{cf}$	Ratio
1	2.097(-2)		2.03(-6)	
1/2	2.605(-3)	8.04	9.18(-9)	221
1/4	3.255(-4)	8.00	3.73(-11)	246
1/8	4.069(-5)	8.00	1.47(-13)	253
1/16	5.086(-6)	8.00	5.77(-16)	255

Table 4. Type (1,1) approximation of  $e^x$  on  $[-\epsilon, \epsilon]$  for various  $\epsilon$ .

however, is dependent on the smoothness of  $F$ . With  $F(x) = |x|$ , for example, cutting  $\epsilon$  in half is equivalent to dividing  $F$  by 2, and therefore the effect will be to cut  $\lambda$  and  $E^{cf} - E_{min}^{cf}$  exactly in half, no matter what  $m$  and  $n$  are. Thus for  $F(x) = |x|$  there is nothing to be gained by shrinking the interval, although the CF method still improves if  $m$  and  $n$  are increased.

Our final example is associated with some further conjectures about asymptotic degree of approximation. In a paper of Cody, Meinardus, and Varga [9], the problem of approximating  $e^{-t}$  on the semi-infinite interval  $[0, \infty)$  was studied. They proved that in rational approximation of type  $(0, n)$  or  $(n, n)$ , the error decreases geometrically as  $n \rightarrow \infty$ , but did not determine an asymptotic rate of decrease. For approximation of type  $(0, n)$ , they gave numerical results that suggested the limiting behavior

$$\lim_{n \rightarrow \infty} (E_{0n}^*)^{1/n} = \frac{1}{3}$$

and this equality was later proved valid by A. Schönhage [35]. For approximation of type  $(n, n)$ , their numerical results reported for  $n \leq 14$  suggest to us

$$\lim_{n \rightarrow \infty} (E_{nn}^*)^{1/n} = \lim_{n \rightarrow \infty} \frac{E_{n+1, n+1}^*}{E_{nn}^*} = \frac{1}{9.28\dots}, \quad (3.3)$$

and a limit  $1/9$  has also been conjectured. But no result of this kind has been established.

Despite appearances, this problem can be approached by the CF method. The function

$$t = \frac{1-x}{1+x}$$

maps  $[0, \infty]$  bijectively onto  $[-1, 1]$ , inducing a one-to-one correspondence between rational functions  $R(t)$  and  $R(x)$  in  $V_{nn}$ . Under this transplantation an equioscillating curve on one domain maps to an equioscillating curve on the other, and as a consequence it can be shown that the given problem is equivalent to the problem of approximating

$$F(x) = e^{(x-1)/(x+1)}$$

on  $[-1, 1]$ , which can be treated by the CF method. (For justification see the theory of [3]; this transplantation only works when  $m = n$ .) Here  $F$  is  $C^\infty$  on  $[-1, 1]$ , but analytic only on  $(-1, 1)$ , so its Chebyshev series decreases faster than any polynomial but not geometrically. We took  $M = 200$ , leading to truncated terms  $|a_k| < 10^{-23}$  for  $k \geq M$ , and calculated eigenvalues in quadruple precision on the IBM 370/168. This gave us  $\lambda_{n+1}$  for  $0 \leq n \leq 18$  accurate to many places, and for  $n \geq 5$ ,  $|\lambda|$  agrees with the values  $E^*$  reported by Cody, Meinardus and Varga to all four places that they give. We have little doubt that  $|\lambda| = E^*(1 + o(1))$  as  $n \rightarrow \infty$ .

On the basis of these numbers we conjecture

$$\left. \begin{array}{l} |\lambda_{n+1}| \\ E_{nn}^* \end{array} \right\} = \frac{A}{B^n} \left(1 + O\left(\frac{1}{n}\right)\right)$$

for some constants  $A \approx .656$ ,  $B \approx 9.28903$ . The evidence is summarized in Table 5. Remarkably, in the course of this writing Schönhage [36] has independently conjectured that (3.3) approaches a limit

$$\frac{3}{2}(2 - \sqrt{3})^2 \approx \frac{1}{9.28547}.$$

In fact he proves that  $\liminf (E_{nn}^*)^{1/n}$  is at least two-thirds of this value. The closeness but inequality of these two conjectured limits is striking.

<u>n</u>	<u><math> \lambda_{n+1} </math></u>	Ratio <u><math>\rho_n =  \lambda_n / \lambda_{n+1} </math></u>	Richardson extrapolant <u><math>\rho_n + \frac{1}{3}(\rho_n - \rho_{n/2})</math></u>

Table 5. Eigenvalues  $|\lambda|$  in  $(n,n)$  approximation of  $\exp(\frac{x-1}{x+1})$  on  $[-1,1]$  for various  $n$ . This is equivalent to approximation of  $e^{-t}$  on  $[0,\infty)$ . Digits agreeing with the values of  $E^*$  given by Cody, Meinardus, and Varga [9] have been underlined. (The results of [9] were given to four places and for  $n \leq 14$  only.) The ratio appears to approach a limiting value 9.28903....
